Preface

The handbook series published by CRC Press represents a truly unique approach to disseminating technical information. Starting with the first edition of *The Electrical Engineering Handbook*, edited by Richard Dorf and published in 1993, this series is dedicated to the idea that a reader should be able to pull one of these handbooks off the shelf and, at least 80% of the time, find what he or she needs to know about a subject area. As handbooks, these books are also different in that they are more than just a dry listing of facts and data, filled mostly with tables. In fact, a hallmark of these handbooks is that the articles or chapters are designed to be relatively short, written as tutorials or overviews, so that once the reader locates the broader topic, it is easy to find an answer to a specific question.

Of course, the authors are the key to achieving the overall goal of the handbook, and, having read all of the chapters personally, the results are impressive. The chapters are authoritative, to-the-point, and enjoyable to read. Answers to frequently asked questions, facts, and figures are available almost at a glance. Since the authors are experts in their field, it is understandable that the content is excellent. Additionally, the authors were encouraged to put some of their own interpretations and insights into the chapters, which greatly enhances the readability. However, I am most impressed by the ability of the authors to condense so much information into so few pages. These chapters are unlike any ever written—they are not research journal articles, they are not textbooks, they are not long tutorial review articles for magazines. They really are a new format.

In reading drafts of the chapters, I applied two tests. If the chapter covered a topic with which I was familiar, I checked to see if it contained what I thought were the essential facts and ideas. If the chapter was in an area of communications less familiar to me, I looked for definitions of terms I had heard of or for a discussion that informed me why this area is important and what is happening in the field today. I was amazed at what I learned.

Using *The Communications Handbook* is simple. Look up your topic of interest either in the [Table of Contents](#) or the Index. Go directly to the relevant chapter. As you are reading the chosen chapter, you may wish to refer to other chapters in the same main heading. If you need some background information in the general communications field, you need only consult [Section I, Basic Principles](#). There is no need to read *The Communications Handbook* beginning-to-end, start-to-finish. Look up what you need right now, read it, and go back to the task at hand.

The pleasure of such a project as this is in working with the authors, and I am gratified to have had this opportunity and to be associated with each of them. The first edition of this handbook was well-received and served an important role in providing information on communications to technical and non-technical readers alike. I hope that this edition is found to be equally useful.

It is with great pleasure that I acknowledge the encouragement and patience of my editor at CRC Press, Nora Konopka, and the efforts of both Nora and Helena Redshaw in finally getting this edition in print.

Jerry D. Gibson
Editor-in-Chief

Editor-in-Chief

Jerry D. Gibson currently serves as chairman of the Department of Electrical Engineering at Southern Methodist University in Dallas, Texas. From 1987 to 1997, he held the J. W. Runyon, Jr. Professorship in the Department of Electrical Engineering at Texas A&M University. He also has held positions at General Dynamics—Fort Worth, the University of Notre Dame, and the University of Nebraska—Lincoln, and during the fall of 1991, Dr. Gibson was on sabbatical with the Information Systems Laboratory and the Telecommunications Program in the Department of Electrical Engineering at Stanford University.

He is co-author of the books *Digital Compression for Multimedia* (Morgan–Kaufmann, 1998) and *Introduction to Nonparametric Detection with Applications* (Academic Press, 1975 and IEEE Press, 1995) and author of the textbook *Principles of Digital and Analog Communications* (Prentice-Hall, 2nd ed., 1993). He is editor-in-chief of *The Mobile Communications Handbook* (CRC Press, 2nd ed., 1999) and *The Communications Handbook* (CRC Press, 1996) and editor of the book *Multimedia Communications: Directions and Innovations* (Academic Press, 2000).

Dr. Gibson was associate editor for speech processing for the *IEEE Transactions on Communications* from 1981 to 1985 and associate editor for communications for the *IEEE Transactions on Information Theory* from 1988 to 1991. He has served as a member of the Speech Technical Committee of the IEEE Signal Processing Society (1992–1995), the IEEE Information Theory Society Board of Governors (1990–1998), and the Editorial Board for the *Proceedings of the IEEE*. He was president of the IEEE Information Theory Society in 1996. Dr. Gibson served as technical program chair of the 1999 IEEE Wireless Communications and Networking Conference, technical program chair of the 1997 Asilomar Conference on Signals, Systems, and Computers, finance chair of the 1994 IEEE International Conference on Image Processing, and general co-chair of the 1993 IEEE International Symposium on Information Theory. Currently, he serves on the steering committee for the Wireless Communications and Networking Conference.

In 1990, Dr. Gibson received The Fredrick Emmons Terman Award from the American Society for Engineering Education, and, in 1992, was elected fellow of the IEEE “for contributions to the theory and practice of adaptive prediction and speech waveform coding.” He was co-recipient of the 1993 IEEE Signal Processing Society Senior Paper Award for the field of speech processing.

His research interests include data, speech, image, and video compression, multimedia over networks, wireless communications, information theory, and digital signal processing.

Contents

SECTION I Basic Principles

- 1 Complex Envelope Representations
for Modulated Signals *Leon W. Couch, II*
- 2 Sampling *Hwei P. Hsu*
- 3 Pulse Code Modulation *Leon W. Couch, II*
- 4 Probabilities and Random Variables *Michael O'Flynn*
- 5 Random Processes, Autocorrelation, and Spectral
Densities *Lew E. Franks*
- 6 Queuing *Richard H. Williams*
- 7 Multiplexing *Martin S. Roden*
- 8 Pseudonoise Sequences *Tor Helleseth and P. Vijay Kumar*
- 9 D/A and A/D Converters *Susan A.R. Garrod*
- 10 Signal Space *Roger E. Ziemer*
- 11 Channel Models *David R. Smith*
- 12 Optimum Receivers *Geoffrey C. Orsak*

- 13 Forward Error Correction Coding *Vijay K. Bhargava and Ivan J. Fair*
- 14 Automatic Repeat Request *David Haccoun and Samuel Pierre*
- 15 Spread Spectrum Communications *Laurence B. Milstein and Marvin K. Simon*
- 16 Diversity *Arogyaswami J. Paulraj*
- 17 Information Theory *Bixio Rimoldi and Rüdiger Urbanke*
- 18 Digital Communication System Performance *Bernard Sklar*
- 19 Synchronization *Costas N. Georghiades*
- 20 Digital Modulation Techniques *Ezio Biglieri*

SECTION II Telephony

- 21 Plain Old Telephone Service (POTS) *A. Michael Noll*
- 22 FDM Hierarchy *Pierre Catala*
- 23 Analog Telephone Channels and the Subscriber Loop
Whitham D. Reeve
- 24 Baseband Signalling and Pulse Shaping *Michael L. Honig and Melbourne Barton*
- 25 Channel Equalization *John G. Proakis*
- 26 Pulse-Code Modulation Codec-Filters *Michael D. Floyd and Garth D. Hillman*

27 Digital Hierarchy *B.P. Lathi and Maynard A. Wright*

28 Line Coding *Joseph L. LoCicero and Bhasker P. Patel*

29 Telecommunications Network Synchronization
Madihally J. Narasimha

30 Echo Cancellation *Giovanni Cherubini*

SECTION III Networks

31 The Open Systems Interconnections (OSI) Seven-Layer Model *Frederick Halsall*

32 Ethernet Networks *Ramesh R. Rao*

33 Fiber Distributed Data Interface and Its Use for Time-Critical Applications
Biao Chen, Nicholas Malcolm, and Wei Zhao

34 Broadband Local Area Networks *Joseph A. Bannister*

35 Multiple Access Methods for Communications Networks *Izhak Rubin*

36 Routing and Flow Control *Rene L. Cruz*

37 Transport Layer *A. Udaya Shankar*

38 Gigabit Networks *Jonathan M. Smith*

39 Local Area Networks *Thomas G. Robertazzi*

40 Asynchronous Time Division Switching *Achille Pattavina*

Michel Daoud Yacoub and Paula R. C. Gomez
- 76 Fixed and Dynamic Channel Assignment *Bijan Jabbari*
- 77 Radiolocation Techniques *Gordon L. Stüber
and James J. Caffery, Jr.*
- 78 Power Control *Roman Pichna and Qiang Wang*
- 79 Enhancements in Second Generation Systems
Marc Delprat and Vinod Kumar
- 80 The Pan-European Cellular System *Lajos Hanzo*
- 81 Speech and Channel Coding for North American TDMA
Cellular Systems *Paul Mermelstein*
- 82 The British Cordless Telephone Standard: CT-2 *Lajos Hanzo*
- 83 Half-Rate Standards *Wai-Yip Chan, Ira Gerson, and Toshio Miki*

- 84 **Wireless Video Communications** *Madhukar Budagavi and Raj Talluri*
- 85 **Wireless LANs** *Suresh Singh*
- 86 **Wireless Data** *Allen H. Levesque and Kaveh Pahlavan*
- 87 **Wireless ATM: Interworking Aspects** *Melbourne Barton, Matthew Cheng, and Li Fung Chang*
- 88 **Wireless ATM: QoS and Mobility Management** *Bala Rajagopalan and Daniel Reininger*
- 89 **An Overview of cdma2000, WCDMA, and EDGE** *Tero Ojanperä and Steven D. Gray*
- 90 **Multiple-Input Multiple-Output (MIMO) Wireless Systems** *Helmut Bölcskei and Arogyaswami J. Paulraj*
- 91 **Near-Instantaneously Adaptive Wireless Transceivers of the Near Future** *Lie-Liang Yang and Lajos Hanzo*
- 92 **Ad-Hoc Routing Techniques for Wireless LANs** *Ahmed K. Elhakeem*

SECTION VII Source Compression

- 93 **Lossless Compression** *Khalid Sayood and Nasir D. Memon*
- 94 **Facsimile** *Nasir D. Memon and Khalid Sayood*
- 95 **Speech** *Boneung Koo*
- 96 **Video** *Eric Dubois*

97 High Quality Audio Coding *Peter Noll*

98 Cable *Jeff Hamilton, Mark Kolber, Charles E. Schell,
and Len Taupier*

99 Video Servers *A. L. Narasimha Reddy and Roger Haskin*

100 Videoconferencing *Madhukar Budagavi*

SECTION VIII Data Recording

101 Magnetic Storage *Jaekyun Moon*

102 Magneto-Optical Disk Data Storage *Masud Mansuripur*

Basic Principles

- 1 Complex Envelope Representations for Modulated Signals** *Leon W. Couch, II*
Introduction • Complex Envelope Representation • Representation of Modulated Signals • Generalized Transmitters and Receivers • Spectrum and Power of Bandpass Signals • Amplitude Modulation • Phase and Frequency Modulation • QPSK, $\pi/4$ QPSK, QAM, and OOK Signalling
- 2 Sampling** *Hwei P. Hsu*
Introduction • Instantaneous Sampling • Sampling Theorem • Sampling of Sinusoidal Signals • Sampling of Bandpass Signals • Practical Sampling • Sampling Theorem in the Frequency Domain • Summary and Discussion

1.1 Introduction

What is a general representation for bandpass digital and analog signals? How do we represent a **modulated signal**? How do we evaluate the spectrum and the power of these signals? These are some of the questions that are answered in this chapter.

A *baseband* waveform has a spectral magnitude that is nonzero for frequencies in the vicinity of the origin (i.e., $f = 0$) and negligible elsewhere. A *bandpass* waveform has a spectral magnitude that is nonzero for frequencies in some band concentrated about a frequency $f = \pm f_c$ (where $f_c \gg 0$), and the spectral magnitude is negligible elsewhere. f_c is called the *carrier frequency*. The value of f_c may be arbitrarily assigned for mathematical convenience in some problems. In others, namely, **modulation** problems, f_c is the frequency of an oscillatory signal in the transmitter circuit and is the assigned frequency of the transmitter, such as 850 kHz for an AM broadcasting station.

In communication problems, the information source signal is usually a baseband signal, for example, a transistor–transistor logic (TTL) waveform from a digital circuit or an audio (analog) signal from a microphone. The communication engineer has the job of building a system that will transfer the information from this source signal to the desired destination. As shown in Fig. 1.1, this usually requires the use of a bandpass signal, $s(t)$, which has a bandpass spectrum that is concentrated at $\pm f_c$, where f_c is selected so that $s(t)$ will propagate across the communication channel (either a wire or a wireless channel).

Modulation is the process of imparting the source information onto a bandpass signal with a carrier frequency f_c by the introduction of amplitude and/or phase perturbations. This bandpass signal is called the *modulated* signal $s(t)$, and the baseband source signal is called the *modulating* signal $m(t)$. Examples of

*Source: Couch, L. W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ.

FIGURE 1.1 Bandpass communication system. *Source:* Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, p. 231. With permission.

exactly how modulation is accomplished are given later in this chapter. This definition indicates that modulation may be visualized as a mapping operation that maps the source information onto the bandpass signal $s(t)$ that will be transmitted over the channel.

As the modulated signal passes through the channel, noise corrupts it. The result is a bandpass signal-plus-noise waveform that is available at the receiver input, $r(t)$, as illustrated in Fig. 1.1. The receiver has the job of trying to recover the information that was sent from the source; \tilde{m} denotes the corrupted version of m .

1.2 Complex Envelope Representation

All bandpass waveforms, whether they arise from a modulated signal, interfering signals, or noise, may be represented in a convenient form given by the following theorem. $v(t)$ will be used to denote the **bandpass waveform** canonically. That is, $v(t)$ can represent the signal when $s(t) \equiv v(t)$, the noise when $n(t) \equiv v(t)$, the filtered signal plus noise at the channel output when $r(t) \equiv v(t)$, or any other type of bandpass waveform.*

Theorem 1.1 Any physical bandpass waveform can be represented by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (1.1a)$$

$\text{Re}\{\cdot\}$ denotes the real part of $\{\cdot\}$. $g(t)$ is called the complex envelope of $v(t)$, and f_c is the associated carrier frequency (hertz) where $\omega_c = 2\pi f_c$. Furthermore, two other equivalent representations are

$$v(t) = R(t)\cos[\omega_c t + \theta(t)] \quad (1.1b)$$

and

$$v(t) = x(t)\cos\omega_c t - y(t)\sin\omega_c t \quad (1.1c)$$

where

$$g(t) = x(t) + jy(t) = |g(t)|e^{j\angle g(t)} \equiv R(t)e^{j\theta(t)} \quad (1.2)$$

$$x(t) = \text{Re}\{g(t)\} \equiv R(t)\cos\theta(t) \quad (1.3a)$$

$$y(t) = \text{Im}\{g(t)\} \equiv R(t)\sin\theta(t) \quad (1.3b)$$

$$R(t) \triangleq |g(t)| \equiv \sqrt{x^2(t) + y^2(t)} \quad (1.4a)$$

$$\theta(t) \triangleq \angle g(t) = \tan^{-1}\left(\frac{y(t)}{x(t)}\right) \quad (1.4b)$$

*The symbol \equiv denotes an equivalence and the symbol \triangleq denotes a definition.

The waveforms $g(t)$, $x(t)$, $y(t)$, $R(t)$, and $\theta(t)$ are all **baseband waveforms**, and, except for $g(t)$, they are all real waveforms. $R(t)$ is a nonnegative real waveform. Equation (1.1) is a low-pass-to-bandpass transformation. The $e^{j\omega_c t}$ factor in Eq. (1.1a) shifts (i.e., translates) the spectrum of the baseband signal $g(t)$ from baseband up to the carrier frequency f_c . In communications terminology, the frequencies in the baseband signal $g(t)$ are said to be *heterodyned* up to f_c . The **complex envelope**, $g(t)$, is usually a complex function of time and it is the generalization of the phasor concept. That is, if $g(t)$ happens to be a complex constant, then $v(t)$ is a pure sine wave of frequency f_c and this complex constant is the phasor representing the sine wave. If $g(t)$ is not a constant, then $v(t)$ is not a pure sine wave because the amplitude and phase of $v(t)$ varies with time, caused by the variations of $g(t)$.

Representing the complex envelope in terms of two real functions in Cartesian coordinates, we have

$$g(x) \equiv x(t) + jy(t) \quad (1.5)$$

where $x(t) = \text{Re}\{g(t)\}$ and $y(t) = \text{Im}\{g(t)\}$. $x(t)$ is said to be the *in-phase modulation* associated with $v(t)$, and $y(t)$ is said to be the *quadrature modulation* associated with $v(t)$. Alternatively, the polar form of $g(t)$, represented by $R(t)$ and $\theta(t)$, is given by Eq. (1.2), where the identities between Cartesian and polar coordinates are given by Eqs. (1.3) and (1.4). $R(t)$ and $\theta(t)$ are real waveforms, and, in addition, $R(t)$ is always nonnegative. $R(t)$ is said to be the *amplitude modulation* (AM) on $v(t)$, and $\theta(t)$ is said to be the *phase modulation* (PM) on $v(t)$.

The usefulness of the complex envelope representation for bandpass waveforms cannot be overemphasized. In modern communication systems, the bandpass signal is often partitioned into two channels, one for $x(t)$ called the I (in-phase) channel and one for $y(t)$ called the Q (quadrature-phase) channel. In digital computer simulations of bandpass signals, the sampling rate used in the simulation can be minimized by working with the complex envelope, $g(t)$, instead of with the bandpass signal, $v(t)$, because $g(t)$ is the baseband equivalent of the bandpass signal [1].

1.3 Representation of Modulated Signals

Modulation is the process of encoding the source information $m(t)$ (modulating signal) into a bandpass signal $s(t)$ (modulated signal). Consequently, the modulated signal is just a special application of the bandpass representation. The *modulated signal* is given by

$$s(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (1.6)$$

where $\omega_c = 2\pi f_c$. f_c is the carrier frequency. The complex envelope $g(t)$ is a function of the modulating signal $m(t)$. That is,

$$g(t) = g[m(t)] \quad (1.7)$$

Thus $g[\cdot]$ performs a mapping operation on $m(t)$. This was shown in Fig. 1.1.

Table 1.1 gives an overview of the *big picture* for the modulation problem. Examples of the mapping function $g[m]$ are given for amplitude modulation (AM), double-sideband suppressed carrier (DSB-SC), phase modulation (PM), frequency modulation (FM), single-sideband AM suppressed carrier (SSB-AM-SC), single-sideband PM (SSB-PM), single-sideband FM (SSB-FM), single-sideband envelope detectable (SSB-EV), single-sideband square-law detectable (SSB-SQ), and quadrature modulation (QM). For each $g[m]$, Table 1.1 also shows the corresponding $x(t)$ and $y(t)$ quadrature modulation components and the corresponding $R(t)$ and $\theta(t)$ amplitude and phase modulation components. Digitally modulated bandpass signals are obtained when $m(t)$ is a digital baseband signal, for example, the output of a transistor transistor logic (TTL) circuit.

Obviously, it is possible to use other $g[m]$ functions that are not listed in Table 1.1. The question is: are they useful? $g[m]$ functions are desired that are easy to implement and that will give desirable spectral

TABLE 1.1 Complex Envelope Functions for Various Types of Modulation^a

Type of Modulation	Mapping Function $g(m)$	Corresponding Quadrature Modulation	
		$x(t)$	$y(t)$
AM	$A_c[1 + m(t)]$	$A_c[1 + m(t)]$	0
DSB-SC	$A_c m(t)$	$A_c m(t)$	0
PM	$A_c e^{jD_p m(t)}$	$A_c \cos[D_p m(t)]$	$A_c \sin[D_p m(t)]$
FM	$A_c e^{jD_f \int_{-\infty}^t m(\sigma) d\sigma}$	$A_c \cos\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$	$A_c \sin\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$
SSB-AM-SC ^b	$A_c[m(t) \pm j\hat{m}(t)]$	$A_c m(t)$	$\pm A_c \hat{m}(t)$
SSB-PM ^b	$A_c e^{jD_p[m(t) \pm j\hat{m}(t)]}$	$A_c e^{\mp D_p \hat{m}(t)} \cos[D_p m(t)]$	$A_c e^{\mp D_p \hat{m}(t)} \sin[D_p m(t)]$
SSB-FM ^b	$A_c e^{jD_f \int_{-\infty}^t [m(\sigma) \pm j\hat{m}(\sigma)] d\sigma}$	$A_c e^{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma} \cos\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$	$A_c e^{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma} \sin\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$
SSB-EV ^b	$A_c e^{\{ \ln[1+m(t)] \pm j\hat{m}(t) \}}$	$A_c [1 + m(t)] \cos\left\{ \hat{m}(t) \right\}$	$\pm A_c [1 + m(t)] \sin\left\{ \hat{m}(t) \right\}$
SSB-SQ ^b	$A_c e^{(1/2)\{ \ln[1+m(t)] \pm j\hat{m}(t) \}}$	$A_c \sqrt{1 + m(t)} \cos\left\{ \frac{1}{2} \hat{m}(t) \right\}$	$\pm A_c \sqrt{1 + m(t)} \sin\left\{ \frac{1}{2} \hat{m}(t) \right\}$
QM	$A_c[m_1(t) + jm_2(t)]$	$A_c m_1(t)$	$A_c m_2(t)$

Type of Modulation	Corresponding Amplitude and Phase Modulation		Linearity	Remarks
	$R(t)$	$\theta(t)$		
AM	$A_c 1 + m(t) $	$\begin{cases} 0, & m(t) > -1 \\ 180^\circ, & m(t) < -1 \end{cases}$	L ^c	$m(t) > -1$ required for envelope detection
DSB-SC	$A_c m(t) $	$\begin{cases} 0, & m(t) > 0 \\ 180^\circ, & m(t) < 0 \end{cases}$	L	Coherent detection required
PM	A_c	$D_p m(t)$	NL	D_p is the phase deviation constant (rad/volt)
FM	A_c	$D_f \int_{-\infty}^t m(\sigma) d\sigma$	NL	D_f is the frequency deviation constant (rad/volt-sec)
SSB-AM-SC ^b	$A_c \sqrt{[m(t)]^2 + [\hat{m}(t)]^2}$	$\tan^{-1}[\pm \hat{m}(t)/m(t)]$	L	Coherent detection required
SSB-PM ^b	$A_c e^{\pm D_p \hat{m}(t)}$	$D_p m(t)$	NL	
SSB-FM ^b	$A_c e^{\pm D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma}$	$D_f \int_{-\infty}^t m(\sigma) d\sigma$	NL	
SSB-EV ^b	$A_c 1 + m(t) $	$\pm \hat{m}(t)$	NL	$m(t) > -1$ is required so that the $\ln(\cdot)$ will have a real value
SSB-SQ ^b	$A_c \sqrt{1 + m(t)}$	$\pm \frac{1}{2} \hat{m}(t)$	NL	$m(t) > -1$ is required so that the $\ln(\cdot)$ will have a real value
QM	$A_c \sqrt{m_1^2(t) + m_2^2(t)}$	$\tan^{-1}[m_2(t)/m_1(t)]$	L	Used in NTSC color television; requires coherent detection

^a $A_c > 0$ is a constant that sets the power level of the signal as evaluated by use of Eq. (1.11); L, linear; NL, nonlinear; and $[\hat{\cdot}]$ is the Hilbert transform (a -90° phase-shifted version of $[\cdot]$). For example, $\hat{m}(t) = m(t) * \frac{1}{\pi t} = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{m(\lambda)}{t-\lambda} d\lambda$.

^b Use upper signs for upper sideband signals and lower signals for lower sideband signals.

^c In the strict sense, AM signals are not linear because the carrier term does not satisfy the linearity (superposition) condition.

properties. Furthermore, in the receiver, the inverse function $m[g]$ is required. The inverse should be single valued over the range used and should be easily implemented. The inverse mapping should suppress as much noise as possible so that $m(t)$ can be recovered with little corruption.

1.4 Generalized Transmitters and Receivers

A more detailed description of transmitters and receivers, as first shown in Fig. 1.1, will now be illustrated.

There are two canonical forms for the generalized transmitter, as indicated by Eqs. (1.1b) and (1.1c). Equation (1.1b) describes an AM-PM type circuit, as shown in Fig. 1.2. The baseband signal processing circuit generates $R(t)$ and $\theta(t)$ from $m(t)$. The R and θ are functions of the modulating signal $m(t)$, as given in Table 1.1, for the particular modulation type desired. The signal processing may be implemented either by using nonlinear analog circuits or a digital computer that incorporates the R and θ algorithms under software program control. In the implementation using a digital computer, one analog-to-digital converter (ADC) will be needed at the input of the baseband signal processor, and two digital-to-analog converters (DACs) will be needed at the output. The remainder of the AM-PM canonical form requires radio frequency (RF) circuits, as indicated in the figure.

Figure 1.3 illustrates the second canonical form for the generalized transmitter. This uses in-phase and quadrature-phase (IQ) processing. Similarly, the formulas relating $x(t)$ and $y(t)$ to $m(t)$ are shown in

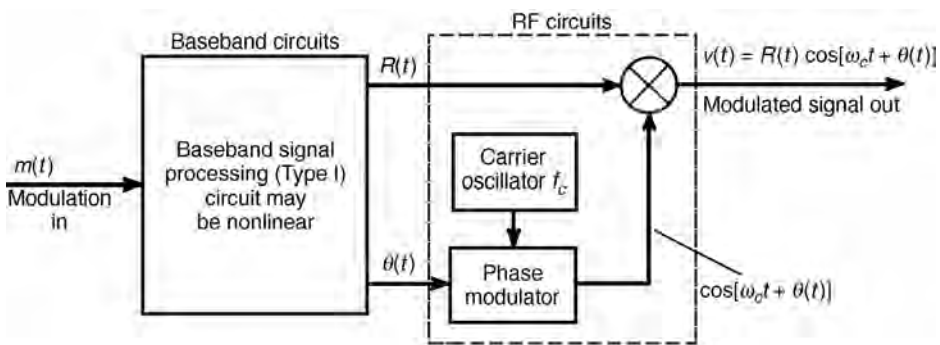

FIGURE 1.2 Generalized transmitter using the AM-PM generation technique. Source: Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, p. 282. With permission.

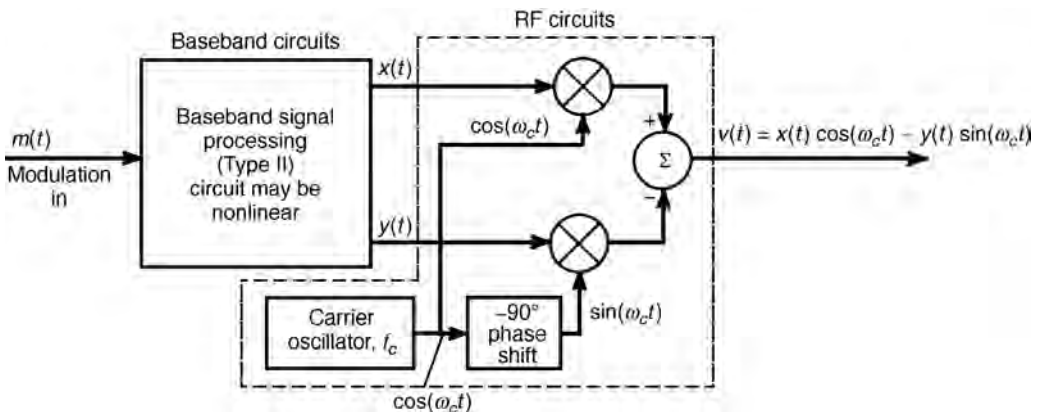

FIGURE 1.3 Generalized transmitter using the quadrature generation technique. Source: Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, p. 283. With permission.

Table 1.1, and the baseband signal processing may be implemented by using either analog hardware or digital hardware with software. The remainder of the canonical form uses RF circuits as indicated. Modern transmitters and receivers, such as those used in cellular telephones, often use IQ processing.

Analogous to the transmitter realizations, there are two canonical forms of receiver. Each one consists of RF carrier circuits followed by baseband signal processing, as illustrated in Fig. 1.1. Typically, the carrier circuits are of the superheterodyne-receiver type which consist of an RF amplifier, a down converter (mixer plus local oscillator) to some intermediate frequency (IF), an IF amplifier, and then detector circuits [1]. In the first canonical form of the receiver, the carrier circuits have amplitude and phase detectors that output $\tilde{R}(t)$ and $\tilde{\theta}(t)$, respectively. This pair, $\tilde{R}(t)$ and $\tilde{\theta}(t)$, describe the polar form of the received complex envelope, $\tilde{g}(t)$. $\tilde{R}(t)$ and $\tilde{\theta}(t)$ are then fed into the signal processor, which uses the inverse functions of Table 1.1 to generate the recovered modulation, $\tilde{m}(t)$. The second canonical form of the receiver uses quadrature product detectors in the carrier circuits to produce the Cartesian form (IQ processing) of the received complex envelope, $\tilde{x}(t)$ and $\tilde{y}(t)$. $\tilde{x}(t)$ and $\tilde{y}(t)$ are then inputted to the signal processor, which generates $\tilde{m}(t)$ at its output.

Once again, it is stressed that any type of signal modulation (see Table 1.1) may be generated (transmitted) or detected (received) by using either of these two canonical forms. Both of these forms conveniently separate baseband processing from RF processing. Digital signal processing (DSP) techniques are especially useful to realize the baseband processing portion. Furthermore, if DSP circuits are used, any desired modulation type can be realized by selecting the appropriate software algorithm. This is the basis for software radios [1].

1.5 Spectrum and Power of Bandpass Signals

The spectrum of the bandpass signal is the translation of the spectrum of its complex envelope. Taking the **Fourier transform** of Eq. (1.1a), the spectrum of the bandpass waveform is [1]

$$V(f) = \frac{1}{2}[G(f - f_c) + G^*(-f - f_c)] \quad (1.8)$$

where $G(f)$ is the Fourier transform of $g(t)$,

$$G(f) = \int_{-\infty}^{\infty} g(t)e^{-j2\pi ft} dt$$

and the asterisk superscript denotes the complex conjugate operation. The *power spectra density* (PSD) of the bandpass waveform is [1]

$$\mathcal{P}_v(f) = \frac{1}{4}[\mathcal{P}_g(f - f_c) + \mathcal{P}_g(-f - f_c)] \quad (1.9)$$

where $\mathcal{P}_g(f)$ is the PSD of $g(t)$.

The average power dissipated in a resistive load is V_{rms}^2/R_L or $I_{\text{rms}}^2 R_L$, where V_{rms} is the rms value of the voltage waveform across the load and I_{rms} is the rms value of the current through the load. For bandpass waveforms, Eq. (1.1) may represent either the voltage or the current. Furthermore, the rms values of $v(t)$ and $g(t)$ are related by [1]

$$v_{\text{rms}}^2 = \langle v^2(t) \rangle = \frac{1}{2} \langle |g(t)|^2 \rangle = \frac{1}{2} g_{\text{rms}}^2 \quad (1.10)$$

where $\langle \cdot \rangle$ denotes the time average and is given by

$$\left\langle \left[\begin{array}{c} \\ \\ \end{array} \right] \right\rangle = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} \left[\begin{array}{c} \\ \\ \end{array} \right] dt$$

Thus, if $v(t)$ of Eq. (1.1) represents the bandpass voltage waveform across a resistive load, the average power dissipated in the load is

$$P_L = \frac{v_{\text{rms}}^2}{R_L} = \frac{\langle v^2(t) \rangle}{R_L} = \frac{\langle |g(t)|^2 \rangle}{2R_L} = \frac{g_{\text{rms}}^2}{2R_L} \quad (1.11)$$

where g_{rms} is the rms value of the complex envelope, and R_L is the resistance of the load.

1.6 Amplitude Modulation

Amplitude modulation (AM) will now be examined in more detail. From Table 1.1, the complex envelope of an AM signal is

$$g(t) = A_c[1 + m(t)] \quad (1.12)$$

so that the spectrum of the complex envelope is

$$G(f) = A_c\delta(f) + A_cM(f) \quad (1.13)$$

Using Eq. (1.6), we obtain the AM signal waveform

$$s(t) = A_c[1 + m(t)]\cos\omega_c t \quad (1.14)$$

and, using Eq. (1.8), the AM spectrum

$$S(f) = \frac{1}{2}A_c[\delta(f-f_c) + M(f-f_c) + \delta(f+f_c) + M(f+f_c)] \quad (1.15)$$

where $\delta(f) = \delta(-f)$ and, because $m(t)$ is real, $M^*(f) = M(-f)$. Suppose that the magnitude spectrum of the modulation happens to be a triangular function, as shown in Fig. 1.4(a). This spectrum might arise from an analog audio source where the bass frequencies are emphasized. The resulting AM spectrum, using Eq. (1.15), is shown in Fig. 1.4(b). Note that because $G(f-f_c)$ and $G^*(-f-f_c)$ do not overlap, the magnitude spectrum is

$$|S(f)| = \begin{cases} \frac{1}{2}A_c\delta(f-f_c) + \frac{1}{2}A_c|M(f-f_c)|, & f > 0 \\ \frac{1}{2}A_c\delta(f+f_c) + \frac{1}{2}A_c|M(-f-f_c)|, & f < 0 \end{cases} \quad (1.16)$$

The 1 in

$$g(t) = A_c[1 + m(t)]$$

causes delta functions to occur in the spectrum at $f = \pm f_c$, where f_c is the assigned carrier frequency. Also, from Fig. 1.4 and Eq. (1.16), it is realized that the bandwidth of the AM signal is 2B. That is, the bandwidth of the AM signal is twice the bandwidth of the baseband modulating signal.

The average power dissipated into a resistive load is found by using Eq. (1.11).

$$P_L = \frac{A_c^2}{2R_L} \langle |1 + m(t)|^2 \rangle = \frac{A_c^2}{2R_L} [1 + 2\langle m(t) \rangle + \langle m^2(t) \rangle]$$

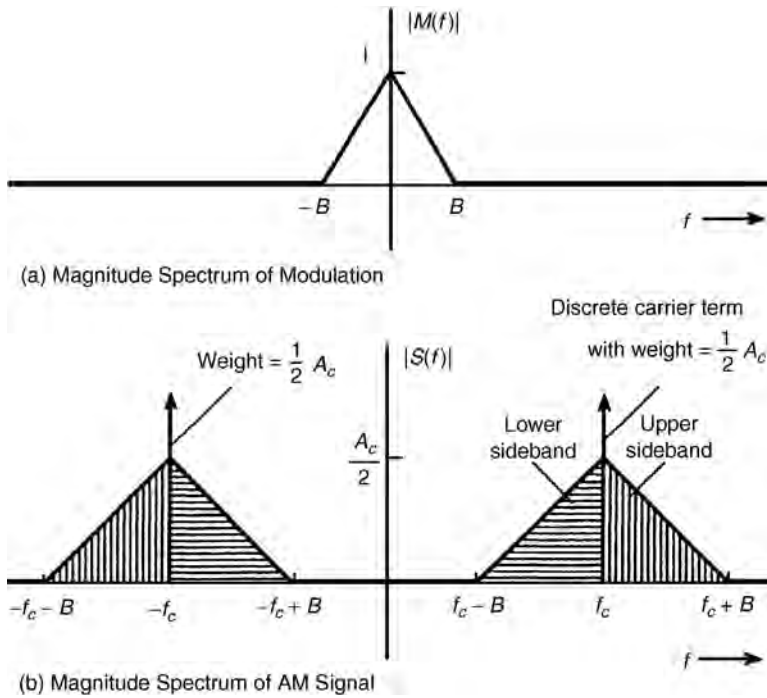

FIGURE 1.4 Spectrum of an AM signal. *Source:* Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, p. 239. With permission.

If we assume that the *dc* value of the modulation is zero, $\langle m(t) \rangle = 0$, then the average power dissipated into the load is

$$P_L = \frac{A_c^2}{2R_L} \langle 1 + m_{\text{rms}}^2 \rangle \quad (1.17)$$

where m_{rms} is the rms value of the modulation, $m(t)$. Thus, the average power of an AM signal changes if the rms value of the modulating signal changes. For example, if $m(t)$ is a sine wave test tone with a peak value of 1.0 for 100% modulation,

$$m_{\text{rms}} = 1/\sqrt{2}$$

Assume that $A_c = 1000$ volts and $R_L = 50$ ohms, which are typical values used in AM broadcasting. Then, the average power dissipated into the 50Ω load for this AM signal is

$$P_L = \frac{(1000)^2}{2(50)} \left[1 + \frac{1}{2} \right] = 15,000 \text{ watts} \quad (1.18)$$

The Federal Communications Commission (FCC) rated carrier power is obtained when $m(t) = 0$. In this case, Eq. (1.17) becomes $P_L = (1000)^2/100 = 10,000$ watts, and the FCC would rate this as a 10,000 watt AM station. The sideband power for 100% sine wave modulation is 5000 watts.

Now let the modulation on the AM signal be a binary digital signal such that $m(t) = \pm 1$ where +1 is used for a binary one and -1 is used for a binary 0. Referring to Eq. (1.14), this AM signal becomes an *on-off keyed* (OOK) digital signal where the signal is on when a binary one is transmitted and off when a binary zero is transmitted. For $A_c = 1000$ and $R_L = 50 \Omega$, the average power dissipated would be 20,000 watts since $m_{\text{rms}} = 1$ for $m(t) = \pm 1$.

1.7 Phase and Frequency Modulation

Phase modulation (PM) and *frequency modulation* (FM) are special cases of angle-modulated signalling. In angle-modulated signalling, the complex envelope is

$$g(t) = A_c e^{j\theta(t)} \quad (1.19)$$

Using Eq. (1.6), the resulting *angle-modulated* signal is

$$s(t) = A_c \cos[\omega_c + \theta(t)] \quad (1.20)$$

For PM, the phase is directly proportional to the modulating signal:

$$\theta(t) = D_p m(t) \quad (1.21)$$

where the proportionality constant D_p is the phase sensitivity of the phase modulator, having units of radians per volt [assuming that $m(t)$ is a voltage waveform]. For FM, the phase is proportional to the integral of $m(t)$:

$$\theta(t) = D_f \int_{-\infty}^t m(\sigma) d\sigma \quad (1.22)$$

where the frequency deviation constant D_f has units of radians/volt-second. These concepts are summarized by the PM and FM entries in [Table 1.1](#).

By comparing the last two equations, it is seen that if we have a PM signal modulated by $m_p(t)$, there is *also* FM on the signal corresponding to a *different* modulating waveshape that is given by

$$m_f(t) = \frac{D_p}{D_f} \left[\frac{dm_p(t)}{dt} \right] \quad (1.23)$$

where the subscripts f and p denote frequency and phase, respectively. Similarly, if we have an FM signal modulated by $m_f(t)$, the corresponding phase modulation on this signal is

$$m_p(t) = \frac{D_f}{D_p} \int_{-\infty}^t m_f(\sigma) d\sigma \quad (1.24)$$

By using Eq. (1.24), a PM circuit may be used to synthesize an FM circuit by inserting an integrator in cascade with the phase modulator input.

Other properties of PM and FM are that the **real envelope**, $R(t) = |g(t)| = A_c$, is a constant, as seen from Eq. (1.19). Also, $g(t)$ is a *nonlinear* function of the modulation. However, from Eqs. (1.21) and (1.22), $\theta(t)$ is a linear function of the modulation $m(t)$. Using Eq. (1.11), the average power dissipated by a PM or FM signal is the constant

$$P_L = \frac{A_c^2}{2R_L} \quad (1.25)$$

That is, the average power of a PM or FM signal does not depend on the modulating waveform $m(t)$.

The *instantaneous frequency deviation* for an FM signal from its carrier frequency is given by the derivative of its phase $\theta(t)$. Taking the derivative of Eq. (1.22), the *peak frequency deviation* is

$$\Delta F = \frac{1}{2\pi} D_f M_p \text{ Hz} \quad (1.26)$$

where $M_p = \max[m(t)]$ is the peak value of the modulation waveform and the derivative has been divided by 2π to convert from radians/sec to Hz units.

For FM and PM signals, Carson's rule estimates the transmission bandwidth containing approximately 98% of the total power. This FM or PM signal bandwidth is

$$B_T = 2(\beta + 1)B \quad (1.27)$$

where B is bandwidth (highest frequency) of the modulation. The modulation index β , is $\beta = \Delta F/B$ for FM and $\beta = \max[D_p m(t)] = D_p M_p$ for PM.

The AMPS (Advanced Mobile Phone System) analog cellular phones use FM signalling. A peak deviation of 12 kHz is specified with a modulation bandwidth of 3 kHz. From Eq. (1.27), this gives a bandwidth of 30 kHz for the AMPS signal and allows a channel spacing of 30 kHz to be used. To accommodate more users, narrow-band AMPS (NAMPS) with a 5 kHz peak deviation is used in some areas. This allows 10 kHz channel spacing if the carrier frequencies are carefully selected to minimize interference to used adjacent channels. A maximum FM signal power of 3 watts is allowed for the AMPS phones. However, hand-held AMPS phones usually produce no more than 600 mW, which is equivalent to 5.5 volts rms across the 50 Ω antenna terminals.

The GSM (Group Special Mobile) digital cellular phones use FM with *minimum frequency-shift-keying* (MSK) where the peak frequency deviation is selected to produce orthogonal waveforms for binary one and binary zero data. (Digital phones use a speech codec to convert the analog voice source to a digital data source for transmission over the system.) Orthogonality occurs when $\Delta F = 1/4R$ where R is the bit rate (bits/sec)[1]. Actually, GSM uses Gaussian shaped MSK (GMSK). That is, the digital data waveform (with rectangular binary one and binary zero pulses) is first filtered by a low-pass filter having a Gaussian shaped frequency response (to attenuate the higher frequencies). This Gaussian filtered data waveform is then fed into the frequency modulator to generate the GMSK signal. This produces a digitally modulated FM signal with a relatively small bandwidth.

Other digital cellular standards use QPSK signalling, as discussed in the next section.

1.8 QPSK, $\pi/4$ QPSK, QAM, and OOK Signalling

Quadrature phase-shift-keying (QPSK) is a special case of quadrature modulation, as shown in Table 1.1, where $m_1(t) = \pm 1$ and $m_2(t) = \pm 1$ are two binary bit streams. The complex envelope for QPSK is

$$g(t) = x(t) + jy(t) = A_c[m_1(t) + jm_2(t)]$$

where $x(t) = \pm A_c$ and $y(t) = \pm A_c$. The permitted values for the complex envelope are illustrated by the QPSK **signal constellation** shown in Fig. 1.5a. The *signal constellation* is a plot of the permitted values for the complex envelope $g(t)$. QPSK may be generated by using the quadrature generation technique of Fig. 1.3, where the baseband signal processor is a serial-to-parallel converter that reads in two bits of data at a time from the serial binary input stream, $m(t)$, and outputs the first of the two bits to $x(t)$ and the second bit to $y(t)$. If the two input bits are both binary ones, (11), then $m_1(t) = +A_c$ and $m_2(t) = +A_c$. This is represented by the top right-hand dot for $g(t)$ in the signal constellation for QPSK signalling in Fig. 1.5a. Likewise, the three other possible two-bit words, (10), (01), and (00), are also shown. The QPSK signal is also equivalent to a four-phase phase-shift-keyed signal (4PSK) since all the points in the signal constellation fall on a circle where the permitted phases are $\theta(t) = 45^\circ, 135^\circ, 225^\circ, \text{ and } 315^\circ$. There is no amplitude modulation on the QPSK signal since the distances from the origin to all the signal points on the signal constellation are equal.

For QPSK, the spectrum of $g(t)$ is of the $\sin x/x$ type since $x(t)$ and $y(t)$ consist of rectangular data pulses of value $\pm A_c$. Moreover, it can be shown that for equally likely independent binary one and binary zero data, the power spectral density of $g(t)$ for digitally modulated signals with M point signal constellations is [1]

$$\mathcal{P}_g(f) = K \left(\frac{\sin \pi f \ell T_b}{\pi f \ell T_b} \right)^2 \quad (1.28)$$

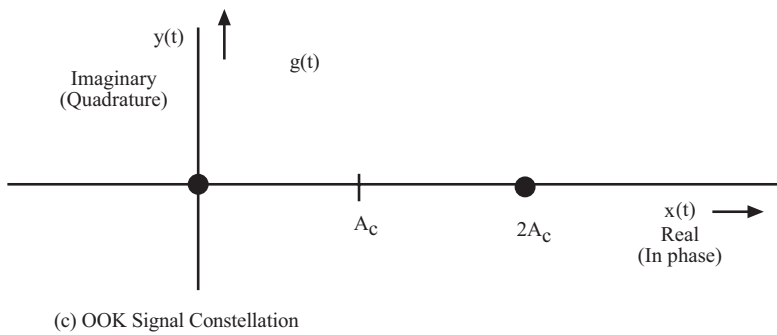

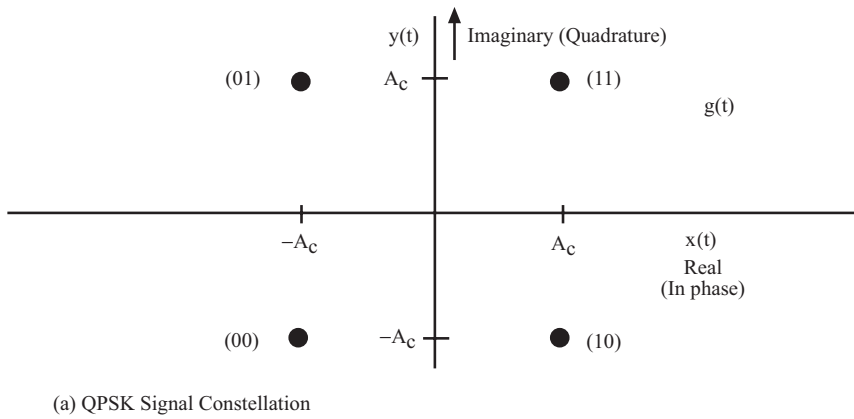

FIGURE 1.5 Signal constellations (permitted values of the complex envelope).

FIGURE 1.6 PSD for the complex envelope of MPSK and QAM where $M = 2^\ell$ and R is bit rate (positive frequencies shown). Source: Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, p. 358. With permission.

where K is a constant, $R = 1/T_b$ is the data rate (bits/sec) of $m(t)$, and $M = 2^\ell$. M is the number of points in the signal constellation. For QPSK, $M = 4$ and $\ell = 2$. This PSD for the complex envelope, $\mathcal{P}_g(f)$, is plotted in Fig. 1.6. The PSD for the QPSK signal ($\ell = 2$) is given by translating $\mathcal{P}_g(f)$ up to the carrier frequency as indicated by Eq. (1.9).

Referring to Fig. 1.6 or using Eq. (1.28), the first-null bandwidth of $g(t)$ is R/ℓ Hz. Consequently, the null-to-null bandwidth of the modulated RF signal is

$$B_{\text{null}} = \frac{2R}{\ell} \text{ Hz} \quad (1.29)$$

For example, if the data rate of the baseband information source is 9600 bits/sec, then the null-to-null bandwidth of the QPSK signal would be 9.6 kHz since $\ell = 2$.

Referring to Fig. 1.6, it is seen that the sidelobes of the spectrum are relatively large, so, in practice, the sidelobes of the spectrum are filtered off to prevent interference to the adjacent channels. This filtering rounds off the edges of the rectangular data pulses and this causes some amplitude modulation on the QPSK signal. That is, the points in the signal constellation for the filtered QPSK signal would be fuzzy since the transition from one constellation point to another point is not instantaneous because the filtered data pulses are not rectangular. QPSK is the modulation used for digital cellular phones with the IS-95 Code Division Multiple Access (CDMA) standard.

$\pi/4$ QPSK is generated by alternating symbols between a signal constellation shown by Fig. 1.5a and a signal constellation (of Fig. 1.5a) rotated by 45° . $\pi/4$ QPSK has the same spectrum as QPSK. However, the peak-to-average power ratio of filtered $\pi/4$ QPSK is much lower than that for filtered QPSK because there are no 180° phase transitions (from symbol to symbol) in the $\pi/4$ QPSK signal. $\pi/4$ QPSK is the modulation technique used for IS-136 TDMA digital cellular phones.

Equation (1.28) and Fig. 1.6 also represent the spectrum for *quadrature modulation amplitude modulation* (QAM) signalling. QAM signalling allows more than two values for $x(t)$ and $y(t)$. For example,

QAM where $M = 16$ has 16 points in the signal constellation with 4 values for $x(t)$ and 4 values for $y(t)$ such as, for example, $x(t) = +A_c, -A_c, +3A_c, -3A_c$ and $y(t) = +A_c, -A_c, +3A_c, -3A_c$. This is shown in Fig. 1.5b. Each point in the $M = 16$ QAM signal constellation would represent a unique four-bit data word, as compared with the $M = 4$ QPSK signal constellation shown in Fig. 1.5a, where each point represents a unique two-bit data word. For an $R = 9600$ bits/sec information source data rate, an $M = 16$ QAM signal would have a null-to-null bandwidth of 4.8 kHz since $\ell = 4$.

For OOK signalling, as described at the end of Section 1.6, the signal constellation would consist of $M = 2$ points along the x axis where $x = 0, 2A_c$ and $y = 0$. This is illustrated in Fig. 1.5c. For an $R = 9600$ bit/sec information source data rate, an OOK signal would have a null-to-null bandwidth of 19.2 kHz since $\ell = 1$.

Defining Terms

Bandpass waveform: The spectrum of the waveform is nonzero for frequencies in some band concentrated about a frequency $f_c \gg 0$; f_c is called the carrier frequency.

Baseband waveform: The spectrum of the waveform is nonzero for frequencies near $f = 0$.

Complex envelope: The function $g(t)$ of a bandpass waveform $v(t)$ where the bandpass waveform is described by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$$

Fourier transform: If $w(t)$ is a waveform, then the Fourier transform of $w(t)$ is

$$W(f) = \mathfrak{F}[w(t)] = \int_{-\infty}^{\infty} w(t)e^{-j2\pi ft} dt$$

where f has units of hertz.

Modulated signal: The bandpass signal

$$s(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$$

where fluctuations of $g(t)$ are caused by the information source such as audio, video, or data.

Modulation: The information source, $m(t)$, that causes fluctuations in a bandpass signal.

Real envelope: The function $R(t) = |g(t)|$ of a bandpass waveform $v(t)$ where the bandpass waveform is described by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$$

Signal constellation: The permitted values of the complex envelope for a digital modulating source.

2.1 Introduction

To transmit analog message signals, such as speech signals or video signals, by digital means, the signal has to be converted into digital form. This process is known as analog-to-digital conversion. The sampling process is the first process performed in this conversion, and it converts a continuous-time signal into a discrete-time signal or a sequence of numbers. Digital transmission of analog signals is possible by virtue of the sampling theorem, and the sampling operation is performed in accordance with the sampling theorem.

In this chapter, using the Fourier transform technique, we present this remarkable sampling theorem and discuss the operation of sampling and practical aspects of sampling.

2.2 Instantaneous Sampling

Suppose we sample an arbitrary analog signal $m(t)$ shown in Fig. 2.1(a) instantaneously at a uniform rate, once every T_s seconds. As a result of this sampling process, we obtain an infinite sequence of samples $\{m(nT_s)\}$, where n takes on all possible integers. This form of sampling is called *instantaneous sampling*. We refer to T_s as the **sampling interval** and to its reciprocal $1/T_s = f_s$ as the **sampling rate**. Sampling rate (samples per second) is often cited in terms of sampling frequency expressed in hertz.

Ideal Sampled Signal

Let $m_s(t)$ be obtained by multiplication of $m(t)$ by the unit impulse train $\delta_T(t)$ with period T_s [Fig. 2.1(c)], that is,

$$\begin{aligned} m_s(t) &= m(t)\delta_{T_s}(t) = m(t) \sum_{n=-\infty}^{\infty} \delta(t - nT_s) \\ &= \sum_{n=-\infty}^{\infty} m(t)\delta(t - nT_s) = \sum_{n=-\infty}^{\infty} m(nT_s)\delta(t - nT_s) \end{aligned} \quad (2.1)$$

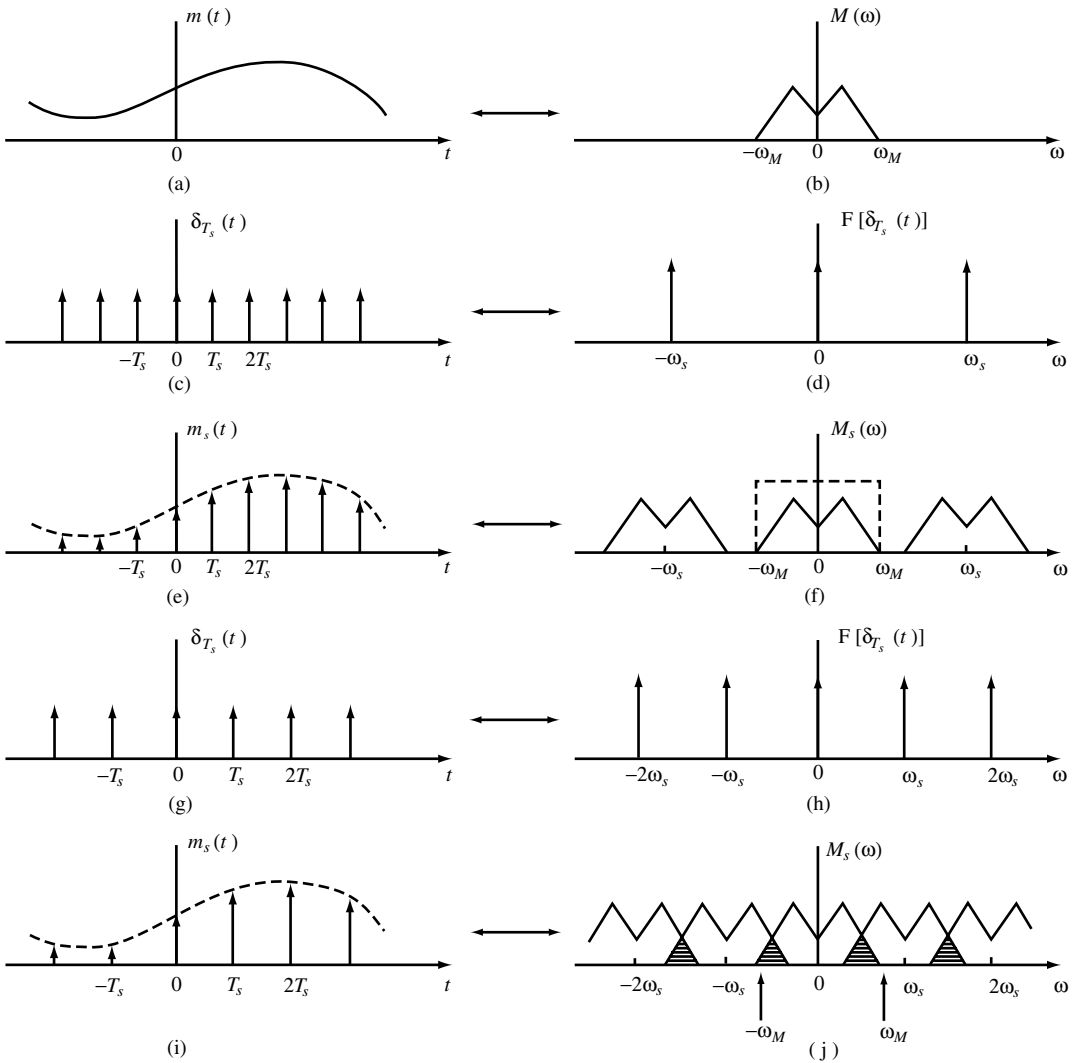

FIGURE 2.1 Illustration of instantaneous sampling and sampling theorem.

where we used the property of the δ function, $m(t)\delta(t - t_0) = m(t_0)\delta(t - t_0)$. The signal $m_s(t)$ [Fig. 2.1(e)] is referred to as the **ideal sampled signal**.

Band-Limited Signals

A real-valued signal $m(t)$ is called a **band-limited signal** if its Fourier transform $M(\omega)$ satisfies the condition

$$M(\omega) = 0 \quad \text{for } |\omega| > \omega_M \quad (2.2)$$

where $\omega_M = 2\pi f_M$ [Fig. 2.1(b)]. A band-limited signal specified by Eq. (2.2) is often referred to as a *low-pass signal*.

2.3 Sampling Theorem

The sampling theorem states that a band-limited signal $m(t)$ specified by Eq. (2.2) can be uniquely determined from its values $m(nT_s)$ sampled at uniform interval T_s if $T_s \leq \pi/\omega_M = 1/(2f_M)$. In fact, when $T_s = \pi/\omega_M$, $m(t)$ is given by

$$m(t) = \sum_{n=-\infty}^{\infty} m(nT_s) \frac{\sin \omega_M(t - nT_s)}{\omega_M(t - nT_s)} \quad (2.3)$$

which is known as the **Nyquist–Shannon interpolation formula** and is also sometimes called the *cardinal series*. The sampling interval $T_s = 1/(2f_M)$ is called the *Nyquist interval* and the minimum rate $f_s = 1/T_s = 2f_M$ is known as the **Nyquist rate**.

Illustration of the instantaneous sampling process and the sampling theorem is shown in Fig. 2.1. The Fourier transform of the unit impulse train is given by [Fig. 2.1(d)]

$$\mathcal{F}\{\delta_{T_s}(t)\} = \omega_s \sum_{n=-\infty}^{\infty} \delta(\omega - n\omega_s) \quad \omega_s = 2\pi/T_s \quad (2.4)$$

Then, by the convolution property of the Fourier transform, the Fourier transform $M_s(\omega)$ of the ideal sampled signal $m_s(t)$ is given by

$$\begin{aligned} M_s(\omega) &= \frac{1}{2\pi} \left[M(\omega) * \omega_s \sum_{n=-\infty}^{\infty} \delta(\omega - n\omega_s) \right] \\ &= \frac{1}{T_s} \sum_{n=-\infty}^{\infty} M(\omega - n\omega_s) \end{aligned} \quad (2.5)$$

where $*$ denotes convolution and we used the convolution property of the δ -function $M(\omega) * \delta(\omega - \omega_0) = M(\omega - \omega_0)$. Thus, the sampling has produced images of $M(\omega)$ along the frequency axis. Note that $M_s(\omega)$ will repeat periodically without overlap as long as $\omega_s \geq 2\omega_M$ or $f_s \geq 2f_M$ [Fig. 2.1(f)]. It is clear from Fig. 2.1(f) that we can recover $M(\omega)$ and, hence, $m(t)$ by passing the sampled signal $m_s(t)$ through an ideal low-pass filter having frequency response

$$H(\omega) = \begin{cases} T_s, & |\omega| \leq \omega_M \\ 0, & \text{otherwise} \end{cases} \quad (2.6)$$

where $\omega_M = \pi/T_s$. Then

$$M(\omega) = M_s(\omega)H(\omega) \quad (2.7)$$

Taking the inverse Fourier transform of Eq. (2.6), we obtain the impulse response $h(t)$ of the ideal low-pass filter as

$$h(t) = \frac{\sin \omega_M t}{\omega_M t} \quad (2.8)$$

Taking the inverse Fourier transform of Eq. (2.7), we obtain

$$\begin{aligned}
 m(t) &= m_s(t) * h(t) \\
 &= \sum_{n=-\infty}^{\infty} m(nT_s) \delta(t - nT_s) * \frac{\sin \omega_M t}{\omega_M t} \\
 &= \sum_{n=-\infty}^{\infty} m(nT_s) \frac{\sin \omega_M (t - nT_s)}{\omega_M (t - nT_s)}
 \end{aligned} \tag{2.9}$$

which is Eq. (2.3).

The situation shown in Fig. 2.1(j) corresponds to the case where $f_s < 2f_M$. In this case, there is an overlap between $M(\omega)$ and $M(\omega - \omega_M)$. This overlap of the spectra is known as *aliasing* or *foldover*. When this aliasing occurs, the signal is distorted and it is impossible to recover the original signal $m(t)$ from the sampled signal. To avoid aliasing, in practice, the signal is sampled at a rate slightly higher than the Nyquist rate. If $f_s > 2f_M$, then, as shown in Fig. 2.1(f), there is a gap between the upper limit ω_M of $M(\omega)$ and the lower limit $\omega_s - \omega_M$ of $M(\omega - \omega_s)$. This range from ω_M to $\omega_s - \omega_M$ is called a *guard band*. As an example, speech transmitted via telephone is generally limited to $f_M = 3.3$ kHz (by passing the sampled signal through a low-pass filter). The Nyquist rate is, thus, 6.6 kHz. For digital transmission, the speech is normally sampled at the rate $f_s = 8$ kHz. The guard band is then $f_s - 2f_M = 1.4$ kHz. The use of a sampling rate higher than the Nyquist rate also has the desirable effect of making it somewhat easier to design the low-pass reconstruction filter so as to recover the original signal from the sampled signal.

2.4 Sampling of Sinusoidal Signals

A special case is the sampling of a sinusoidal signal having the frequency f_M . In this case, we require that $f_s > 2f_M$ rather than $f_s \geq 2f_M$. To see that this condition is necessary, let $f_s = 2f_M$. Now, if an initial sample is taken at the instant the sinusoidal signal is zero, then all successive samples will also be zero. This situation is avoided by requiring $f_s > 2f_M$.

2.5 Sampling of Bandpass Signals

A real-valued signal $m(t)$ is called a **bandpass signal** if its Fourier transform $M(\omega)$ satisfies the condition

$$M(\omega) = 0 \quad \text{except for} \quad \begin{cases} \omega_1 < \omega < \omega_2 \\ -\omega_2 < \omega < -\omega_1 \end{cases} \tag{2.10}$$

where $\omega_1 = 2\pi f_1$ and $\omega_2 = 2\pi f_2$ [Fig. 2.2(a)].

The sampling theorem for a band-limited signal has shown that a sampling rate of $2f_2$ or greater is adequate for a low-pass signal having the highest frequency f_2 . Therefore, treating $m(t)$ specified by Eq. (2.10) as a special case of such a low-pass signal, we conclude that a sampling rate of $2f_2$ is adequate for the sampling of the bandpass signal $m(t)$. But it is not necessary to sample this fast. The minimum allowable sampling rate depends on f_1, f_2 , and the bandwidth $f_B = f_2 - f_1$.

Let us consider the direct sampling of the bandpass signal specified by Eq. (2.10). The spectrum of the sampled signal is periodic with the period $\omega_s = 2\pi f_s$, where f_s is the sampling frequency, as in Eq. (2.4). Shown in Fig. 2.2(b) are the two right shifted spectra of the negative side spectrum $M_-(\omega)$. If the recovering of the bandpass signal is achieved by passing the sampled signal through an ideal bandpass

FIGURE 2.2 (a) Spectrum of a bandpass signal; (b) Shifted spectra of $M_-(\omega)$.

filter covering the frequency bands $(-\omega_2, -\omega_1)$ and (ω_1, ω_2) , it is necessary that there be no aliasing problem. From Fig. 2.2(b), it is clear that to avoid overlap it is necessary that

$$\omega_s \geq 2(\omega_2 - \omega_1) \quad (2.11)$$

$$(k-1)\omega_s - \omega_1 \leq \omega_1 \quad (2.12)$$

and

$$k\omega_s - \omega_2 \geq \omega_2 \quad (2.13)$$

where $\omega_1 = 2\pi f_1$, $\omega_2 = 2\pi f_2$, and k is an integer ($k = 1, 2, \dots$). Since $f_1 = f_2 - f_B$, these constraints can be expressed as

$$1 \leq k \leq \frac{f_2}{f_B} \leq \frac{k}{2} \frac{f_s}{f_B} \quad (2.14)$$

and

$$\frac{k-1}{2} \frac{f_s}{f_B} \leq \frac{f_2}{f_B} - 1 \quad (2.15)$$

A graphical description of Eqs. (2.14) and (2.15) is illustrated in Fig. 2.3. The unshaded regions represent where the constraints are satisfied, whereas the shaded regions represent the regions where the

FIGURE 2.3 Minimum and permissible sampling rates for a bandpass signal.

constraints are not satisfied and overlap will occur. The solid line in Fig. 2.3 shows the locus of the minimum sampling rate. The minimum sampling rate is given by

$$\min\{f_s\} = \frac{2f_2}{m} \quad (2.16)$$

where m is the largest integer not exceeding f_2/f_B . Note that if the ratio f_2/f_B is an integer, then the minimum sampling rate is $2f_B$. As an example, consider a bandpass signal with $f_1 = 1.5$ kHz and $f_2 = 2.5$ kHz. Here, $f_B = f_2 - f_1 = 1$ kHz and $f_2/f_B = 2.5$. Then, from Eq. (2.16) and Fig. 2.3, we see that the minimum sampling rate is $2f_2/2 = f_2 = 2.5$ kHz, and allowable ranges of sampling rate are $2.5 \text{ kHz} \leq f_s \leq 3 \text{ kHz}$ and $f_s \geq 5 \text{ kHz}$ ($= 2f_2$).

2.6 Practical Sampling

In practice, the sampling of an analog signal is performed by means of high-speed switching circuits, and the sampling process takes the form of *natural sampling* or **flat-top sampling**.

Natural Sampling

Natural sampling of a band-limited signal $m(t)$ is shown in Fig. 2.4. The sampled signal $m_{ns}(t)$ can be expressed as

$$m_{ns}(t) = m(t)x_p(t) \quad (2.17)$$

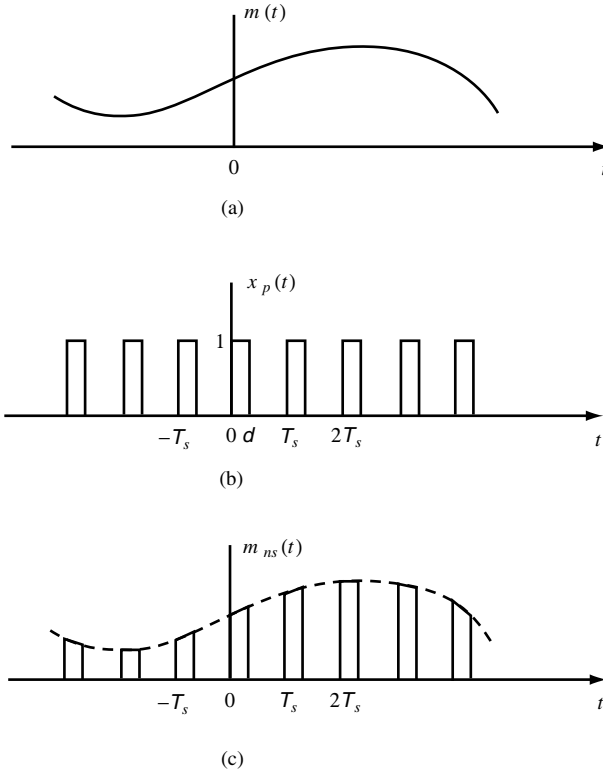

FIGURE 2.4 Natural sampling.

where $x_p(t)$ is the periodic train of rectangular pulses with fundamental period T_s , and each rectangular pulse in $x_p(t)$ has duration d and unit amplitude [Fig. 2.4(b)]. Observe that the sampled signal $m_{ns}(t)$ consists of a sequence of pulses of varying amplitude whose tops follow the waveform of the signal $m(t)$ [Fig. 2.4(c)].

The Fourier transform of $x_p(t)$ is

$$X_p(\omega) = \sum_{n=-\infty}^{\infty} c_n \delta(\omega - n\omega_s) \quad \omega_s = 2\pi/T_s \quad (2.18)$$

where

$$c_n = \frac{d \sin(n\omega_s d/2)}{T_s n\omega_s d/2} e^{-jn\omega_s d/2} \quad (2.19)$$

Then the Fourier transform of $m_{ns}(t)$ is given by

$$M_{ns}(\omega) = M(\omega) * X_p(\omega) = \sum_{n=-\infty}^{\infty} c_n M(\omega - n\omega_s) \quad (2.20)$$

from which we see that the effect of the natural sampling is to multiply the n th shifted spectrum $M(\omega - n\omega_s)$ by a constant c_n . Thus, the original signal $m(t)$ can be reconstructed from $m_{ns}(t)$ with no distortion by passing $m_{ns}(t)$ through an ideal low-pass filter if the sampling rate f_s is equal to or greater than the Nyquist rate $2f_M$.

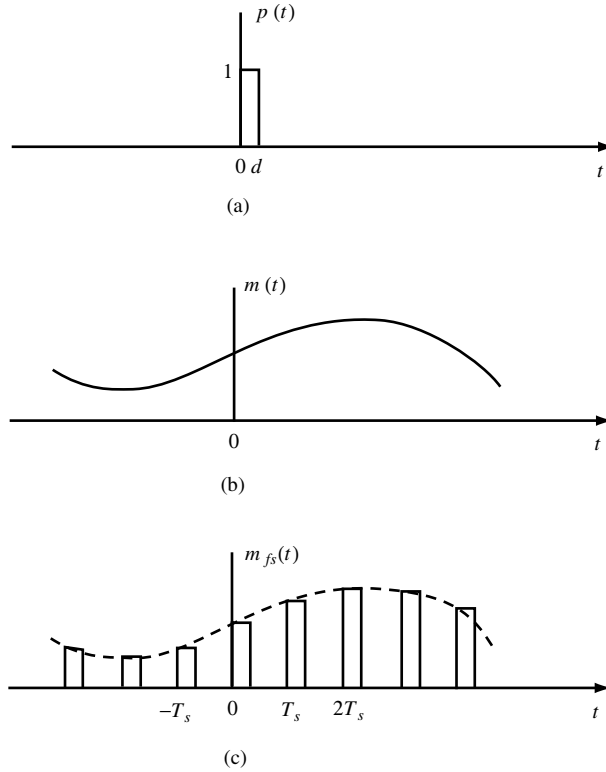

FIGURE 2.5 Flat-top sampling.

Flat-Top Sampling

The sampled waveform, produced by practical sampling devices that are the sample and hold types, has the form [Fig. 2.5(c)]

$$m_{fs}(t) = \sum_{n=-\infty}^{\infty} m(nT_s)p(t - nT_s) \quad (2.21)$$

where $p(t)$ is a rectangular pulse of duration d with unit amplitude [Fig. 2.5(a)]. This type of sampling is known as **flat-top sampling**. Using the ideal sampled signal $m_s(t)$ of Eq. (2.1), $m_{fs}(t)$ can be expressed as

$$m_{fs}(t) = p(t) * \left[\sum_{n=-\infty}^{\infty} m(nT_s)\delta(t - nT_s) \right] = p(t) * m_s(t) \quad (2.22)$$

Using the convolution property of the Fourier transform and Eq. (2.4), the Fourier transform of $m_{fs}(t)$ is given by

$$M_{fs}(\omega) = P(\omega)M_s(\omega) = \frac{1}{T_s} \sum_{n=-\infty}^{\infty} P(\omega)M(\omega - n\omega_s) \quad (2.23)$$

where

$$P(\omega) = d \frac{\sin(\omega d/2)}{\omega d/2} e^{-j\omega d/2} \quad (2.24)$$

From Eq. (2.23) we see that by using flat-top sampling we have introduced amplitude distortion and time delay, and the primary effect is an attenuation of high-frequency components. This effect is known as the *aperture effect*. The aperture effect can be compensated by an equalizing filter with a frequency response $H_{\text{eq}}(\omega) = 1/P(\omega)$. If the pulse duration d is chosen such that $d \ll T_s$, however, then $P(\omega)$ is essentially constant over the baseband and no equalization may be needed.

2.7 Sampling Theorem in the Frequency Domain

The sampling theorem expressed in Eq. (2.4) is the time-domain sampling theorem. There is a dual to this time-domain sampling theorem, i.e., the sampling theorem in the frequency domain.

Time-limited signals: A continuous-time signal $m(t)$ is called **time limited** if

$$m(t) = 0 \quad \text{for } |t| > |T_0| \quad (2.25)$$

Frequency-domain sampling theorem: The frequency-domain sampling theorem states that the Fourier transform $M(\omega)$ of a time-limited signal $m(t)$ specified by Eq. (2.25) can be uniquely determined from its values $M(n\omega_s)$ sampled at a uniform rate ω_s if $\omega_s \leq \pi/T_0$. In fact, when $\omega_s = \pi/T_0$, then $M(\omega)$ is given by

$$M(\omega) = \sum_{n=-\infty}^{\infty} M(n\omega_s) \frac{\sin T_0(\omega - n\omega_s)}{T_0(\omega - n\omega_s)} \quad (2.26)$$

2.8 Summary and Discussion

The sampling theorem is the fundamental principle of digital communications. We state the sampling theorem in two parts.

Theorem 2.1. *If the signal contains no frequency higher than f_M Hz, it is completely described by specifying its samples taken at instants of time spaced $1/2f_M$ s.*

Theorem 2.2. *The signal can be completely recovered from its samples taken at the rate of $2f_M$ samples per second or higher.*

The preceding sampling theorem assumes that the signal is strictly band limited. It is known that if a signal is band limited, it cannot be time limited, and vice versa. In many practical applications, the signal to be sampled is time limited and, consequently, it cannot be strictly band limited. Nevertheless, we know that the frequency components of physically occurring signals attenuate rapidly beyond some defined bandwidth, and for practical purposes we consider these signals band limited. This approximation of real signals by band limited ones introduces no significant error in the application of the sampling theorem. When such a signal is sampled, we band limit the signal by filtering before sampling and sample at a rate slightly higher than the nominal Nyquist rate.

Defining Terms

Band-limited signal: A signal whose frequency content (Fourier transform) is equal to zero above some specified frequency.

Bandpass signal: A signal whose frequency content (Fourier transform) is nonzero only in a band of frequencies not including the origin.

Flat-top sampling: Sampling with finite width pulses that maintain a constant value for a time period less than or equal to the sampling interval. The constant value is the amplitude of the signal at the desired sampling instant.

Ideal sampled signal: A signal sampled using an ideal impulse train.

Nyquist rate: The minimum allowable sampling rate of $2f_M$ samples per second, to reconstruct a signal band limited to f_M hertz.

Nyquist-Shannon interpolation formula: The infinite series representing a time domain waveform in terms of its ideal samples taken at uniform intervals.

Sampling interval: The time between samples in uniform sampling.

Sampling rate: The number of samples taken per second (expressed in Hertz and equal to the reciprocal of the sampling interval).

Time-limited: A signal that is zero outside of some specified time interval.

Leon W. Couch, II
University of Florida

3.1 Introduction

Pulse code modulation (PCM) is analog-to-digital conversion of a special type where the information contained in the instantaneous samples of an analog signal is represented by digital words in a serial bit stream.

If we assume that each of the digital words has n binary digits, there are $M = 2^n$ unique code words that are possible, each code word corresponding to a certain amplitude level. Each sample value from the analog signal, however, can be any one of an infinite number of levels, so that the digital word that represents the amplitude closest to the actual sampled value is used. This is called **quantizing**. That is, instead of using the exact sample value of the analog waveform, the sample is replaced by the closest allowed value, where there are M allowed values, and each allowed value corresponds to one of the code words.

PCM is very popular because of the many advantages it offers. Some of these advantages are as follows.

- Relatively inexpensive digital circuitry may be used extensively in the system.
- PCM signals derived from all types of analog sources (audio, video, etc.) may be time-division multiplexed with data signals (e.g., from digital computers) and transmitted over a common high-speed digital communication system.
- In long-distance digital telephone systems requiring repeaters, a *clean* PCM waveform can be regenerated at the output of each repeater, where the input consists of a noisy PCM waveform. The noise at the input, however, may cause bit errors in the regenerated PCM output signal.
- The noise performance of a digital system can be superior to that of an analog system. In addition, the probability of error for the system output can be reduced even further by the use of appropriate coding techniques.

These advantages usually outweigh the main disadvantage of PCM: a much wider bandwidth than that of the corresponding analog signal.

3.2 Generation of PCM

The PCM signal is generated by carrying out three basic operations: sampling, quantizing, and encoding (see Fig. 3.1). The sampling operation generates an instantaneously-sampled flat-top **pulse-amplitude modulated** (PAM) signal.

The quantizing operation is illustrated in Fig. 3.2 for the $M = 8$ level case. This quantizer is said to be *uniform* since all of the steps are of equal size. Since we are approximating the analog sample values by using a finite number of levels ($M = 8$ in this illustration), *error* is introduced into the recovered output analog signal because of the quantizing effect. The error waveform is illustrated in Fig. 3.2c. The quantizing error consists of the difference between the analog signal at the sampler input and the output of the quantizer. Note that the peak value of the error (± 1) is one-half of the quantizer step size [2]. If we sample at the Nyquist rate ($2B$, where B is the absolute bandwidth, in hertz, of the input analog signal) or faster and there is negligible channel noise, there will still be noise, called *quantizing noise*, on the recovered analog waveform due to this error. The quantizing noise can also be thought of as a round-off error. The quantizer output is a *quantized* (i.e., only M possible amplitude values) PAM signal.

The PCM signal is obtained from the quantized PAM signal by encoding each quantized sample value into a digital word. It is up to the system designer to specify the exact code word that will represent a particular quantized level. If a Gray code of Table 3.1 is used, the resulting PCM signal is shown in Fig. 3.2d where the PCM word for each quantized sample is strobed out of the encoder by the next clock pulse. The Gray code was chosen because it has only 1-b change for each step change in the quantized level. Consequently, single errors in the received PCM code word will cause minimum errors in the recovered analog level, provided that the sign bit is not in error.

Here we have described PCM systems that represent the quantized analog sample values by *binary* code words. Of course, it is possible to represent the quantized analog samples by digital words using other than base 2. That is, for base q , the number of quantized levels allowed is $M = q^n$, where n is the number of q base digits in the code word. We will not pursue this topic since binary ($q = 2$) digital circuits are most commonly used.

3.3 Percent Quantizing Noise

The quantizer at the PCM encoder produces an error signal at the PCM decoder output, as illustrated in Fig. 3.2c. The peak value of this error signal may be expressed as a percentage of the maximum possible analog signal amplitude. Referring to Fig. 3.2c, a peak error of 1 V occurs for a maximum analog signal amplitude of $M = 8$ V, as shown in Fig. 3.1c. Thus, in general,

$$\frac{2P}{100} = \frac{1}{M} = \frac{1}{2^n}$$

or

$$2^n = \frac{50}{P} \tag{3.1}$$

where P is the peak percentage error for a PCM system that uses n bit code words. The design value of n needed in order to have less than P percent error is obtained by taking the base 2 logarithm of both sides of Eq. (3.1), where it is realized that $\log_2(x) = [\log_{10}(x)]/\log_{10}(2) = 3.32 \log_{10}(x)$. That is,

$$n \geq 3.32 \log_{10} \left(\frac{50}{P} \right) \tag{3.2}$$

where n is the number of bits needed in the PCM word in order to obtain less than P percent error in the recovered analog signal (i.e., decoded PCM signal).

3.4 Practical PCM Circuits

Three techniques are used to implement the analog-to-digital converter (ADC) encoding operation. These are the *counting* or *ramp*, *serial* or *successive approximation*, and *parallel* or *flash* encoders.

In the counting encoder, at the same time that the sample is taken, a ramp generator is energized and a binary counter is started. The output of the ramp generator is continuously compared to the sample value; when the value of the ramp becomes equal to the sample value, the binary value of the counter is read. This count is taken to be the PCM word. The binary counter and the ramp generator are then reset to zero and are ready to be reenergized at the next sampling time. This technique requires only a few components, but the speed of this type of ADC is usually limited by the speed of the counter. The Maxim ICL7126 CMOS ADC integrated circuit uses this technique.

The serial encoder compares the value of the sample with trial quantized values. Successive trials depend on whether the past comparator outputs are positive or negative. The trial values are chosen first in large steps and then in small steps so that the process will converge rapidly. The trial voltages are generated by a series of voltage dividers that are configured by (on-off) switches. These switches are controlled by digital logic. After the process converges, the value of the switch settings is read out as the PCM word. This technique requires more precision components (for the voltage dividers) than the ramp technique. The speed of the feedback ADC technique is determined by the speed of the switches. The National Semiconductor ADC0804 eight-bit ADC uses this technique.

The parallel encoder uses a set of parallel comparators with reference levels that are the permitted quantized values. The sample value is fed into all of the parallel comparators simultaneously. The high or low level of the comparator outputs determines the binary PCM word with the aid of some digital logic. This is a fast ADC technique but requires more hardware than the other two methods. The Harris CA3318 eight-bit ADC integrated circuit is an example of the technique.

All of the integrated circuits listed as examples have parallel digital outputs that correspond to the digital word that represents the analog sample value. For generation of PCM, the parallel output (digital word) needs to be converted to serial form for transmission over a two-wire channel. This is accomplished by using a parallel-to-serial converter integrated circuit, which is also known as a **serial-input-output** (SIO) chip. The SIO chip includes a shift register that is set to contain the parallel data (usually, from 8 or 16 input lines). Then the data are shifted out of the last stage of the shift register bit by bit onto a single output line to produce the serial format. Furthermore, the SIO chips are usually full duplex; that is, they have two sets of shift registers, one that functions for data flowing in each direction. One shift register converts parallel input data to serial output data for transmission over the channel, and, simultaneously, the other shift register converts received serial data from another input to parallel data that are available at another output. Three types of SIO chips are available: the *universal asynchronous receiver/transmitter* (UART), the *universal synchronous receiver/transmitter* (USRT), and the *universal synchronous/asynchronous receiver transmitter* (USART). The UART transmits and receives asynchronous serial data, the USRT transmits and receives synchronous serial data, and the USART combines both a UART and a USRT on one chip.

At the receiving end, the PCM signal is decoded back into an analog signal by using a digital-to-analog converter (DAC) chip. If the DAC chip has a parallel data input, the received serial PCM data are first converted to a parallel form using a SIO chip as described in the preceding paragraph. The parallel data are then converted to an approximation of the analog sample value by the DAC chip. This conversion is usually accomplished by using the parallel digital word to set the configuration of electronic switches on a resistive current (or voltage) divider network so that the analog output is produced. This is called a *multiplying* DAC since the analog output voltage is directly proportional to the divider reference voltage multiplied by the value of the digital word. The Motorola MC1408 and the National Semiconductor DAC0808 eight-bit DAC chips are examples of this technique. The DAC chip outputs samples of the quantized analog signal that approximate the analog sample values. This may be smoothed by a low-pass reconstruction filter to produce the analog output.

The Communications Handbook [6, pp 107–117] and *The Electrical Engineering Handbook* [5, pp 771–782] give more details on ADC, DAC, and PCM circuits.

3.5 Bandwidth of PCM

A good question to ask is: what is the spectrum of a PCM signal? For the case of PAM signalling, the spectrum of the PAM signal could be obtained as a function of the spectrum of the input analog signal because the PAM signal is a linear function of the analog signal. This is not the case for PCM. As shown in Figs. 3.1 and 3.2, the PCM signal is a nonlinear function of the input signal. Consequently, the spectrum of the PCM signal is not directly related to the spectrum of the input analog signal. It can be shown that the spectrum of the (serial) binary PCM signal depends on the bit rate, the correlation of the PCM data, and on the PCM waveform pulse shape (usually rectangular) used to describe the bits [2, 3]. From Fig. 3.2, the bit rate is

$$R = nf_s \quad (3.3)$$

where n is the number of bits in the PCM word ($M = 2^n$) and f_s is the sampling rate. For no aliasing, we require $f_s \geq 2B$ where B is the bandwidth of the analog signal (that is to be converted to the PCM signal). The dimensionality theorem [2, 3] shows that the bandwidth of the PCM waveform is bounded by

$$B_{\text{PCM}} \geq \frac{1}{2}R = \frac{1}{2}nf_s \quad (3.4)$$

where equality is obtained if a $(\sin x)/x$ type of pulse shape is used to generate the PCM waveform. The exact spectrum for the PCM waveform will depend on the pulse shape that is used as well as on the type

TABLE 3.2 Performance of a PCM System with Uniform Quantizing and No Channel Noise

of line encoding. For example, if one uses a rectangular pulse shape with polar nonreturn to zero (NRZ) line coding, the first null bandwidth is simply

$$B_{PCM} = R = nf_s \text{ Hz} \quad (3.5)$$

Table 3.2 presents a tabulation of this result for the case of the minimum sampling rate, $f_s = 2B$. Note that Eq. (3.4) demonstrates that the bandwidth of the PCM signal has a lower bound given by

$$B_{PCM} \geq nB \quad (3.6)$$

where $f_s > 2B$ and B is the bandwidth of the corresponding analog signal. Thus, for reasonable values of n , the bandwidth of the PCM signal will be significantly larger than the bandwidth of the corresponding analog signal that it represents. For the example shown in Fig. 3.2 where $n = 3$, the PCM signal bandwidth will be at least three times wider than that of the corresponding analog signal. Furthermore, if the bandwidth of the PCM signal is reduced by improper filtering or by passing the PCM signal through a system that has a poor frequency response, the filtered pulses will be elongated (stretched in width) so that pulses corresponding to any one bit will smear into adjacent bit slots. If this condition becomes too serious, it will cause errors in the detected bits. This pulse smearing effect is called **intersymbol interference (ISI)**.

3.6 Effects of Noise

The analog signal that is recovered at the PCM system output is corrupted by noise. Two main effects produce this noise or distortion: (1) quantizing noise that is caused by the M -step quantizer at the PCM transmitter and (2) bit errors in the recovered PCM signal. The bit errors are caused by *channel noise* as well as improper channel filtering, which causes ISI. In addition, if the input analog signal is not strictly

band limited, there will be some aliasing noise on the recovered analog signal [12]. Under certain assumptions, it can be shown that the recovered analog *average* signal power to the average noise power [2] is

$$\left(\frac{S}{N}\right)_{\text{out}} = \frac{M^2}{1 + 4(M^2 - 1)P_e} \quad (3.7)$$

where M is the number of uniformly spaced quantizer levels used in the PCM transmitter and P_e is the probability of bit error in the recovered binary PCM signal at the receiver DAC before it is converted back into an analog signal. Most practical systems are designed so that P_e is negligible. Consequently, if we assume that there are no bit errors due to channel noise (i.e., $P_e = 0$), the S/N due only to quantizing errors is

$$\left(\frac{S}{N}\right)_{\text{out}} = M^2 \quad (3.8)$$

Numerical values for these S/N ratios are given in [Table 3.2](#).

To realize these S/N ratios, one critical assumption is that the peak-to-peak level of the analog waveform at the input to the PCM encoder is set to the design level of the quantizer. For example, referring to [Fig. 3.2](#), this corresponds to the input traversing the range $-V$ to $+V$ volts where $V = 8$ V is the design level of the quantizer. Equation (3.7) was derived for waveforms with equally likely values, such as a triangle waveshape, that have a peak-to-peak value of $2V$ and an rms value of $V/\sqrt{3}$, where V is the design peak level of the quantizer.

From a practical viewpoint, the quantizing noise at the output of the PCM decoder can be categorized into four types depending on the operating conditions. The four types are overload noise, random noise, granular noise, and hunting noise. As discussed earlier, the level of the analog waveform at the input of the PCM encoder needs to be set so that its peak level does not exceed the design peak of V volts. If the peak input does exceed V , the recovered analog waveform at the output of the PCM system will have flat tops near the peak values. This produces *overload noise*. The flat tops are easily seen on an oscilloscope, and the recovered analog waveform sounds are distorted since the flat topping produces unwanted harmonic components.

The second type of noise, *random noise*, is produced by the random quantization errors in the PCM system under normal operating conditions when the input level is properly set. This type of condition is assumed in Eq. (3.8). Random noise has a white hissing sound. If the input level is not sufficiently large, the S/N will deteriorate from that given by Eq. (3.8); the quantizing noise will still remain more or less random.

If the input level is reduced further to a relatively small value with respect to the design level, the error values are not equally likely from sample to sample, and the noise has a harsh sound resembling gravel being poured into a barrel. This is called *granular noise*. This type of noise can be randomized (noise power decreased) by increasing the number of quantization levels and, consequently, increasing the PCM bit rate. Alternatively, granular noise can be reduced by using a nonuniform quantizer, such as the μ -law or A-law quantizers that are described in [Section 3.7](#).

The fourth type of quantizing noise that may occur at the output of a PCM system is *hunting noise*. It can occur when the input analog waveform is nearly constant, including when there is no signal (i.e., zero level). For these conditions, the sample values at the quantizer output (see [Fig. 3.2](#)) can oscillate between two adjacent quantization levels, causing an undesired sinusoidal type tone of frequency $1/2f_s$ at the output of the PCM system. Hunting noise can be reduced by filtering out the tone or by designing the quantizer so that there is no vertical step at the constant value of the inputs, such as at 0-V input for the no signal case. For the no signal case, the hunting noise is also called *idle channel noise*. Idle channel noise can be reduced by using a horizontal step at the origin of the quantizer output-input characteristic instead of a vertical step as shown in [Fig. 3.2](#).

Recalling that $M = 2^n$, we may express Eq. (3.8) in decibels by taking $10 \log_{10}(\cdot)$ of both sides of the equation,

$$\left(\frac{S}{N}\right)_{\text{dB}} = 6.02n + \alpha \quad (3.9)$$

where n is the number of bits in the PCM word and $\alpha = 0$. This equation—called the 6-dB rule—points out the significant performance characteristic for PCM: an additional 6-dB improvement in S/N is obtained for each bit added to the PCM word. This is illustrated in Table 3.2. Equation (3.9) is valid for a wide variety of assumptions (such as various types of input waveshapes and quantification characteristics), although the value of α will depend on these assumptions [7]. Of course, it is assumed that there are no bit errors and that the input signal level is large enough to range over a significant number of quantizing levels.

One may use Table 3.2 to examine the design requirements in a proposed PCM system. For example, high fidelity enthusiasts are turning to digital audio recording techniques. Here, PCM signals are recorded instead of the analog audio signal to produce superb sound reproduction. For a dynamic range of 90 dB, it is seen that at least 15-b PCM words would be required. Furthermore, if the analog signal had a bandwidth of 20 kHz, the first null bandwidth for rectangular bit-shape PCM would be $2 \times 20 \text{ kHz} \times 15 = 600 \text{ kHz}$. Consequently, video-type tape recorders are needed to record and reproduce high-quality digital audio signals. Although this type of recording technique might seem ridiculous at first, it is realized that expensive high-quality analog recording devices are hard pressed to reproduce a dynamic range of 70 dB. Thus, digital audio is one way to achieve improved performance. This is being proven in the marketplace with the popularity of the digital compact disk (CD). The CD uses a 16-b PCM word and a sampling rate of 44.1 kHz on each stereo channel [9, 10]. Reed–Solomon coding with interleaving is used to correct burst errors that occur as a result of scratches and fingerprints on the compact disk.

3.7 Nonuniform Quantizing: μ -Law and A-Law Companding

Voice analog signals are more likely to have amplitude values near zero than at the extreme peak values allowed. For example, when digitizing voice signals, if the peak value allowed is 1 V, weak passages may have voltage levels on the order of 0.1 V (20 dB down). For signals such as these with nonuniform amplitude distribution, the granular quantizing noise will be a serious problem if the step size is not reduced for amplitude values near zero and increased for extremely large values. This is called nonuniform quantizing since a variable step size is used. An example of a nonuniform quantizing characteristic is shown in Fig. 3.3.

The effect of nonuniform quantizing can be obtained by first passing the analog signal through a compression (nonlinear) amplifier and then into the PCM circuit that uses a uniform quantizer. In the U.S., a μ -law type of compression characteristic is used. It is defined [11] by

$$|w_2(t)| = \frac{\ln(1 + \mu|w_1(t)|)}{\ln(1 + \mu)} \quad (3.10)$$

where the allowed peak values of $w_1(t)$ are ± 1 (i.e., $|w_1(t)| \leq 1$) and μ is a positive constant that is a parameter. This compression characteristic is shown in Fig. 3.3(b) for several values of μ , and it is noted that $\mu \rightarrow 0$ corresponds to linear amplification (uniform quantization overall). In the United States, Canada, and Japan, the telephone companies use a $\mu = 255$ compression characteristic in their PCM systems [4].

In practice, the smooth nonlinear characteristics of Fig. 3.3b are approximated by piecewise linear chords as shown in Fig. 3.3d for the $\mu = 255$ characteristic [4]. Each chord is approximated by a uniform quantizer with 16 steps and an input step size that is set by the particular segment number. That is, 16

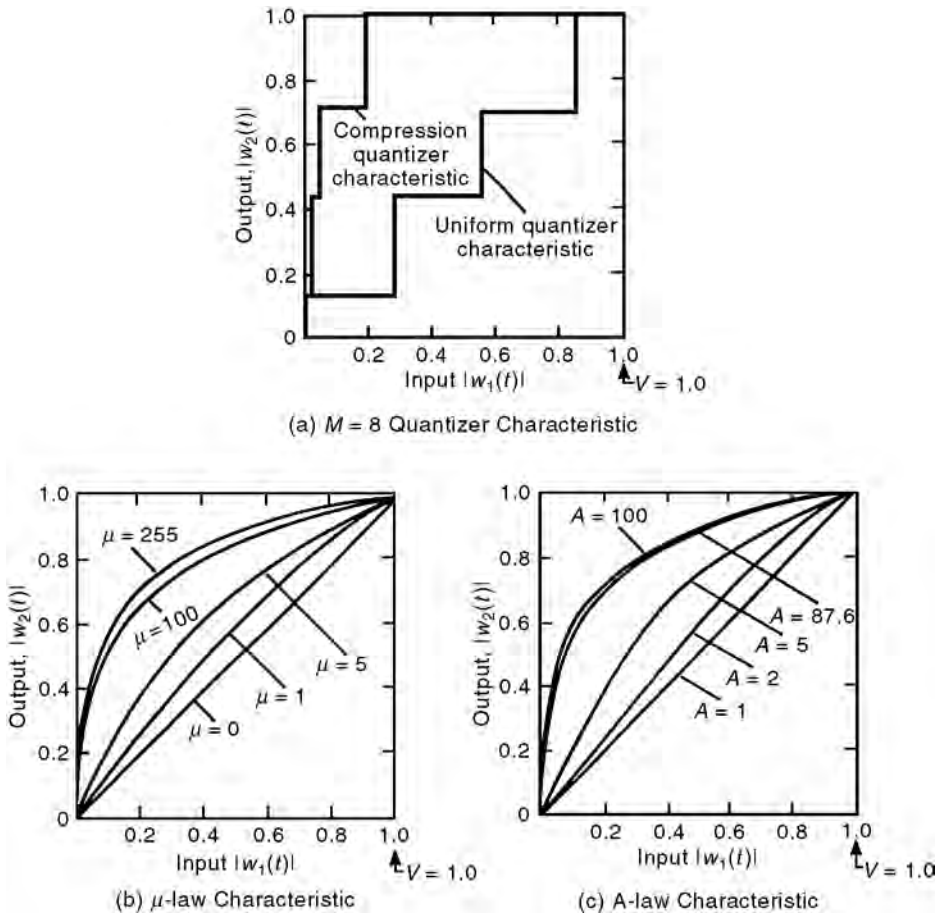

FIGURE 3.3 Compression characteristics (first quadrant shown). *Source:* Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, pp. 148–149. With permission.

steps (including a half-width step on each side of zero) of width Δ are used for Segment 1, 16 steps of width 2Δ are used for Segment 2, 16 steps of width 4Δ for Segment 3, etc. The value of Δ is chosen so that the full-scale value (last step of Segment 8) matches the peak value of the input analog signal. This segmenting technique is now accepted worldwide for the $\mu = 255$ characteristic. As shown in Fig. 3.3d, the eight-bit PCM code word consists of a sign bit that denotes a positive or negative input voltage, three chord bits that denote the segment number, and four step bits that denote the particular step within the segment. For more details, see the data sheet for the Motorola MC145500 series of PCM codecs, available on the World Wide Web from Motorola Semiconductor Products at the company's Web site, <http://www.motorola.com>.

Another compression law, used mainly in Europe, is the A-law characteristic. It is defined [1] by

$$|w_2(t)| = \begin{cases} \frac{A|w_1(t)|}{1 + \ln A}, & 0 \leq |w_1(t)| \leq \frac{1}{A} \\ \frac{1 + \ln(A|w_1(t)|)}{1 + \ln A}, & \frac{1}{A} \leq |w_1(t)| \leq 1 \end{cases} \quad (3.11)$$

where $|w_1(t)| < 1$ and A is a positive constant. The A-law compression characteristic is shown in Fig. 3.3(c). The typical value for A is 87.6.

FIGURE 3.3 (Continued)

When compression is used at the transmitter, *expansion* (i.e., decompression) must be used at the receiver output to restore signal levels to their correct relative values. The *expander* characteristic is the inverse of the compression characteristic, and the combination of a compressor and an expander is called a *compandor*.

Once again, it can be shown that the output S/N follows the 6-dB law [2]

$$\left(\frac{S}{N}\right)_{\text{dB}} = 6.02 + \alpha \quad (3.12)$$

where, for uniform quantizing,

$$\alpha = 4.77 - 20 \log(V/x_{\text{rms}}) \quad (3.13)$$

and for sufficiently large input levels* for μ -law companding

$$\alpha \approx 4.77 - 20 \log[\ln(1 + \mu)] \quad (3.14)$$

*See Lathi, 1998 for a more complicated expression that is valid for any input level.

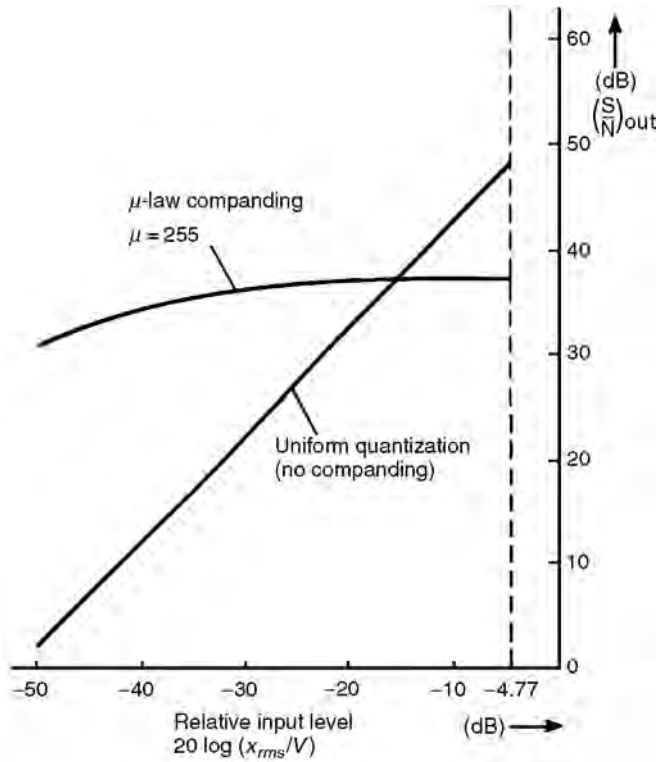

FIGURE 3.4 Output S/N of 8-b PCM systems with and without companding. Source: Couch, L.W., II. 2001. *Digital and Analog Communication Systems*, 6th ed., Prentice Hall, Upper Saddle River, NJ, p. 151. With permission.

and for A-law companding [7]

$$\alpha \approx 4.77 - 20 \log[1 + \ln A] \tag{3.15}$$

n is the number of bits used in the PCM word, V is the peak design level of the quantizer, and x_{rms} is the rms value of the input analog signal. Notice that the output S/N is a function of the input level for the uniform quantizing (no companding) case but is relatively insensitive to input level for μ -law and A-law companding, as shown in Fig. 3.4. The ratio V/x_{rms} is called the *loading factor*. The input level is often set for a loading factor of 4 (12 dB) to ensure that the overload quantizing noise will be negligible. In practice, this gives $\alpha = -7.3$ for the case of uniform encoding as compared to $\alpha = 0$, which was obtained for the ideal conditions associated with Eq. (3.8).

3.8 Example: Design of a PCM System

Assume that an analog voice-frequency signal, which occupies a band from 300 to 3400 Hz, is to be transmitted over a binary PCM system. The minimum sampling frequency would be $2 \times 3.4 = 6.8$ kHz. In practice, the signal is oversampled, and in the U.S., a sampling frequency of 8 kHz is the standard used for voice-frequency signals in telephone communication systems. Assume that each sample value is represented by 8 b; then the bit rate of the PCM signal is

$$\begin{aligned} R &= (f_s \text{ samples/s})(n \text{ b/s}) \\ &= (8k \text{ samples/s})(8 \text{ b/s}) = 64 \text{ kb/s} \end{aligned} \tag{3.16}$$

Referring to the dimensionality theorem [Eq. (3.4)], we realize that the theoretically minimum absolute bandwidth of the PCM signal is

$$B_{\min} = \frac{1}{2}R = 32 \text{ kHz} \quad (3.17)$$

and this is realized if the PCM waveform consists of $(\sin x)/x$ pulse shapes. If rectangular pulse shaping is used, the absolute bandwidth is infinity, and the first null bandwidth [Eq. (3.5)] is

$$B_{\text{null}} = R = \frac{1}{T_b} = 64 \text{ kHz} \quad (3.18)$$

That is, we require a bandwidth of 64 kHz to transmit this digital voice PCM signal where the bandwidth of the original analog voice signal was, at most, 4 kHz. Using $n = 8$ in Eq. (3.1), the error on the recovered analog signal is $\pm 0.2\%$. Using Eqs. (3.12) and (3.13) for the case of uniform quantizing with a loading factor, V/x_{rms} , of 10 (20 dB), we get, for uniform quantizing,

$$\left(\frac{S}{N}\right)_{\text{dB}} = 32.9 \text{ dB} \quad (3.19)$$

Using Eqs. (3.12) and (3.14) for the case of $\mu = 255$ companding, we get

$$\left(\frac{S}{N}\right) = 38.05 \text{ dB} \quad (3.20)$$

These results are illustrated in [Fig. 3.4](#).

Defining Terms

Intersymbol interference: Filtering of a digital waveform so that a pulse corresponding to 1 b will smear (stretch in width) into adjacent bit slots.

Pulse amplitude modulation: An analog signal is represented by a train of pulses where the pulse amplitudes are proportional to the analog signal amplitude.

Pulse code modulation: A serial bit stream that consists of binary words which represent quantized sample values of an analog signal.

Quantizing: Replacing a sample value with the closest allowed value.

4.1 Introduction

Probability theory is presented here for those who use it in communication theory and signal processing of random waveforms. The concept of **sampling a finite power waveform**, where a value of time t or n is uniformly chosen over a long time and $x(t)$ or $x(n)$ is observed, is introduced early. All **first-** and **second-order time averages** are visualized statistically. The topics covered with some highlights are as follows:

1. *Discrete probability theory.* The definitions of probability and conditional probability and their evaluation for outcomes of a **random phenomenon** using relative frequency and *axiomatic* formulas are given. The *theorem of total probability*, which elegantly subdivides compound problems into weighted subproblems, is highlighted along with Bayes' theorem.
2. *The theory of one random variable.* The use of **random variables** allows for the solution of probabilistic problems using integration and summations for sequences. The bridge from theory to applications is very short as in the relationship between finding the density or mass function of a function of a random variable and the communication problem of finding statistics of a system's random output given statistics of its random input.
3. *The theory of two random variables.* **Joint distribution, density, and mass functions** give complete probabilistic information about two random variables and are the key to solving most

applications involving continuous and discrete random waveforms and later random processes. Again, the bridge from theory to application is short as in the relationship between finding the density or mass function of a function of two random variables and the communication problem of finding statistics of a system's random output when two random inputs are combined by operations such as summing or multiplying (modulation).

4.2 Discrete Probability Theory

Probability theory concerns itself with assumed random phenomena, which are characterized by outcomes which occur with statistical regularity. These statistical regularities define the probability $p(A)$ of any outcome A and the conditional probability of A given B , $p(A/B)$ by

$$p(A) = \lim_{N \rightarrow \infty} \frac{N_A}{N} \quad \text{and} \quad p(A/B) = \lim_{N \rightarrow \infty} \frac{N_{AB}}{N_B} \quad (4.1)$$

where N , N_A , N_{AB} , and N_B denote the total number of trials, those for which A occurs, those for which both A and B occur, and those for which B occurs, respectively. In order to use these definitions, it is required to know *counting theory* or *permutations and combinations*.

Counting Formulas

A permutation of size k is an ordered array of k objects and a combination of size k is a group or set of size k where order of inclusion is immaterial. From four basic counting formulas, which are inductively developed, plus an understanding of counting factors, probabilities of complex outcomes may be found. These counting formulas are:

$$P_{n,k} = (n)_k = n(n-1) \times \dots \times (n-k+1) \quad (4.2)$$

which is the number of permutations of size k from n different objects,

$$P_{n,n(n_1,n_2,\dots,n_k)} = \frac{n!}{n_1!n_2! \times \dots \times n_k!} \quad (4.3)$$

which is the number of permutations of size n from a total of n objects of which n_1 are identical of type 1 and so on until n_k are identical of type k , and

$$P_{\infty,k(a \text{ types})} = (a)^k \quad (4.4)$$

which is the number of permutations of size k from an infinite supply of a different types.

For example, there are $(10)_3 = 720$ different possible results from a race with 10 competitors where only the first three positions are listed, there are 56 different 8-bit words that can be formed from five 1s and three 0s, and there are $6^5 = 7776$ different results from rolling a die five times and stating the result of each roll.

The only formula used for combinations, which is the most versatile formula in counting, is

$$C_{n,k} = \binom{n}{k} = \frac{(n)_k}{k!} \quad (4.5)$$

for the number of combinations of size k from n different objects.

For example, given 52 balls which come in four colors with each color numbered from 1 to 13, we can form

$$\binom{13}{1}\binom{12}{1}\binom{4}{3}\binom{4}{2}$$

combinations of size 5 where each contains three of one number and two of another number and

$$\binom{13}{3}\binom{4}{2}\binom{4}{2}\binom{4}{2}$$

combinations of size 6 where each contains two each of three different numbers. Also, the number of permutations of size 5 where each contains three of one number and two of another number is

$$\binom{13}{1}\binom{12}{1}\binom{4}{3}\binom{4}{2}5!$$

A sample problem will be solved using the relative frequency definitions of probabilities and counting formulas.

Problem 1

Consider an urn with 50 balls of which 20 are red and 30 have other colors. If a sample of size 6 is drawn from the urn, find the following probabilities:

1. Exactly four red balls are drawn.
2. Exactly four red balls given at least three are red.

Consider the case drawing the sample with and without replacement.

Solution

1. Case without replacement between draws:

$$P[\text{exactly 4 red}] = \frac{\binom{20}{4}\binom{30}{2}}{\binom{50}{6}}$$

or

$$= \frac{(20)_4(30)_2 \frac{6!}{4!2!}}{(50)_6} = 0.13$$

$$P[(\text{exactly 4 red})/(\text{at least 3 red})] = \frac{\binom{20}{4}\binom{30}{2}}{\binom{50}{6} - \left[\binom{30}{6} + \binom{30}{5}\binom{20}{1} + \binom{30}{4}\binom{20}{2} \right]}$$

or

$$= \frac{(20)_4(30)_2 \frac{6!}{4!2!}}{(50)_6 - \left[(30)_6 + (30)_5(20) \frac{6!}{5!1!} + (30)_4(20)_2 \frac{6!}{4!2!} \right]}$$

$$= 0.291$$

2. Case with replacement between draws:

$$\begin{aligned}
 P[\text{exactly 4 red}] &= \frac{20^4 30^2 \frac{6!}{4!2!}}{(50)^6} = (0.4)^4 (0.6)^2 \frac{6!}{4!2!} = 0.138 \\
 P[(\text{exactly 4 red})/(\text{at least 3 red})] \\
 &= \frac{(20)^4 (30)^2 \frac{6!}{4!2!}}{(50)^6 - \left[(30)^6 + (30)^5 (20) \frac{6!}{5!2!} + (30)^4 (20)^2 \frac{6!}{4!2!} \right]} \\
 &= 0.303
 \end{aligned}$$

On reflection, much philosophy is involved in this problem. In order to use the relative frequency formulas, we imagine all of the balls are different and, from symmetry, know the answer is correct. In the case without replacement, we can consider drawing a sample of six balls at once or drawing one at a time and noting the result.

Axiomatic Formulas of Probability Theory

The axioms of probability state that a probability is between zero and one and that the probability of the union of mutually exclusive outcomes is the sum of their probabilities. The axiomatic formulas are:

$$P(A/B) = \frac{P(AB)}{P(B)} \quad \text{if } P(B) \neq 0 \quad (4.6)$$

and

$$p(AB) = P(A)P(B/A) \quad (4.7)$$

Equation (4.7) may be extended for the intersection of n outcomes to give

$$P\left[\bigcap_{i=1}^n A_i\right] = p(A_1)p(A_2/A_1) \times \dots \times p\left(A_n/\bigcap_{i=1}^{n-1} A_i\right) \quad (4.8)$$

Also, two outcomes are independent if

$$P(AB) = P(A)P(B) \quad \text{or} \quad P(A/B) = P(A) \quad (4.9)$$

and this may be extended to n outcomes. Let us now resolve part of Problem 1 using the axiomatic formulas.

Solution

1. Without replacement:

$$P[(\text{exactly 4 red})] = \left(\frac{20}{50} \times \frac{19}{49} \times \frac{18}{48} \times \frac{17}{47} \times \frac{30}{46} \times \frac{29}{45}\right) \frac{6!}{4!2!}$$

The outcome of exactly 4 red is the union of $6!/4!2!$ mutually exclusive outcomes, each with the same probability.

2. With replacement:

$$P[(\text{exactly 4 red})] = [(0.4)^4(0.6)^2] \frac{6!}{4!2!}$$

as before.

The Theorem of Total Probability and Bayes' Theorem

An historically elegant theorem which simplifies compound problems is *Bayes' Theorem*, and we will state it in a casual manner and note some applications.

Bayes' Theorem(s)

Consider a random phenomenon where one trial consists in performing a trial of one of m random phenomena B_1, B_2, \dots, B_m where the probability of performing a trial of B_1 is $P(B_1)$ and so on until $P(B_m)$ is the probability of performing a trial of B_m . Then, for any outcome A ,

$$P(A) = P(B_1)P(A/B_1) + P(B_2)P(A/B_2) + \dots + P(B_m)P(A/B_m) \quad (4.10)$$

This is the *theorem of total probability*. Using the axiomatic formula, we obtain

$$P(B_k/A) = \frac{P(B_k)P(A/B_k)}{\sum_{i=1}^m P(B_i)P(A/B_i)} \quad (4.11)$$

This is Bayes' theorem.

Problem 2

Consider the random phenomenon of sampling the periodic waveform

$$x(t) = \sum_n g(t - 5n)$$

which is shown plotted in Fig. 4.1. A value of time is uniformly chosen over a long time (or over exactly one period) and $x(t)$ is observed. First find

$$P[-0.2 < x(t) \leq 2.3]$$

then find

$$P\left[\left(x(t) \text{ from } \frac{1}{t} \text{ part}\right) / (-0.2 < x(t) \leq 2.3)\right]$$

Solution

Let us define the Bayesian space (B_1, B_2, B_3) to denote sampling the $\frac{1}{t}$ portion, the $x(t) = -1$ portion, or the $2t - 8$ portion, respectively, with probabilities $p(B_1) = 0.4$, $p(B_2) = 0.2$, and $p(B_3) = 0.4$. If we let A be the event $(-0.2 < x(t) \leq 2.3)$, then, using the theorem of total probability,

$$\begin{aligned} P(A) &= P(B_1)P(A/B_1) + P(B_2)P(A/B_2) + P(B_3)P(A/B_3) \\ &= 0.4 \frac{(2 - 0.43)}{2} + 0.2(0) + 0.4 \frac{5 - 3.9}{5 - 3} = 0.534 \end{aligned}$$

FIGURE 4.1 The periodic function for Problem 2.

and

$$p(B_1/A) = \frac{0.2(2 - 0.43)}{0.534} = 0.59$$

using Bayes' theorem.

Structured Problem Solving

Whenever many probabilistic questions are asked about a random phenomenon, a structured outline is given for the solution in three steps.

In step 1, an appropriate *event space* or the **sample description space** of the phenomenon is listed. The sample description space is the set of finest grain, mutually exclusive, collectively exhaustive outcomes, whereas an event space is a listing of mutually exclusive, collectively exhaustive outcomes. In step 2, a probability is assigned to each outcome of the chosen space using the relative frequency or axiomatic formulas. In step 3, any desired probabilities are found by using the axiomatic formulas.

For example, consider a seven-game playoff series between two teams *A* and *B*, which terminates when a team wins four games. Assume that for any game, $P(A \text{ wins}) = 0.6$ and $P(B \text{ wins}) = 0.4$. If our interest is in how long the series lasts and who wins in how many games, then an appropriate event space is

$$E = \{e_{A4}, e_{A5}, e_{A6}, e_{A7}, e_{B4}, e_{B5}, e_{B6}, e_{B7}\}$$

where, for example, e_{B6} is the outcome *B* wins in exactly six games and

$$p(e_{B6}) = (0.4)^4(0.6)^2 \frac{5!}{3!2!} = 0.092$$

Similarly, we can find the probabilities for the other seven outcomes. Some problems which now can be easily solved are

$$P[(\text{series lasts at least 6 games})] = p(e_{A6}) + p(e_{A7}) + p(e_{B6}) + p(e_{B7})$$

and

$$\begin{aligned}
 &P[(A \text{ wins in at most 6 games}) / (\text{series lasts at least 5 games})] \\
 &= (p[e_{A5}] + p[e_{A6}]) \div \left(\sum_{i=5}^7 p(e_{Ai}) + \sum_{i=5}^7 p(e_{Bi}) \right)
 \end{aligned}$$

4.3 The Theory of One Random Variable

A random variable X assigns to every outcome of the sample description space of a random phenomenon a real number $X(s_i)$. Associated with X are three very important functions:

1. The **cumulative distribution function** $F_X(\alpha)$ defined by

$$F_X(\alpha) = P[X \leq \alpha], \quad -\infty < \alpha < \infty \tag{4.12}$$

2. The density function $f_X(\alpha)$ defined by

$$f_X(\alpha) = \frac{d}{d\alpha} F_X(\alpha)$$

3. If appropriate, the probability mass function $p_X(\alpha_i)$ defined by $p_X(\alpha_i) = P[X = \alpha_i]$.

Given a random phenomenon, finding $F_X(\alpha)$, $f_X(\alpha)\Delta\alpha$, or $p_X(\alpha_i)$ are problems in discrete probability.

Problem 3

Given the periodic waveform

$$x(t) = \sum_n g(t - 5n)$$

of Fig. 4.1, let the **random variable** X describe sampling $x(t)$ with a one-to-one mapping. Find and plot $F_X(\alpha)$ and $f_X(\alpha)$.

Solution

Observing $x(t)$ in Fig. 4.1, we will define X_1 as sampling $x(t) = 1/t$, X_2 as sampling $x(t) = -1$, and X_3 as sampling $x(t) = 2t - 8$. Figure 4.2(a) shows the solution for $F_{X_1}(\alpha)$ and $f_{X_1}(\alpha)$ and Fig. 4.2(b) uses the theorem of total probability to find $F_X(\alpha)$ as $0.4F_{X_1}(\alpha) + 0.2F_{X_2}(\alpha) + 0.4F_{X_3}(\alpha)$ and, similarly, $f_X(\alpha)$ is found. In this case, X is said to be a mixed random variable as $F_X(\alpha)$ changes both continuously and in jumps. The delta function allows for the inclusion of a point taking on a specific probability in $f_X(\alpha)$.

Figure 4.3 shows density or mass functions for four of the most commonly occurring random variables: the continuous uniform and Gaussian density functions and the discrete binomial and Poisson mass functions. Also included are some statistics to be encountered later.

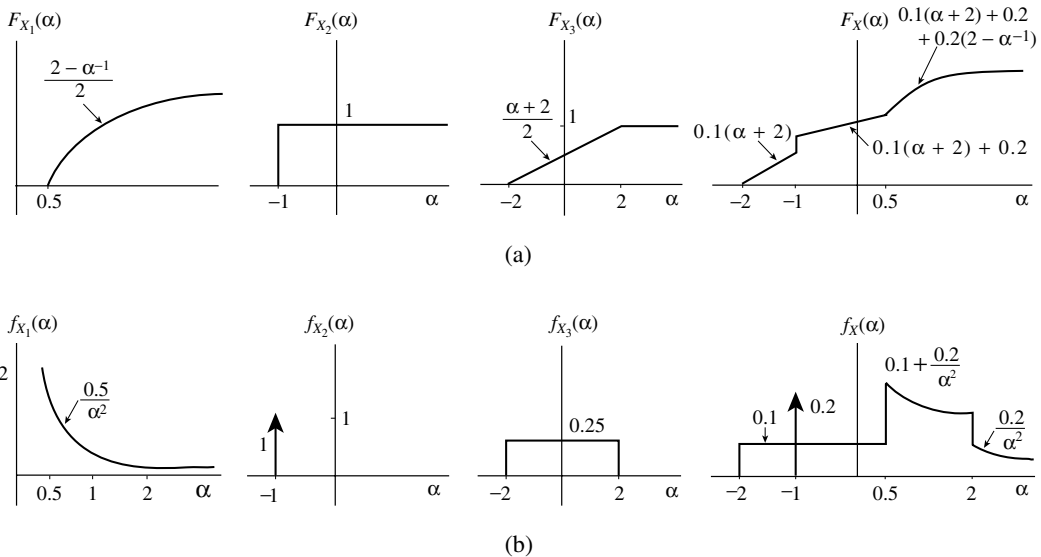

FIGURE 4.2 (a) $F_X(\alpha)$ for $x(t)$ in Fig. 4.1 for Problem 3 and (b) $f_X(\alpha)$ for $x(t)$ in Fig. 4.1.

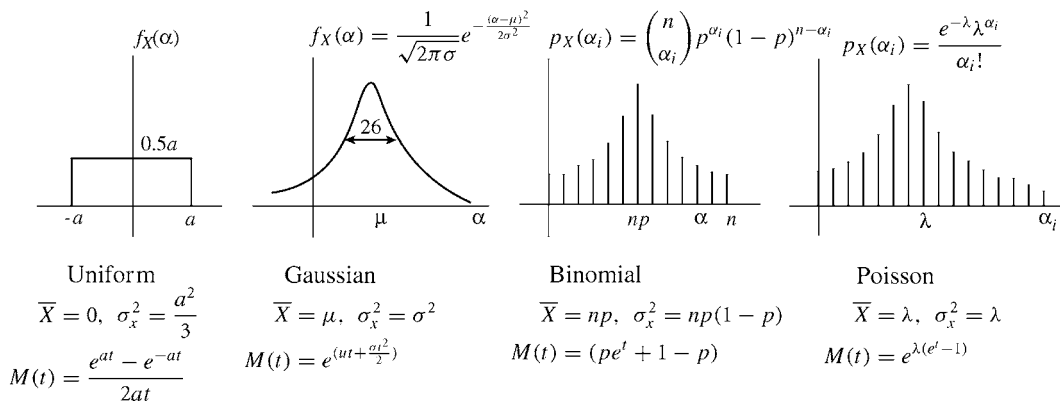

FIGURE 4.3 Important density and mass functions.

FIGURE 4.4 Density function $f_X(\alpha)$ for Problem 4.

Finding Probabilities from Density and Mass Functions

Density and mass functions allow for the use of integration and summations to answer probabilistic questions about a random variable. This is illustrated with two problems.

Problem 4

Consider the density function $f_X(\alpha) = e^{2\alpha}$, $-\infty < \alpha \leq 0$; $f_X(\alpha) = 0.11(\alpha - 2)$, $2 \leq \alpha \leq 5$; and $f_X(\alpha) = 0$ otherwise. Find $P[(-1.0 < X < 4.0)/(-X^2 < -5)]$.

Solution

A sketch of $f_X(\alpha)$ is shown in Fig. 4.4. Using the axiomatic formula,

$$\begin{aligned}
 P[(-1.0 < X < 4.0)/(-X^2 < -5)] &= \frac{0 + \int_{2.24}^4 0.11(\alpha - 2) d\alpha}{\int_{-\infty}^{-2.24} 0.5e^{\alpha} d\alpha + \int_{2.24}^5 0.11(\alpha - 2) d\alpha} \\
 &= 0.398
 \end{aligned}$$

Problem 5

Given the probability mass function $p_X(\alpha_i) = 0.01$, $-40 \leq \alpha_i \leq -10$, α_i integer; $p_X(\alpha_i) = 0.10(0.9)^{\alpha_i}$, $\alpha_i \geq 5$, α_i integer; and $p_X(\alpha_i) = 0$ otherwise. Find (1) $P[(|X| \leq 20)/(X^2 > 200)]$ and (2) $p_X[\alpha_i/(X^2 > 200)]$.

Solution

1. A sketch of $p_X(\alpha_i)$ is shown in Fig. 4.5(a). Using the axiomatic formula,

$$P[(|X| \leq 20)/(X^2 > 200)] = \frac{\sum_{-20}^{-15} 0.01 + \sum_{15}^{20} 0.10(0.9)^{\alpha_i}}{\sum_{-40}^{-15} 0.01 + \sum_{15}^{\infty} 0.10(0.9)^{\alpha_i}} = \frac{0.156}{0.467} = 0.34$$

FIGURE 4.5 Probability mass function $p_X(\alpha_i)$ and $p_X(\alpha_i/X^2 > 200)$ for Problem 5.

The formulas for a finite geometric progression

$$\sum_{p=0}^n \alpha^p = (1 - \alpha^{n+1}) \div (1 - \alpha)$$

and for a geometric progression

$$\sum_{p=0}^{\infty} \alpha^p = (1 - \alpha)^{-1}, \quad |\alpha| < 1$$

were used in the calculation.

2. The second solution is

$$\begin{aligned} p_X(\alpha_i / (X^2 > 200)) &= \frac{p_X(\alpha_i)}{P[X^2 > 200]}, \quad \alpha_i^2 > 200 \\ &= 0, \quad \text{otherwise} \end{aligned}$$

and is shown plotted in Fig. 4.5(b).

The Density or Mass Function of a Function of a Known Random Variable

Continuous Case

Consider the problem: Given $Y = g(X)$ where $f_X(\alpha)$ is known, find $f_Y(\beta)$.

$$F_Y(\beta) = P[g(X) \leq \beta] = \int_{\alpha} f_X(\alpha) d\alpha \quad \text{where } g(\alpha) \leq \beta$$

In order to find $f_Y(\beta)$ directly, Leibnitz's rule is used. Leibnitz's rule states

$$\frac{d}{d\beta} \int_{k_1(\beta)}^{k_2(\beta)} f_X(\alpha) d\alpha = f_X(k_2(\beta))k_2'(\beta) - f_X(k_1(\beta))k_1'(\beta) \quad (4.13)$$

For example, if

$$f_X(\alpha) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(\alpha-\mu)^2}{2\sigma^2}}$$

and $Y = aX + b$, where $a > 0$,

$$F_Y(\beta) = P[aX + b \leq \beta] = \int_{-\infty}^{\frac{\beta-b}{a}} f_X(\alpha) d\alpha$$

Using Leibnitz's rule,

$$f_Y(\beta) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(\beta-b-a\mu)^2}{2a^2\sigma^2}} \frac{1}{a} = N(a\mu + b, (a\sigma)^2)$$

which means Y is also Gaussian with $\mu_Y = a\mu + b$ and $\sigma_Y^2 = (a\sigma)^2$.

Discrete Case

The discrete case is much more direct. If $Y = g(x)$ where $p_X(\alpha_i)$ is known, then $p_Y(\beta_j) = p_X(g^{-1}(\beta))$. For example, if $Y = X^2$, then $p_Y(\beta_j) = p_X(\sqrt{\beta_j}) + p_X(-\sqrt{\beta_j})$.

Problem 6

Given the probability mass function $p_X(\alpha_i) = 0.096(0.9)^{\alpha_i+5}$, $-5 \leq \alpha_i \leq 30$, α_i integer, $p_X(\alpha_i) = 0$ otherwise, and $Y = |2X|$, find $p_Y(\beta_j)$.

Solution

$$Y = |2X| = 2X, \quad X \geq 0 \\ = -2X, \quad X < 0$$

$$p_Y(0) = 0.096(0.9)^5$$

Range 1: $\beta_j = 2, 4, 6, 8, 10$ or $\beta_j = |2\alpha_i|$, $\alpha_i = \pm 1, \dots, \pm 5$,

$$p_Y(\beta_j) = 0.096 \left[(0.9)^{\frac{\beta_j+10}{2}} + (0.9)^{\frac{-\beta_j+10}{2}} \right]$$

Range 2: $\beta_j = 12, 14, \dots, 60$, $\beta_j = 2\alpha_i$, $\alpha_i = 6, 30$

$$p_Y(\beta_j) = 0.096 \left[(0.9)^{\frac{\beta_j+10}{2}} \right]$$

Statistics of a Random Variable

The three most widely used statistics of a random variable are

$$\bar{X} = \int_{-\infty}^{\infty} \alpha f_X(\alpha) d\alpha$$

or

$$= \sum_{\alpha_i} \alpha_i p_X(\alpha_i)$$

$$\overline{X^2} = \int_{-\infty}^{\infty} \alpha^2 f_X(\alpha) d\alpha$$

or

$$= \sum_{\alpha_i} \alpha_i^2 p_X(\alpha_i)$$

and

$$\sigma_X^2 = \overline{(X - \bar{X})^2} = \int_{-\infty}^{\infty} (\alpha - \bar{X})^2 f_X(\alpha) d\alpha = \bar{X}^2 - (\bar{X})^2$$

These are the mean or average value, the mean squared value, and the variance, respectively. The formulas follow from a relative frequency interpretation based on a large number of trials of a phenomenon. Higher order statistics are defined by

$$\begin{aligned} m_n &= \bar{X}^n = \int_{-\infty}^{\infty} \alpha^n f_X(\alpha) d\alpha \\ &\text{or} \\ &= \sum_{\alpha_i} \alpha_i^n p_X(\alpha_i) \end{aligned}$$

and

$$\begin{aligned} \overline{(X - \bar{X})^n} &= \int_{-\infty}^{\infty} (\alpha - \bar{X})^n f_X(\alpha) d\alpha \\ &\text{or} \\ &= \sum_{\alpha_i} (\alpha_i - \bar{X})^n p_X(\alpha_i) \end{aligned}$$

These are called moments and central moments, respectively. General expressions for higher order statistics may be found using the moment generation function $M(t)$ defined by

$$\begin{aligned} M(t) &= \overline{e^{tX}} = \sum_{\alpha_i} e^{t\alpha_i} p_X(\alpha_i) \\ &\text{or} \\ &= \int_{-\infty}^{\infty} e^{t\alpha} f_X(\alpha) d\alpha \end{aligned} \quad (4.14)$$

where $\bar{X}^n = M^n(0)$ for $n \geq 1$. In Fig. 4.3, moment generating functions plus \bar{X} and σ_X^2 are given for the uniform, Gaussian, binomial, and Poisson random variables.

Time Averages as Statistical Averages for Finite Power Waveforms

Continuous Waveforms

A finite power waveform is defined as one for which

$$P_{av} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x^2(t) dt$$

exists.

The time average definition for some first-order time averages are

$$\widetilde{x(t)} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x(t) dt \quad \text{and} \quad \widetilde{x^2 t} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x^2(t) dt \quad (4.15)$$

called the average and mean squared value, respectively.

FIGURE 4.6 (a) Waveform $x(t) = \sum_n g(t - 3n)$ and $f_X(\alpha)$ for sampling $x(t)$, and (b) waveform $x(n) = \sum_k g(n - 3k)$ and $p_X(\alpha_i)$ for sampling $x(n)$.

Applying these definitions to the periodic waveform

$$x(t) = \sum_n g(t - 3n)$$

shown in Fig. 4.6(a), it is easy to find the average and mean squared values,

$$\begin{aligned} \widetilde{x(t)} &= \frac{1}{3} \int_0^3 x(t) dt = \frac{1}{3} \left[\int_0^2 (-1 + 2t) dt + \int_2^3 1 dt \right] = 1.0 \\ \widetilde{x^2(t)} &= \frac{1}{3} \left[\int_0^2 (-1 + 2t)^2 dt + \int_2^3 1 dt \right] = 1.89 \quad \text{and} \quad \sigma_{x(t)}^2 = 0.89 \end{aligned}$$

We will now interpret these averages statistically. Let the random variable X describe sampling t over a long time and observing $x(t)$. The density function $f_X(\alpha)$ is shown plotted in Fig. 4.6(a), and it is easy to show

$$\widetilde{x(t)} = \bar{X} = \left[\int_{-1}^3 \alpha \frac{1}{6} d\alpha + \int_{-\infty}^{\infty} \alpha \frac{1}{3} \delta(\alpha - 1) d\alpha \right] = 1.0$$

and

$$\widetilde{x^2(t)} = \bar{X^2} = \left[\int_{-1}^3 \alpha^2 \frac{1}{6} d\alpha + \int_{-\infty}^{\infty} \alpha^2 \frac{1}{3} \delta(\alpha - 1) d\alpha \right] = 1.89$$

The general formula for any first-order statistic is

$$\widetilde{g(x(t))} = \int_{-\infty}^{\infty} g(\alpha) f_X(\alpha) d\alpha \quad (4.16)$$

Discrete Waveforms

A finite power discrete waveform is one for which

$$P_{\text{av}} = \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{n=-N}^N x^2(n)$$

exists.

The time average definitions for some first-order time averages are

$$\widetilde{x(n)} = \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{n=-N}^N x(n) \quad \text{and} \quad \widetilde{x^2(n)} = \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{n=-N}^N x^2(n) \quad (4.17)$$

called the average and mean square value, respectively. Applying these definitions to the periodic waveform

$$x(n) = \sum_{k=-\infty}^{\infty} g(n-3k)$$

shown in Fig. 4.6(b), it is easy to find the average, mean square, and variance of $x(n)$,

$$\widetilde{x(n)} = \frac{1}{3} [3 + (-1) + 2] = 1.33$$

$$\widetilde{x^2(n)} = \frac{1}{3} [9 + 1 + 4] = 4.67 \quad \text{and} \quad \sigma_{x(n)}^2 = 4.67 - 1.78 = 2.89$$

If the random variable X describes uniformly choosing an integer n , $-N \leq n \leq N$ and observing $x(n)$, then the statistical definition for any first-order time average $\widetilde{g(x(n))}$ is

$$\begin{aligned} \widetilde{g[x(n)]} &= \overline{g(X)} = \int g(\alpha) f_X(\alpha) d\alpha \\ &\text{or} \\ &= \sum g(\alpha_i) p_X(\alpha_i) \end{aligned}$$

which is identical to Eq. (4.16). $P_X(\alpha_i)$ is shown in Fig. 4.6(b), $\widetilde{x(n)} = \bar{X} = 3(\frac{1}{3}) + (-1)(\frac{1}{3}) + 2(\frac{1}{3}) = 1.33$, and $\widetilde{x^2(n)} = \bar{X^2} = 9(\frac{1}{3}) + 1(\frac{1}{3}) + 4(\frac{1}{3}) = 4.67$ as before.

Random Waveforms

A finite-power random or noise waveform is defined as being nondeterministic and such that statistics of a large section or of the whole waveform exist. Often, $x(t)$ or $x(n)$ is represented by a formula involving time and random variables,

$$x(t) = f(t, r, \text{ vs}) \quad \text{or} \quad x(n) = f(n, r, \text{ vs})$$

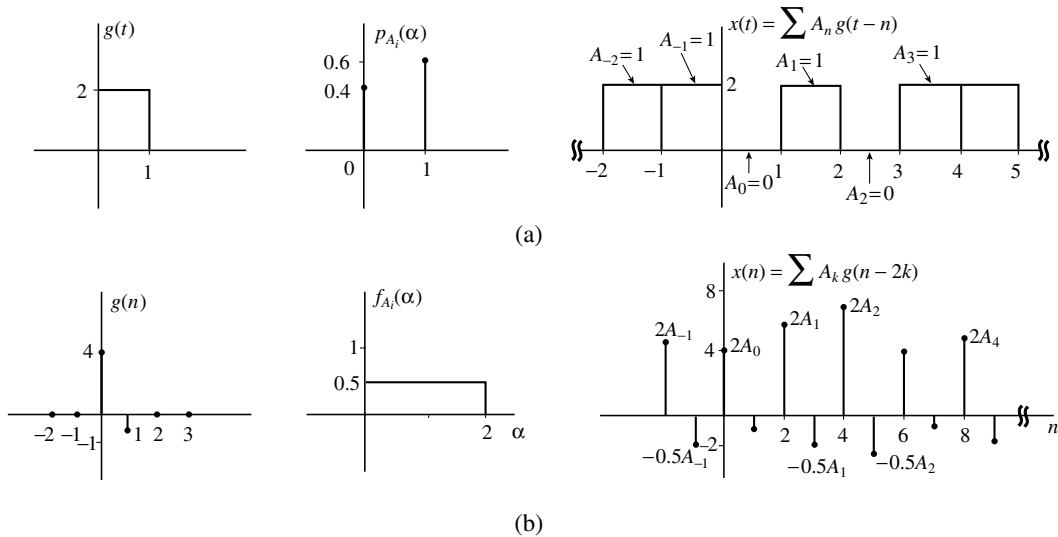

FIGURE 4.7 The random waveforms: (a) $x(t) = \sum_n A_n g(t - n)$ and (b) $x(n) = \sum_k A_k g(n - 2k)$.

where “r. vs” denotes “random variables.” For example,

$$x(t) = \sum_{n=-\infty}^{\infty} A_n g(t - nT_0)$$

is a periodic function with each period weighted by a value statistically determined by the density or joint density functions for the A_s . Consider when $g(t) = 2, 0 \leq t \leq 1$, and $T_0 = 1$ and the A_s are independent, each with $p_{A_i}(1) = 0.6$ and $p_{A_i}(0) = 0.4$.

A section of $x(t)$ may be as shown in Fig. 4.7(a). Consider

$$x(n) = \sum_k A_k g(n - 2k)$$

where $g(n) = 4\delta(n) - \delta(n - 1)$ and the A_s are independent random variables each with $f_{A_i}(\alpha) = 0.5, 0 \leq \alpha \leq 2$; $f_{A_i}(\alpha) = 0$ otherwise. A typical section of $x(n)$ may appear as in Fig. 4.7(b).

If X describes sampling $x(t)$ or $x(n)$ where t is uniformly chosen $-T < t < T$ and $x(t)$ observed or n is discretely uniformly chosen $-N \leq n \leq N$ and $x(n)$ observed, then, as T or N approach infinity, $f_X(\alpha)$ or $p_X(\alpha_i)$ may be found.

Any time average may be found by the statistical formula (4.16)

$$\begin{aligned} \widetilde{g(x(t))} \quad \text{or} \quad \widetilde{g[x(n)]} &= \int_{-\infty}^{\infty} g(\alpha) f_X(\alpha) d\alpha \\ &\text{or} \\ &= \sum_{\alpha_i} g(\alpha_i) p_X(\alpha_i) \end{aligned}$$

Two simple examples will be used for demonstration.

(a)

(b)

FIGURE 4.8 The random waveform of (a) Problem 7 and $f_X(\alpha)$ and (b) Problem 8 and $p_X(\alpha_i)$.

Problem 7

Given the random waveform

$$x(t) = \sum_n A_n g(t - 3n)$$

where $g(t) = 3, 0 \leq t \leq 2$; $g(t) = -4, 2 < t \leq 3$; $g(t) = 0$ otherwise and the A s are independent random variables with $f_{A_1}(\alpha) = \frac{1}{3}, -1 \leq \alpha \leq 2$; $f_{A_2}(\alpha) = 0$ otherwise, find $f_X(\alpha)$, $x(t)$, and $x^2(t)$.

Solution

Figure 4.8(a) shows a plot of a typical section of $x(t)$. We notice the front two units of a pulse take on values uniformly from -3 to 6 and the last unit takes on that value multiplied by -1.33 . Using the theorem of total probability, $f_X(\alpha) = \frac{2}{3}f_{X_1}(\alpha) + \frac{1}{3}f_{X_2}(\alpha)$ where X_1 and X_2 describe sampling the first two and last

unit of a pulse, respectively. The density function $f_X(\alpha)$ is shown in Fig. 4.8(a) and it is easy to find; $\overline{x(t)} = \overline{X} = \frac{2}{3}(3\overline{A_i}) + \frac{1}{3}(-4\overline{A_i}) = 0.33$ and $\overline{x^2(t)} = \overline{X^2} = \frac{2}{3}(9\overline{A_i^2}) + \frac{1}{3}(16\overline{A_i^2}) = 11.33$.

Problem 8

Given the random waveform

$$x(n) = \sum_k A_k \delta(n - k)$$

where the A_s are independent random variables with $p_{A_i}(1) = 0.7$ and $p_{A_i}(0) = 0.3$, find $p_X(\alpha_i)$, $\overline{x(t)}$ and $\overline{x^2(t)}$.

Solution

Figure 4.8(b) shows a plot for a typical section of $x(n)$ and $p_X(\alpha_i)$. $\overline{x(n)} = \overline{X} = (1)0.7$ and $\overline{x^2(t)} = \overline{X^2} = 0.7$.

Finally, let us consider an application for the density function of a known random variable.

The Square Wave Detector

Consider a noise waveform input to a system where the output and input are related by $y(t) = x^2(t)$. If the density function for sampling the input $x(t)$ is

$$f_X(\alpha) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(\alpha-\mu)^2}{2\sigma^2}}$$

find $f_Y(\beta)$ for sampling the output $y(t)$.

Solution

$$F_Y(\beta) = 2 \int_0^{\sqrt{\beta}} \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(\alpha-\mu)^2}{2\sigma^2}} d\alpha$$

and by Leibnitz's rule

$$f_Y(\beta) = \frac{2}{\sqrt{2\pi}\sigma} e^{-\frac{(\sqrt{\beta}-\mu)^2}{2\sigma^2}} 0.5(\beta)^{-0.5}$$

which is the famous chi-squared density function.

4.4 The Theory of Two Random Variables

Definitions of Joint Distribution, Density, and Mass Functions

Given a random phenomenon, two random variables X and Y map every point of the sample description space onto an α - β plane via $X(s_i)$ and $Y(s_i)$. The following important functions are associated with X and Y :

$$F_{XY}(\alpha, \beta) = P[(X \leq \alpha) \cap (Y \leq \beta)], \quad -\infty < \alpha \leq \infty, \quad -\infty < \beta < \infty \quad (4.18)$$

This is the joint cumulative distribution function.

$$f_{XY}(\alpha, \beta) = \frac{\partial^2}{\partial \alpha \partial \beta} F_{XY}(\alpha, \beta) \quad (4.19)$$

is the joint density function and

$$p_{XY}(\alpha_i, \beta_j) = P[(X = \alpha_i) \cap (Y = \beta_j)] \quad (4.20)$$

is the joint mass function when appropriate.

Finding $F_{XY}(\alpha, \beta)$, $f_{XY}(\alpha, \beta) \Delta\alpha \Delta\beta$, or $p_{XY}(\alpha_i, \beta_j)$ are problems in discrete probability theory. Knowing $f_{XY}(\alpha, \beta)$ and $p_{XY}(\alpha_i, \beta_j)$ or $F_{XY}(\alpha, \beta)$, it is possible to answer any probabilistic question about X and Y , X given a condition on Y , or Y given a condition on X . The following are some formulas which are easy to derive starting from a statement with probabilistic meaning:

$$f_X(\alpha) = \int_{-\infty}^{\infty} f_{XY}(\alpha, \beta) d\beta, \quad p_Y(\beta_j) = \sum_{\alpha_i} p_{XY}(\alpha_i, \beta_j) \quad (4.21)$$

$$f_Y(\beta/g(X) < C_1) = \frac{\int f_{XY}(\alpha, \beta) d\alpha}{\int_{-\infty}^{\infty} \int f_{XY}(\alpha, \beta) d\alpha d\beta} \quad (4.22)$$

where the two missing limits of integration are: all α such that $g(\alpha) < C_1$,

$$p_X(\alpha_i/Y^2 \leq 25) = \frac{\sum_{\beta_j=-5}^5 p_{XY}(\alpha_i, \beta_j)}{\sum_{\alpha_i} \sum_{\beta_j=-5}^5 p_{XY}(\alpha_i, \beta_j)} \quad (4.23)$$

and

$$f_Y(\beta/X = \alpha) = \frac{f_{XY}(\alpha, \beta)}{f_X(\alpha)} \quad \text{all } \beta \text{ when } X = \alpha \quad (4.24)$$

The use of these formulas involves detailed attention and care with different ranges.

Finding Density and Mass Functions from Joint Functions

Problem 9

Given $f_{XY}(\alpha, \beta) = -0.0010\beta$, $0.2\beta \leq \alpha \leq -0.2\beta$, $-20 \leq \beta \leq -8$; $f_{XY}(\alpha, \beta) = 0$ otherwise. Find and plot $f_Y(\beta)$ and $f_X(\alpha/(Y = \beta))$.

Solution

The region for which $f_{XY}(\alpha, \beta)$ is defined is shown in Fig. 4.9(a). Using

$$f_Y(\beta) = \int_{-\infty}^{\infty} f_{XY}(\alpha, \beta) d\alpha$$

FIGURE 4.9 (a) Region for $f_{XY}(\alpha, \beta)$ for Problem 9 and (b) $f_Y(\beta)$ and $f_X(\alpha/(Y = \beta))$.

FIGURE 4.10 (a) Region for $p_{XY}(\alpha_i, \beta_j)$ for Problem 10 and (b) $p_X(\alpha_i/Y = \beta_j)$.

we obtain the following.

Range 1: $-20 \leq \beta \leq -8$

$$\begin{aligned}
 f_Y(\beta) &= \int_{0.2\beta}^{-0.2\beta} -0.0010\beta \, d\alpha = 0.0004\beta^2, \quad -20 \leq \beta \leq -8 \\
 &= 0 \quad \text{otherwise,} \quad \text{and} \\
 f_X(\alpha/Y = \beta) &= \frac{f_{XY}(\alpha, \beta)}{f_Y(\beta)} \\
 &= \frac{-0.0010\beta}{0.0004\beta^2} = \frac{-2.5}{\beta}, \quad 0.2\beta < \alpha < -0.2\beta \\
 &\quad \text{for any } \beta, \quad -20 \leq \beta \leq -8 \\
 &= 0 \quad \text{otherwise}
 \end{aligned}$$

The density functions are plotted in Fig. 4.9(b).

Problem 10

Given $p_{XY}(\alpha_i, \beta_j) = 0.0033|\beta_j|$, $-\alpha_i \leq \beta_j \leq \alpha_i$, $6 \leq \alpha_i \leq 20$, both integer, $p_{XY}(\alpha_i, \beta_j) = 0$ otherwise, find $p_X(\alpha_i)$ and $p_X(\alpha_i/Y = \beta_j)$ for $-20 \leq \beta_j \leq -6$. Are X and Y independent?

Solution

The region for which $p_{XY}(\alpha_i, \beta_j)$ is defined is shown in Fig. 4.10(a).

Range 1: $6 \leq \alpha_i \leq 20$

$$\begin{aligned}
 p_X(\alpha_i) &= \sum_{\beta_j=-\alpha_i}^{\alpha_i} 0.0033|\beta_j| = 2 \sum_1^{\alpha_i} 0.0033\beta_j \\
 &= 0.0033(2) \frac{(\alpha_i + 1)\alpha_i}{2} = 0.0033(\alpha_i + 1)\alpha_i
 \end{aligned}$$

using the formula for an arithmetic progression. Otherwise, $p_X(\alpha_i) = 0$.

$$p_X[\alpha_i/Y = \beta_j] = \frac{p_{XY}(\alpha_i, \beta_j)}{p_Y(\beta_j)}$$

Looking at Fig. 4.10(a), for the region when $-20 \leq \beta_j \leq -6$, the formula

$$p_Y(\beta_j) = \sum_{\alpha_i} p_{XY}(\alpha_i, \beta_j)$$

becomes

$$p_Y(\beta_j) = \sum_{\alpha_i=-\beta_j}^{20} p_{XY}(\alpha_i, \beta_j) = 0.0033(21 + \beta_j)(-\beta_j)$$

and

$$p_X(\alpha_i/Y = \beta_j) = \frac{0.0033(-\beta_j)}{0.0033(21 + \beta_j)(-\beta_j)} = \frac{1}{21 + \beta_j}, \quad -\beta_j \leq \alpha_i \leq 20, \text{ any } \beta_j, -20 \leq \beta_j \leq -6$$

$$= 0 \quad \text{otherwise.}$$

This conditional mass function is plotted in Fig. 4.10(b). Since $p_X(\alpha_i/(Y = \beta_j))$ does not equal $p_X(\alpha_i)$ for all α_i , then X and Y are not independent.

The Density (or Mass) Function of a Function of Two Random Variables

Continuous Case

Given $Z = g(X, Y)$ where $f_{XY}(\alpha, \beta)$ is known, $f_Z(\gamma)$ is found as

$$f_Z(\gamma) = \frac{d}{d\gamma} F_Z(\gamma) = \frac{d}{d\gamma} \iint f_{XY}(\alpha, \beta) d\alpha d\beta \quad (4.25a)$$

where the limits on the double integral satisfy $g(\alpha, \beta) \leq \gamma$.

By Leibnitz's rule, Eq. (4.25a) becomes, for the case $Z = aX + bY$,

$$f_Z(\gamma) = \int_{-\infty}^{\infty} C_1 f_{XY}(\alpha, g_1(\alpha, \gamma)) d\alpha$$

or

$$= \int_{-\infty}^{\infty} C_2 f_{XY}(g_2(\beta, \gamma), \beta) d\beta \quad (4.25b)$$

Problem 11

Given $f_{XY}(\alpha, \beta) = 0.25; 0 \leq \beta \leq 2\alpha, 0 < \alpha < 2; f_{XY}(\alpha, \beta) = 0$ otherwise, find $f_Z(\gamma)$ when $Z = Y - 2X$.

Solution

Figure 4.11 shows the region for which $f_{XY}(\alpha, \beta)$ is defined. If we visualize the family of curves $\beta - 2\alpha = \gamma$ as γ varies, $-\infty < \gamma < \infty$, we note $F_Z(\gamma)$ is the weighed integral of all points to the right of $\beta - 2\alpha = \gamma$. $F_Z(\gamma) = 0, \gamma < -4$, and $F_Z(\gamma) = 1, \gamma > 0$.

FIGURE 4.11 (a) Region of $f_{XY}(\alpha, \beta)$ for Problem 11 and (b) $f_Z(\gamma), Z = Y - 2X$.

FIGURE 4.12 Function $f_Z(\gamma)$ by convolution when $f_{XY}(\alpha, \beta) = \frac{1}{32}$; $-3 \leq \alpha \leq 5$, $-1 \leq \beta \leq 3$, and $Z = X + Y$.

In general, $F_Z(\gamma) = \int_{-\infty}^{\infty} (\int_{-\infty}^{2\alpha+\gamma} f_{XY}(\alpha, \beta) d\beta) d\alpha$ and using Leibnitz's rule

$$f_Z(\gamma) = \int_{-\infty}^{\infty} f_{XY}(\alpha, 2\alpha + \gamma) d\alpha$$

Observing Fig. 4.11(a),

$$\begin{aligned} f_Z(\gamma) &= \int_{-\frac{\gamma}{2}}^2 0.25 d\alpha \\ &= \frac{1}{8}(\gamma + 4), \quad -4 < \gamma < 0 \end{aligned}$$

which is shown in Fig. 4.11(b).

An important situation occurs when X and Y are independent random variables or when $f_{XY}(\alpha, \beta) = f_X(\alpha) f_Y(\beta)$ for all α, β . In this case, if $Z = X + Y$, then

$$\begin{aligned} f_Z(\gamma) &= f_X(\gamma) * f_Y(\gamma) = \int_{-\infty}^{\infty} f_X(\gamma - \beta) f_Y(\beta) d\beta \\ &\text{or} \\ &= \int_{-\infty}^{\infty} f_X(\alpha) f_Y(\gamma - \alpha) d\alpha \end{aligned} \quad (4.26)$$

which is the convolution of the two density functions. For example, if $f_{XY}(\alpha, \beta) = \frac{1}{32}$, $-3 \leq \alpha \leq 5$, $-1 \leq \beta \leq 3$, $f_{XY}(\alpha, \beta) = 0$ otherwise, then it is easy to find $f_X(\alpha) = \frac{1}{8}$, $-3 \leq \alpha \leq 5$, $f_X(\alpha) = 0$ otherwise and $f_Y(\beta) = \frac{1}{4}$, $-1 \leq \beta \leq 3$, $f_Y(\beta) = 0$ otherwise. Also, X and Y are independent. Figure 4.12 shows $f_{XY}(\alpha, \beta)$, $f_X(\alpha)$, and $f_Y(\beta)$ and gives the convolution of $f_X(\gamma)$ with $f_Y(\gamma)$.

Discrete Case

Given $Z = g(X, Y)$ where $p_{XY}(\alpha_i, \beta_j)$ is known,

$$p_Z(\gamma_i) = \sum_{\beta_j} \sum_{\alpha_i} p_{XY}(\alpha_i, \beta_j)$$

for all α_i, β_j such that $g(\alpha_i, \beta_j) = \gamma_i$. For example, if $Z = XY$,

$$p_Z(\gamma_i) = \sum_{\alpha_i} p_{XY}\left(\alpha_i, \frac{\gamma_i}{\alpha_i}\right) = \sum_{\beta_j} p_{XY}\left(\frac{\gamma_i}{\beta_j}, \beta_j\right)$$

FIGURE 4.13 (a) Region of $p_{XY}(\alpha_i)$ for Problem 12 and (b) $p_X(\alpha_i)$, $p_Y(\gamma_i - \alpha_i)$, $p_{X+Y}(\gamma_i)$, $Z = X + Y$.

Problem 12

Given $p_{XY}(\alpha_i, \beta_j) = \frac{1}{3} (0.5)^{\alpha_i}$, $1 \leq \alpha_i \leq \infty$, $-1 \leq \beta_j \leq 1$, both integers, $p_{XY}(\alpha_i, \beta_j) = 0$ otherwise, and $Z = X + Y$, find (1) $p_Z(\gamma_i)$ directly and (2) if X and Y are independent, find $p_Z(\gamma_i)$ using discrete convolution.

Solution

1. A sketch of the region for which $p_{XY}(\alpha_i, \beta_j)$ exists is shown in Fig. 4.13. Since $Z = X + Y$, then, when $Z = \gamma_i$,

$$p_Z(\gamma_i) = \sum_{\alpha_i} p_{XY}(\alpha_i, \gamma_i - \alpha_i) = \sum_{\beta_j} p_{XY}(\gamma_i - \beta_j, \beta_j)$$

We will use the latter formula as β_j has only three values:

$$p_Z(0) = p_{XY}(1, -1) = \frac{1}{6}$$

$$p_Z(1) = \frac{1}{3} \left[\left(\frac{1}{2} \right)^2 + \left(\frac{1}{2} \right) \right] = \frac{1}{4}$$

and for the range $\gamma_i \geq 2$,

$$\begin{aligned} p_Z(\gamma_i) &= \sum_{\beta_j=-1}^1 p_{XY}(\gamma_i - \beta_j, \beta_j) = \frac{1}{3} \left[\left(\frac{1}{2} \right)^{\gamma_i-1} + \left(\frac{1}{2} \right)^{\gamma_i} + \left(\frac{1}{2} \right)^{\gamma_i+1} \right] \\ &= \frac{7}{6} \left(\frac{1}{2} \right)^{\gamma_i} = 1.17(0.5)^{\gamma_i} \end{aligned}$$

Figure 4.13(b) shows $p_Z(\gamma_i)$ plotted.

2. It is easy to show that $p_X(\alpha_i) = (0.5)^{\alpha_i}$, $\alpha_i \geq 1$ and is zero otherwise and

$$\begin{aligned} p_Y(\beta_j) &= \frac{1}{3} \sum_1^{\infty} (0.5)^{\alpha_i} = \frac{1}{3}, \quad -1 \leq \beta_j \leq 1; \\ &= 0, \quad \text{otherwise} \end{aligned}$$

Since $p_{XY}(\alpha_i, \beta_j) = p_X(\alpha_i)p_Y(\beta_j)$, then X and Y are independent and

$$p_Z(\gamma_i) = \sum_{\beta_j} p_X(\gamma_i - \beta_j)p_Y(\beta_j) \quad \text{or} \quad \sum_{\alpha_i} p_X(\alpha_i)p_Y(\gamma_i - \alpha_i) \quad (4.27)$$

which is the discrete convolution of $p_X(\gamma_i)$ with $p_Y(\gamma_i)$. We will use

$$p_Z(\gamma_i) = \sum_{\alpha_i} p_X(\alpha_i)p_Y(\gamma_i - \alpha_i)$$

For the range $\gamma_i < 0$, $p_Z(\gamma_i) = 0$ as $p_Y(\gamma_i - \alpha_i)$ has not reached $\alpha_i = 1$. $p_Z(0) = \frac{1}{3}(\frac{1}{2}) = \frac{1}{6}$, $p_Z(1) = \frac{1}{3}(\frac{1}{4}) + \frac{1}{3}(\frac{1}{2}) = \frac{1}{4}$, and

$$p_Z(\gamma_i) = \sum_{\gamma_i-1}^{\gamma_i+1} (0.5)^{\alpha_i} \frac{1}{3} = \frac{7}{6}(0.5)^{\gamma_i} = 1.17(0.5)^{\gamma_i}, \quad \gamma_i \geq 2.$$

Statistics of Two Random Variables

Associated with two random variables X and Y , the general second-order moment is

$$\begin{aligned} M_{p,q} &= \overline{X^p Y^q} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \alpha^p \beta^q f_{XY}(\alpha, \beta) d\alpha d\beta \\ &\text{or} \\ &= \sum \sum \alpha_i^p \beta_j^q p_{XY}(\alpha_i, \beta_j) \end{aligned} \quad (4.28)$$

The general second-order central moment $L_{XY} = \overline{(X - \bar{X})^p (Y - \bar{Y})^q}$ is similarly defined. The two most widely used of these are the correlation $R_{XY} = \overline{XY}$ and the covariance $L_{XY} = \overline{(X - \bar{X})(Y - \bar{Y})}$. Associated with these statistics, a two-dimensional moment generating function is defined:

$$M(s, t) = e^{\overline{sX+tY}} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{s\alpha+t\beta} f_{XY}(\alpha, \beta) d\alpha d\beta$$

and

$$\overline{X^p Y^q} = \frac{\delta^{p+q}}{(\delta s)^p (\delta t)^q} M(s, t) \Big|_{s=t=0}$$

The moment generating function is particularly useful for obtaining results for jointly Gaussian random variables.

Second-Order Time Averages for Finite Power Waveforms (FPW)

The time autocorrelation function for a deterministic or random finite power waveform (FPW) is

$$\tilde{R}_{xx}(\tau) = \overbrace{x(t)x(t+\tau)} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x(t)x(t+\tau) dt \quad (4.29)$$

or

$$\tilde{R}_{xx}(k) = \overbrace{x(n)x(n+k)} = \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{n=-N}^N x(n)x(n+k) \quad (4.30)$$

The \sim symbol is used to distinguish them from the fundamental ensemble definition for $R_{xx}(\tau)$ or $R_{xx}(k)$ used for random processes.

These time-average definitions may be assigned an equivalent statistical interpretation. For a continuous FPW $x(t)$, X and Y describe uniformly sampling $x(t)$ at t and $t + \tau$ and observing $X = x(t)$ and $Y = x(t + \tau)$. For N trials as $N \rightarrow \infty$,

$$\tilde{R}_{xx}(\tau) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{i=1}^N x(t_i)x(t_i + \tau) \quad (4.31)$$

where $x(t_i)$ is the value of $x(t)$ on the i th trial, or

$$\begin{aligned} \tilde{R}_{xx}(\tau) &= \overbrace{x(t)x(t + \tau)} = \overline{XY} \\ &= \iint \alpha\beta f_{XY}(\alpha, \beta) d\alpha d\beta \\ &\text{or} \\ &= \sum_i \sum_j \alpha_i \beta_j p_{XY}(\alpha_i, \beta_j) \end{aligned} \quad (4.32)$$

For a discrete FPW $x(n)$, X and Y describe uniformly sampling $x(n)$ at n and $n + k$ and observing $X = x(n)$ and $Y = x(n + k)$. For N trials as $N \rightarrow \infty$,

$$\tilde{R}_{xx}(k) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{i=1}^N x(n_i)x(n_i + k) \quad (4.33)$$

where $x(n_i)$ is the value of $x(n)$ on the i th trial, or

$$\begin{aligned} \tilde{R}_{xx}(k) &= \overbrace{x(n)x(n + k)} = \overline{XY} \\ &= \iint \alpha\beta f_{xy}(\alpha, \beta) d\alpha d\beta \\ &\text{or} \\ &= \sum_i \sum_j \alpha_i \beta_j p_{XY}(\alpha_i, \beta_j) \end{aligned} \quad (4.34)$$

To clarify the relative frequency notation of Eq. (4.31) or (4.33), for example, on the sixth trial, t is chosen uniformly to obtain t_6 and $x(t_6)x(t_6 + \tau)$ and n is chosen uniformly to obtain n_6 and $x(n_6)x(n_6 + k)$. We also note Eqs. (4.32) and (4.34) are identical.

Two illustrative problems will be solved.

Problem 13

Consider the discrete random waveform

$$x(n) = \sum_k A_k g(n - 2k)$$

where $g(n) = 3\delta(n) - \delta(n - 1)$ and the A s are independent random variables, each with mass function $p_{A_i}(1) = p_{A_i}(-1) = 0.5$. Find $\tilde{R}_{xx}(k)$.

Solution

A typical section of $x(n)$ is shown in Fig. 4.14(a). Using formula (4.34) for $\tilde{R}_{xx}(k)$, $\tilde{R}_{xx}(0) = [(3)^2 + (-3)^2 + (1)^2 + (-1)^2] \frac{1}{4} = 5.0$, $\tilde{R}_{xx}(\pm 1) = [3(-1) + (-3)(1)] \frac{1}{4} + [(1)(-3) + (1)(3)] \frac{1}{8}$ + other terms adding to zero = -1.5 , and $\tilde{R}_{xx}(k) = 0$ for all $|k| > 1$. $\tilde{R}_{xx}(k)$ is shown plotted in Fig. 4.14(b).

Problem 14

Consider the continuous random waveform

$$x(t) = \sum_n A_n g(t - n)$$

FIGURE 4.14 (a) A typical section of $x(n)$ for Problem 13 and (b) $\tilde{R}_{xx} = \widetilde{x(n)x(n+k)} = \bar{X}\bar{Y}$.

FIGURE 4.15 (a) A typical section of $x(t)$ for Problem 14 and (b) $\tilde{R}_{xx}(\tau)$.

where $g(t) = 1, 0 \leq t \leq 1; g(t) = 0$ otherwise and the A_s are independent random variables with $f_{A_i}(\alpha) = \frac{1}{2}, 0 \leq \alpha \leq 2, f_{A_i}(\alpha) = 0$ otherwise. Find $\tilde{R}_{xx}(\tau)$.

Solution

A typical section of $x(t)$ is shown in Fig. 4.15(a). Since the A_s are independent, $\bar{A}_i = 1, \bar{A}_i^2 = 1.33,$ and $\bar{A}_i \bar{A}_j = 1$ for all $i \neq j$. Observing Fig. 4.15(a), we obtain the following.

For $0 < \tau < 1$:

$$\begin{aligned} \tilde{R}_{xx}(\tau) &= \bar{A}_i^2(1 - \tau) + \bar{A}_i \bar{A}_{i+1} \tau \\ &= 1.33 - 0.33 \tau \end{aligned}$$

For $\tau > 1$:

$$\tilde{R}_{xx}(\tau) = \overline{A_i A_j} = 1$$

and $\tilde{R}_{xx}(-\tau) = \tilde{R}_{xx}(\tau)$ by symmetry. $\tilde{R}_{xx}(\tau)$ is shown plotted in Fig. 4.15(b). We also note that the same result is obtained when the A s are independent and $f_{A_i}(\alpha)$ or $p_{A_i}(\alpha)$ are such $\overline{A_i} = 1$ and $\overline{A_i^2} = 1.33$. Thus, many different waveforms have the same autocorrelation function.

4.5 Summary and Future Study

The elements of probability and random variable theory were presented as a prerequisite to the study of random processes and communication theory. Highlighted were the concepts of finding first- and second-order time averages statistically, by uniformly sampling a continuous random finite power waveform at t or at $t + \tau$ or discretely uniformly sampling a random finite power discrete waveform at n or at $n + k$. The illustrative problems chosen were simple. When ergodic random processes are later encountered, the time averages for any one member of the ensemble will be equivalent to corresponding ensemble averages. A future task is to approximate time averages on a computer. Here, from a section of a waveform T with its values sampled every τ seconds, an estimate for the autocorrelation function and its Fourier transform $S_{xx}(f)$ called the power spectral density will be found.

Defining Terms

Cumulative distribution, density and mass function: $F_X(\alpha) = P[X \leq \alpha]$, $f_X(\alpha) = d/d\alpha F_X(\alpha)$, $p_X(\alpha_i) = P[X = \alpha_i]$. Other noted distribution or density functions are: total signal energy or total signal power vs. frequency, corresponding to $F_X(\alpha)$; energy or power spectral density vs. frequency, corresponding to $f_X(\alpha)$; total signal power vs. frequency for a periodic waveform, corresponding to $F_X(\alpha)$ for a discrete random variable.

Joint distribution, density and mass function: $F_{XY}(\alpha, \beta) = P[(X \leq \alpha) \cap (Y \leq \beta)]$, $f_{XY}(\alpha, \beta) = \partial^2 / \partial \alpha \partial \beta F_{XY}(\alpha, \beta)$, $p_{XY}(\alpha_i, \beta_j) = P[(X = \alpha_i) \cap (Y = \beta_j)]$.

Joint random variables X and Y: $X(s_i)$ and $Y(s_i)$ jointly map each outcome of the SDS onto an α - β plane.

Probability: $P(A)$ is the statistical regularity of A , $P(A/B)$ is the statistical regularity of A based only on trials when B occurs, axiomatically $P(A) = \sum_{i=1}^n p(s_i)$ if $A = \cup_{i=1}^n s_i$ and $s_i s_j = 0$, $i \neq j$. $P(A/B) = P(AB)/P(B)$ if $P(B) \neq 0$.

Random phenomenon: An experiment which, when performed many times N , yields outcomes that occur with statistical regularity as $N \rightarrow \infty$.

Random variable X: $X(s_i)$ maps the outcomes of the SDS onto a real axis.

Sample description space (SDS): A listing of mutually exclusive, collectively exhaustive, finest grain outcomes.

Special Terminology for Random Finite Power Waveforms

Finite power waveform:

$$P_{av} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x^2(t) dt$$

or

$$= \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{n=-N}^N x^2(n) \quad \text{exists.}$$

First-order time averages:

$$\widetilde{g(x(t))} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T g(x(t)) dt = \int_{-\infty}^{\infty} g(\alpha) f_X(\alpha) d\alpha$$

and

$$\widetilde{g(x(n))} = \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{-N}^N g(x(n)) = \int_{-\infty}^{\infty} g(\alpha) f_X(\alpha) d\alpha$$

The most noted first-order statistics are $\widetilde{x(t)}$ or $\widetilde{x(n)} = \bar{X}$, $\widetilde{x^2(t)}$ or $\widetilde{x^2(n)} = \overline{X^2}$ and $\sigma_X^2 = \overline{(X - \bar{X})^2}$.

Jointly sampling a waveform: Uniformly choosing t and observing $X = x(t)$ and $Y = x(t + \tau)$ or discretely uniformly choosing n and observing $X = x(n)$ and $Y = x(n + k)$.

Sampling a waveform: For a continuous waveform uniformly choosing a value of time over a long time T and observing $X = x(t)$; for a discrete waveform discretely uniformly choosing n , $-N \leq n \leq N$ over a long time $2N + 1$ and observing $x(n)$. The random variable X describes $x(t)$ or $x(n)$.

Second-order time averages:

$$\widetilde{g[x(t), x(t + \tau)]} = \overline{g(X, Y)} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T g[x(t), x(t + \tau)] dt$$

$$\widetilde{g[x(n), x(n + k)]} = \overline{g(X, Y)} = \lim_{N \rightarrow \infty} \frac{1}{2N + 1} \sum_N g[x(n), x(n + k)]$$

and statistically

$$\begin{aligned} \overline{g(X, Y)} &= \iint g(\alpha, \beta) f_{XY}(\alpha, \beta) d\alpha d\beta \\ &\text{or} \\ &= \sum_i \sum_j g(\alpha_i, \beta_j) p_{XY}(\alpha_i, \beta_j) \end{aligned}$$

The most noted second-order statistics are $\widetilde{R_{xx}(\tau)}$ or $\widetilde{R_{xx}(k)} = \overline{XY}$, the time autocorrelation function, and/or $\widetilde{L_{xx}(\tau)}$ or $\widetilde{L_{xx}(k)} = \overline{(X - \bar{X})(Y - \bar{Y})} = \overline{XY} - \bar{X}\bar{Y}$, the covariance function.

Further Information

Some important topics were omitted or only briefly mentioned here. The bivariate Gaussian or normal joint density function is given an excellent treatment in Olkin, Gleser, and Derman [1994, Chap. 12]. The topic of finding the density function of a function of two known random variables can be extended. The case of finding the joint density function for U and V , each defined as a function of two known random variables X and Y , is well handled in Olkin, Gleser, and Derman [1994, Chap. 13]. Finally, the most general transformation problem of finding the joint density function of m random variables, each defined as a linear combination of n known jointly Gaussian random variables, is given in Chap. 9 of O’Flynn [1982].

5.1 Introduction

The modeling of signals and noise in communication systems as random processes is a well-established and proven tradition. Much of the system performance characterization and evaluation can be done in terms of a few low-order statistical moments of these processes. Hence, a system designer often needs to be able to evaluate mean values and the **autocorrelation** of a process and the **cross correlation** of two processes. It is especially true in communication system applications that a frequency-domain-based evaluation is often easier to perform and interpret. Therefore, a knowledge of spectral properties of random processes is valuable.

More recently, engineers are finding that modeling of typical communication signals as **cyclostationary** (CS) processes, rather than stationary processes, more accurately captures their true nature and permits the design of more effective signal processing operations. In the book edited by Gardner [1994], several authors describe applications that have benefited from the exploitation of cyclostationarity. Although these processes are nonstationary, frequency-domain methods prove to be very effective, as in the stationary case.

Another notion that is becoming well accepted by communication engineers is the utility of complex-valued representations of signals. Accordingly, all of the results and relations presented here will be valid for complex-valued random processes.

5.2 Basic Definitions

We consider the random process, $x(t)$, defined as a set of jointly distributed random variables $\{x(t)\}$ indexed by a time parameter t . If the set of values of t is the real line, we say the process is a *continuous-time* process. If the set of values is the integers, we call the process a *discrete-time* process. The *mean* and *autocorrelation* of the process are given by the expected values $E[x(t)]$ and $E[x(t_1)x^*(t_2)]$, respectively.

In dealing with cyclostationary processes, it is often more convenient to define an autocorrelation function in terms of a simple transformation on the t_1 and t_2 variables; namely, let $t = (t_1 + t_2)/2$ and $\tau = t_1 - t_2$ denote the mean value and difference of t_1 and t_2 . Accordingly, we define the autocorrelation function for the process as

$$R_{xx}(t, \tau) = E[x(t + \tau/2)x^*(t - \tau/2)] \quad (5.1)$$

A process is *cyclostationary*, in the wide sense, with period T if both the mean and autocorrelation are periodic in t with period T . Hence, for a cyclostationary process $CS(T)$, we can write*

$$\begin{aligned} m_x(t) &= E[x(t)] = \sum_m M_x(m) e^{j2\pi mt/T} \quad (5.2) \\ R_{xx}(t, \tau) &= \sum_k T c_{xx}(t - kT, \tau) \\ &= \sum_m \tilde{c}_{xx}\left(\frac{m}{T}, \tau\right) e^{j2\pi mt/T} \quad (5.3) \end{aligned}$$

Equation (5.3) results from an application of the **Poisson sum formula** (see Appendix), where $\tilde{c}_{xx}(\nu, \tau)$ is the Fourier transform of $c_{xx}(t, \tau)$ with respect to the t variable; that is,

$$\tilde{c}_{xx}(\nu, \tau) = \int c_{xx}(t, \tau) e^{-j2\pi \nu t} dt \quad (5.4)$$

hence,

$$\tilde{c}_{xx}(m/T, \tau) = \frac{1}{T} \int_0^T R_{xx}(t, \tau) e^{-j2\pi mt/T} dt \quad (5.5)$$

is the m th Fourier coefficient for the t -variation in $R_{xx}(t, \tau)$. It is called the **cyclic autocorrelation function** for $x(t)$ with **cycle frequency** m/T [Gardner, 1989]. Note that the $c_{xx}(t, \tau)$ function in Eq. (5.3) is not uniquely determined by the autocorrelation; only a discrete set of values of its Fourier transform are specified, as indicated in Eq. (5.3). Nevertheless, the notation is useful because the $c_{xx}(t, \tau)$ function arises naturally in modeling typical communication signal time-sequential formats that use sampling, scanning, or multiplexing. The **pulse amplitude modulation (PAM)** signal discussed in [Section 5.4](#) is a good example of this.

A frequency-domain characterization for the $CS(T)$ process is given by the double Fourier transform of $R_{xx}(t, \tau)$.

$$\begin{aligned} S_{xx}(\nu, f) &= \iint R_{xx}(t, \tau) e^{-j2\pi(\nu t + f\tau)} dt d\tau \\ &= \sum_m C_{xx}\left(\frac{m}{T}, f\right) \delta\left(\nu - \frac{m}{T}\right) \quad (5.6) \end{aligned}$$

where $C_{xx}(\nu, f)$ is the double Fourier transform of $c_{xx}(t, \tau)$; hence, it is the Fourier transform, with respect to the τ -variation, of the cyclic autocorrelation. It is called the *cyclic spectral density* for the cycle frequency m/T . Notice that Eq. (5.6) is a set of *impulse fences* located at discrete values of ν in the dual-frequency (ν, f) plane. The impulse fence at $\nu = 0$ has a special significance as the (one-dimensional) **power spectral**

*All summation indices will run from $-\infty$ to ∞ unless otherwise indicated. The same is true for integration limits.

density of the process. The other impulse fences characterize the correlation between signal components in different spectral regions. The physical significance of these concepts is discussed in the next section.

A process is *wide-sense stationary* (WSS) if the mean and autocorrelation are independent of the t variable, that is, if only the $m = 0$ terms in Eqs. (5.2) and (5.3) are nonzero. For the WSS process, we write the autocorrelation function as

$$R_{xx}(\tau) = R_{xx}(0, \tau) = \tilde{c}_{xx}(0, \tau) \quad (5.7)$$

since the cyclic autocorrelation is nonzero only for a cycle frequency of $\nu = 0$. The *power spectral density* of the process is simply the Fourier transform of $R_{xx}(\tau)$:

$$S_{xx}(f) = \int R_{xx}(\tau) e^{-j2\pi f\tau} d\tau \quad (5.8)$$

A CS(T) process can be converted to a WSS process by phase randomization. Let $x'(t) = x(t - \theta)$ where the time shift θ is a random variable which is independent of the other parameters of the process. Then the mean and autocorrelation of the new process are obtained by convolution, with respect to the t variable, with the probability density function $p_\theta(\cdot)$ for the θ variable. Letting $p_\theta(\cdot)$ denote the Fourier transform of $p_\theta(\cdot)$, we have

$$m_{x'}(t) = \sum_m P_\theta\left(\frac{m}{T}\right) M_x(m) e^{j2\pi mt/T}; \quad P_\theta(0) = 1 \quad (5.9a)$$

$$R_{x'x'}(t, \tau) = \sum_m P_\theta\left(\frac{m}{T}\right) \tilde{c}_{xx}\left(\frac{m}{T}, \tau\right) e^{j2\pi mt/T} \quad (5.9b)$$

which indicates that phase randomization tends to suppress the cyclic components with cycle frequencies different from zero. In fact, for a uniform distribution of θ over a T -second interval, only the $m = 0$ terms in Eq. (5.9) remain; hence, $x'(t)$ is WSS. Using the Poisson sum formula, we see that any $p_\theta(\sigma)$ satisfying $\sum_k p_\theta(\sigma - kT) = 1/T$ makes $P_\theta(m/T) = 0$ for $m \neq 0$, hence making $x'(t)$ WSS.

It is important to note [from Eq. (5.5)] that the autocorrelation of the phase-randomized process is the same as the time average of the autocorrelation of the original CS(T) process [Franks, 1969].

For a WSS discrete-time process $a(k)$, where k is an integer, we write the mean and autocorrelation as

$$\bar{a} = E[a(k)] \quad (5.10a)$$

$$R_{aa}(m) = E[a(k+m)a^*(k)] \quad (5.10b)$$

The power spectral density of the discrete-time process is the *discrete-time Fourier transform* (DTFT) of the autocorrelation function; that is,

$$S_{aa}(f) = \sum_m R_{aa}(m) e^{-j2\pi mTf} \quad (5.11)$$

which is always a periodic function of f with a period of $1/T$. A case of frequent interest is when the $a(k)$ are uniformly spaced sample values of a continuous-time WSS random process. Suppose $a(k) = y(kT)$, then using the alternate form of the Poisson sum formula (Appendix), we have $R_{aa}(m) = R_{yy}(mT)$ and

$$S_{aa}(f) = \sum_m R_{yy}(mT) e^{-j2\pi mTf} = \frac{1}{T} \sum_n S_{yy}\left(f - \frac{n}{T}\right) \quad (5.12)$$

In communication system applications, the $a(k)$ sequence usually represents digital information to be transmitted, and the WSS assumption is reasonable. In some cases, such as when synchronizing pulses or other header information are added to the data stream, the $a(k)$ sequence is more appropriately modeled as a cyclostationary process also. The examples we consider here, however, will assume that $a(k)$ is a WSS process

5.3 Properties and Interpretation

Many interesting features of a random process are revealed when the effects of a linear transformation on the first- and second-moment statistics are examined. For this purpose, we use linear transformations which are a combination of frequency shifting and time-invariant filtering, as shown in Fig. 5.1. The exponential multipliers (modulators) provide the frequency shifts, and the filters with transfer functions $H_1(f)$ and $H_2(f)$ provide frequency selective filtering. If $H_1(f)$ and $H_2(f)$ are narrowband low-pass filters, each path of the structure in Fig. 5.1 can be regarded as a sort of heterodyne technique for spectrum analysis. The cross-correlation between the outputs of the two paths provides further useful characterization of the input process.

The cross-correlation function for a pair of jointly random complex processes is defined as

$$R_{yz}(t, \tau) = E[y(t + \tau/2)z^*(t - \tau/2)] \tag{5.13}$$

Substituting the indicated expressions for $y(t)$ and $z(t)$ in Fig. 5.1 and using Eq. (5.3) for the autocorrelation of the $x(t)$ process, we can derive the following general expression for the cross-correlation:

$$R_{yz}(t, \tau) = \sum_m e^{j\pi(f_1+f_2)\tau} \cdot e^{j2\pi(f_1-f_2)\tau} \cdot e^{j2\pi m t/T} \cdot \int H_1\left(f+f_1+\frac{m}{2T}\right) \times H_2^*\left(f+f_2-\frac{m}{2T}\right) C_{xx}\left(\frac{m}{T}, f\right) e^{j2\pi f \tau} df \tag{5.14}$$

First, we consider the case where $H_1(f) = H_2(f) = B(f)$, which is a very narrowband low-pass analysis filter. Let $B(0) = 1$ and let Δ denote the *noise bandwidth* of the filter given by

$$\Delta = \int \left| \frac{B(f)}{B(0)} \right|^2 df \tag{5.15}$$

Hence, an ideal low-pass filter with a rectangular gain shape and a cutoff frequency at $f = \Delta/2$ has a noise bandwidth of Δ . On the other hand, a low-pass filter resulting from averaging a signal over the last T_0 s, that is, one with an impulse response $b(t) = 1/T_0$ in $0 < t < T_0$ and zero elsewhere, has a noise bandwidth

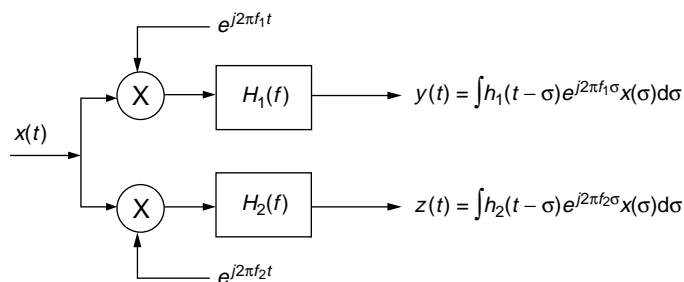

FIGURE 5.1 Conceptual apparatus for analysis of random processes.

of $\Delta = 1/T_0$. Whatever kind of analysis filter we want to use, we shall consider the results as Δ approaches zero so that we can assume that factors of the form $B(f + m/2T)B^*(f - m/2T)$ which will appear in Eq. (5.14) will vanish except for $m = 0$.

For example, let $f_1 = f_2 = -f_0$. Then we see that both paths in the figure are identical, so that $z(t) = y(t)$ and

$$R_{yy}(t, \tau) = e^{-j2\pi f_0 \tau} \int |B(f - f_0)|^2 C_{xx}(0, f) e^{j2\pi f \tau} df \quad (5.16)$$

because only the $m = 0$ term in Eq. (5.14) is nonzero under these conditions. Note also that $y(t)$ is WSS, and its mean-squared value (also called the power of the process) is given by

$$\begin{aligned} E[|y(t)|^2] &= R_{yy}(0) = \int |B(f - f_0)|^2 C_{xx}(0, f) df \\ &\cong \Delta C_{xx}(0, f_0) = \Delta S_{xx}(f_0) \quad \text{as } \Delta \rightarrow 0 \end{aligned} \quad (5.17)$$

This expression, valid for small Δ , gives the power in $x(t)$ due to components in a narrow band centered at a frequency of f_0 . This provides the motivation for calling $S_{xx}(f) = C_{xx}(0, f)$ the power spectral density of the $x(t)$ process. Note that our spectrum analyzer gives the same results for a CS(T) process and its phase-randomized WSS version because of the time averaging inherent in the $B(f)$ analysis filter.

Now, keeping the same low-pass filters, $H_1(f) = H_2(f) = B(f)$, let $f_0 = -(f_1 + f_2)/2$ and $n/T = (f_2 - f_1)$, so that the mean value of the two analysis frequencies is f_0 and their difference is an integer multiple of $1/T$. Then, only the $m = n$ term in Eq. (5.14) is nonzero and we have the following expression for the cross correlation of the $y(t)$ and $z(t)$ processes:

$$\begin{aligned} R_{yz}(t, 0) &= \int |B(f - f_0)|^2 C_{xx}\left(\frac{n}{T}, f\right) df \\ &\cong \Delta C_{xx}(n/T, f_0) \end{aligned} \quad (5.18)$$

for small Δ . Thus, a physical significance of the cyclic spectral density, defined implicitly in Eq. (5.6), is that it represents the correlation that exists between spectral components separated by the cycle frequency. Note that no such spectral correlation exists for a WSS process. This spectral correlation is used to advantage in communication systems to extract timing or synchronization information or to eliminate certain kinds of interference by means of periodically time-varying filtering of signals [Gardner, 1994].

Equation (5.14) is useful to establish many other useful relationships. For example, let $x(t)$ be WSS and let $f_1 = f_2 = 0$, then $y(t)$ and $z(t)$ are jointly WSS and the cross-spectral density is

$$S_{yz}(f) = H_1(f)H_2^*(f)S_{xx}(f) \quad (5.19)$$

and so, if $H_1(f) = H_2(f)$, then $z(t) = y(t)$ and the power spectral density of a filtered WSS process is given by

$$S_{yy}(f) = |H_1(f)|^2 S_{xx}(f) \quad (5.20)$$

whereas letting $H_2(f) = 1$ makes $z(t) = x(t)$ so that the cross-spectral density of the input and output of a filtered WSS process is

$$S_{yx}(f) = H_1(f)S_{xx}(f) \quad (5.21)$$

If $H_1(f)H_2^*(f) = 0$ for all f , then $S_{yz}(f) = 0$, indicating that spectral components in nonoverlapping frequency bands are always uncorrelated. This is a fundamental property of all WSS processes.

5.4 Baseband Digital Data Signals

Perhaps the most basic form of mapping from a discrete-time data sequence $\{a(k)\}$ into a continuous-time signal $x(t)$ for transmission over a communication channel is baseband pulse amplitude modulation. The mapping uses a single carrier pulse shape, $g(t)$, and is a linear function of the data, which we will assume is a WSS discrete-time process [Eq. (5.10)].

$$x(t) = \sum_k a(k)g(t - kT) \quad (5.22)$$

The $x(t)$ process is CS(T) with

$$m_x(t) = \bar{a} \sum_k g(t - kT) = (\bar{a}/T) \sum_m G\left(\frac{m}{T}\right) e^{j2\pi mt/T} \quad (5.23a)$$

$$R_{xx}(t, \tau) = \sum_k \sum_m R_{aa}(m) g\left(t + \frac{\tau}{2} - kT - mT\right) g^*\left(t - \frac{\tau}{2} - kT\right) \quad (5.23b)$$

By inspection, the $c_{xx}(t, \tau)$ function in Eq. (5.3) is

$$c_{xx}(t, \tau) = \frac{1}{T} \sum_m R_{aa}(m) g\left(t + \frac{\tau}{2} - mT\right) g^*\left(t - \frac{\tau}{2}\right) \quad (5.24)$$

so that the cyclic autocorrelation is

$$\tilde{c}_{xx}(n/T, \tau) = \frac{1}{T} \int S_{aa}(f) G\left(\frac{n}{T} + f\right) G^*(f) e^{j2\pi f\tau} df \cdot e^{j\pi n\tau/T} \quad (5.25)$$

Note that the strength of the cyclic autocorrelations (equivalently, the amount of spectral correlation) depends strongly on the amount of overlap of $G(f)$ and its frequency-translated versions. Data carrier pulses are often sharply bandlimited, with **excess bandwidth** factors not exceeding 100%. A pulse with 100% excess bandwidth is bandlimited to the frequency interval $|f| < 1/T$. In this case, $x(t)$ has cycle frequencies of 0 and $\pm 1/T$ only. Note also that an excess bandwidth of less than 100% means that $G(n/T) = 0$ for $n \neq 0$ so that the mean of the PAM signal [Eq. (5.23a)] is constant.

Using time averaging to get the power spectrum of the PAM signal, we can write

$$R_{xx}(\tau) = \frac{1}{T} \sum_m R_{aa}(m) r_g(\tau - mT) \quad (5.26)$$

where

$$r_g(\tau) = \int g(t + \tau) g^*(t) dt \quad (5.27)$$

is the **time-ambiguity function** for the data pulse, $g(t)$ [Franks, 1969]. Its Fourier transform is $|G(f)|^2$, called the *energy spectral density* of the pulse. Hence, taking the Fourier transform of Eq. (5.26), the power spectral density of the PAM signal is

$$S_{xx}(f) = \frac{1}{T} S_{aa}(f) |G(f)|^2 \quad (5.28)$$

which nicely separates the influence of the pulse shape from the correlation structure of the data.

Although it may not be apparent from Eq. (5.28), the power spectrum expression may contain δ -function terms, which represent nonzero concentrations of power at a discrete set of frequencies. In order to make evident the discrete part of the power spectrum, we express the continuous part of the spectrum as the Fourier transform of the autocovariance function, which is the autocorrelation of the zero-mean process, $x'(t) = x(t) - m_x(t)$. Then

$$R_{xx}(t, \tau) = R'_{xx}(t, \tau) + m_x(t + \tau/2)m_x^*(t - \tau/2) \quad (5.29)$$

where

$$R'_{xx}(t, \tau) = R_{x'x'}(t, \tau) = \frac{1}{T} \sum_m R'_{aa}(m)r_g(\tau - mT) \quad (5.30)$$

and

$$R'_{aa}(m) = R_{aa}(m) - |\bar{a}|^2 \quad (5.31)$$

Now, performing the time averaging, the power spectrum is expressed as

$$S_{xx}(f) = \frac{1}{T} S'_{aa}(f)|G(f)|^2 + \left| \frac{\bar{a}}{T} \right|^2 \sum_n \left| G\left(\frac{n}{T}\right) \right|^2 \delta\left(f - \frac{n}{T}\right) \quad (5.32)$$

The second term in Eq. (5.32) is the discrete part of the spectrum. Notice that there are no discrete components for zero-mean data ($\bar{a} = 0$) or if the data pulse has less than 100% excess bandwidth ($G(n/T) = 0$ for $n \neq 0$). For zero-mean independent data, pulse amplitudes are uncorrelated and the power spectrum is simply

$$S_{xx}(f) = \frac{\sigma_a^2}{T} |G(f)|^2 \quad (5.33)$$

where σ_a^2 is the data variance.

A more general format for baseband data signals is to use a separate waveform for each data symbol from the symbol alphabet. Familiar examples are *frequency-shift keying* (FSK), *phase-shift keying* (PSK), and *pulse-position modulation* (PPM). For the binary alphabet case, $[a(k) \in \{0, 1\}]$, the format is basically PAM. Using waveforms $g_0(t)$ and $g_1(t)$ to transmit a zero or one, respectively, we have

$$x(t) = \sum_k [1 - a(k)]g_0(t - kT) + a(k)g_1(t - kT) \quad (5.34)$$

which can be rewritten, using $d(t) = g_1(t) - g_0(t)$, as

$$x(t) = \sum_k g_0(t - kT) + \sum_k a(k)d(t - kT) \quad (5.35)$$

which is a periodic fixed term plus a binary PAM signal. Let $p = Pr[a(k) = 1] = \bar{a}$ and let $P_{11}(m)$ denote the conditional probability, $Pr[a(k+m) = 1|a(k) = 1]$, then with $a'(k) = a(k) - \bar{a}$,

$$\begin{aligned} R'_{aa}(m) &= E[a'(k+m)a'(k)] \\ &= R_{aa}(m) - p^2 = pP_{11}(m) - p^2 \end{aligned} \quad (5.36)$$

and carrying out the calculations, the power spectral density is

$$S_{xx}(f) = \frac{1}{T} s'_{aa}(f) |G_1(f) - G_0(f)|^2 + \left(\frac{1}{T}\right)^2 \sum_n \left| (1-p)G_0\left(\frac{n}{T}\right) + pG_1\left(\frac{n}{T}\right) \right|^2 \delta\left(f - \frac{n}{T}\right) \quad (5.37)$$

where the second term gives the discrete components. Note that the strength of the discrete components depends only on the mean value of the data and not the correlation between data symbols.

To generalize the preceding result to an M -ary symbol alphabet for the data, we write

$$x(t) = \sum_k \sum_{m=0}^{M-1} a_m(k) g_m(t - kT) \quad (5.38)$$

with $a_m(k) \in \{0, 1\}$ and, for each k , only one of the $a_m(k)$ is nonzero for each realization of the process. Then, calculating the autocorrelation function, we find that $c_{xx}(t, \tau)$ in Eq. (5.3) can be expressed as

$$c_{xx}(t, \tau) = \frac{1}{T} \sum_i \sum_{m,n=0}^{M-1} E[a_m(i+j)a_n(i)] g_m\left(t + \frac{\tau}{2} - iT\right) g_n^*\left(t - \frac{\tau}{2}\right) \quad (5.39)$$

We assume that the data process can be modeled as a *Markov chain* characterized by a probability transition matrix $P_{mn}(i)$ giving the probability that $a_m(i+j) = 1$ under the condition that $a_n(j) = 1$. We further assume the process is in a steady-state condition so that it is WSS. This means that the symbol probabilities, $p_n = Pr[a_n(j) = 1]$, must satisfy the homogeneous equation

$$p_m = \sum_{n=0}^{M-1} P_{mn}(1) p_n \quad (5.40)$$

and all of the transition matrices can be generated by recursion:

$$P_{mn}(i+1) = \sum_{k=0}^{M-1} P_{mk}(i) P_{kn}(1); \quad i \geq 1 \quad (5.41)$$

Now, calculation of the autocorrelation can proceed using $E[a_m(i+j)a_n(j)] = q_{mn}(i)$ in Eq. (5.39), where

$$\begin{aligned} q_{mn}(i) &= Pr[a_m(i+j) = 1 \text{ and } a_n(j) = 1] \\ &= P_{mn}(i) p_n \quad \text{for } i > 0 \\ &= \delta_{mn} p_n \quad \text{for } i = 0 \\ &= P_{mn}(-i) p_m \quad \text{for } i < 0 \end{aligned} \quad (5.42)$$

Taking the DTFT of the $q_{mn}(i)$ sequence

$$Q_{mn}(f) = \sum_i q_{mn}(i) e^{-j2\pi i T f} \quad (5.43)$$

we arrive at a remarkably compact expression for the power spectral density of this general form for the baseband data signal

$$S_{xx}(f) = \frac{1}{T} \sum_{m,n=0}^{M-1} Q_{mn}(f) G_m(f) G_n^*(f) \quad (5.44)$$

The power spectrum may contain discrete components. The continuous part of the spectrum can be extracted by replacing the $q_{mn}(i)$ in Eqs. (5.42–5.44) by $q_{mn}(i) - p_m p_n$. Then, the remaining part is the discrete spectrum given by

$$S_{xx}(f)_{\text{discrete}} = \left(\frac{1}{T}\right)^2 \sum_k \left| \sum_{m=0}^{M-1} p_m G_m\left(\frac{k}{T}\right) \right|^2 \delta\left(f - \frac{k}{T}\right) \quad (5.45)$$

For the special case of independent data from symbol to symbol, the probability transition matrix takes on the special form $P_{mn}(i) = p_m$ for each m and each $i > 1$; that is, all columns are identical and consist of the set of steady-state symbol probabilities. In this case, the continuous part of the power spectrum is

$$S_{xx}(f)_{\text{continuous}} = \frac{1}{T} \left[\sum_{m=0}^{M-1} p_m |G_m(f)|^2 - \left| \sum_{m=0}^{M-1} p_m G_m(f) \right|^2 \right] \quad (5.46)$$

and the discrete part is the same as in Eq. (5.45).

As an example of signalling with M different waveforms and with independent, equiprobable data, consider the case of pulse position modulation where

$$g_m(t) = g\left(t - m\frac{T}{M}\right); \quad p_m = 1/M; \quad m = 0, 1, 2, \dots, M-1 \quad (5.47)$$

The resulting power spectrum is

$$S_{xx}(f) = \left(\frac{1}{T}\right) Q(f) |G(f)|^2 + \left(\frac{1}{T}\right)^2 \sum_k \left| G\left(\frac{kM}{T}\right) \right|^2 \delta\left(f - \frac{kM}{T}\right) \quad (5.48)$$

where

$$Q(f) = \left[1 - \left(\frac{1}{M}\right) \frac{\sin^2(\pi T f)}{\sin^2(\pi T f / M)} \right]$$

The continuous part of the spectrum will be broad because pulse widths will be narrow (on the order of T/M s duration) for a reliable determination of which symbol was transmitted. Note, however, that the spectrum has nulls at multiples of $1/T$ due to the shape of the $Q(f)$ factor in Eq. (5.48).

5.5 Coding for Power Spectrum Control

From Eq. (5.28) or (5.44), we see that the shape of the continuous part of the power spectral density of data signals can be controlled either by choice of pulse shapes or by manipulating the correlation structure of the data sequence. Often the latter method is more convenient to implement. This can be accomplished by mapping the data sequence into a new sequence by a procedure called *line coding* [Lee and Messerschmitt, 1988]. The simpler types of line codes are easily handled by Markov chain models. As an example, we consider the *differential binary* (also called NRZI) coding scheme applied to a binary data sequence. Let $a(k) \in \{0, 1\}$ represent the data sequence and $b(k)$ the coded binary sequence. The coding rule is that $b(k)$ differs from $b(k-1)$ if $a(k) = 1$, otherwise $b(k) = b(k-1)$. This can also be

expressed as $b(k) = [b(k-1) + a(k)] \bmod 2$. Letting $q = Pr[a(k) = 1]$, the probability transition matrix can be expressed as

$$P(1) = \begin{bmatrix} 1-q & q \\ q & 1-q \end{bmatrix} \quad (5.49)$$

from which it follows that the steady-state probabilities for $b(k) = 1$ or 0 [Eq. (5.40)] are given by $p = 1 - p = 1/2$, regardless of the uncoded symbol probability q . Because the columns of a transition matrix sum to 1, the evolution of the transition probability [Eq. (5.41)] can be written as a single scalar equation which, in this case, is a first-order difference equation with an initial condition of $P_{11}(0) = 1$.

$$P_{11}(i+1) = (1-2q)P_{11}(i) + q; \quad i \geq 0 \quad (5.50)$$

Using $P_{11}(i) = P_{11}(-i)$, the solution is

$$P_{11}(i) = \frac{1}{2}[(1-2q)^{|i|} + 1] \quad (5.51)$$

Supposing that the transmitted signal is binary PAM using the $b(k)$ sequence, that is,

$$x(t) = \sum_k b(k)g(t-kT) \quad (5.52)$$

then, taking the DTFT of Eq. (5.51) and using Eq. (5.32), the power spectral density becomes [Franks, 1969]

$$S_{xx}(f) = \left(\frac{1}{4T}\right)Q(f)|G(f)|^2 + \left(\frac{1}{2T}\right)^2 \sum_n \left|G\left(\frac{n}{T}\right)\right|^2 \delta\left(f - \frac{n}{T}\right) \quad (5.53)$$

where the spectrum shaping function is

$$Q(f) = q(1-q)[q^2 + (1-2q)\sin^2(\pi T f)]^{-1} \quad (5.54)$$

It is sometimes stated that differential binary (NRZI) coding does not alter the shape of the power spectrum. We see from Eq. (5.54) that this is true only in the case that the original data are equiprobable ($q = 1/2$). As shown in Fig. 5.2, the shaping factor $Q(f)$ differs greatly from a constant as q approaches 0 or 1. Note, however, that the spectrum of the coded signal depends only on the symbol probability q and not the specific correlation structure of the original data sequence.

A more practical line coding scheme is *bipolar coding*, also called *alternate mark inversion* (AMI). It is easily derived from the differential binary code previously discussed. The bipolar line signal is a ternary PAM signal

$$x(t) = \sum_k c(k)g(t-kT) \quad (5.55)$$

where $c(k) = 0$ if $a(k) = 0$ and $c(k) = +1$ or -1 if $a(k) = 1$, with the two pulse polarities forming an alternating sequence; that is, a positive pulse will always be followed by a negative pulse and vice versa. Hence, the bipolar code can be expressed in terms of the differential binary code as

$$c(k) = b(k) - b(k-1) \quad (5.56)$$

FIGURE 5.2 Spectral density shaping function for differential binary coding.

which itself is a form of *partial response coding* [Lee and Messerschmitt, 1988; Proakis and Salehi, 1994]. The autocorrelation function for $c(k)$ is easily expressed in terms of the autocorrelation for $b(k)$,

$$R_{cc}(m) = 2R_{bb}(m) - R_{bb}(m-1) - R_{bb}(m+1) \quad (5.57)$$

and since

$$R_{bb}(m) = \frac{1}{2}P_{11}(m) = \frac{1}{4}[(1-2q)^{|m|} + 1] \quad (5.58)$$

we get

$$\begin{aligned} R_{cc}(0) &= q \\ R_{cc}(m) &= -q^2(1-2q)^{|m-1|}; \quad |m| \geq 1 \end{aligned} \quad (5.59)$$

and, taking the DTFT of $R_{cc}(m)$, the power spectral density for the bipolar signal is

$$S_{xx}(f) = \frac{1}{T}Q(f)|G(f)|^2 \quad (5.60)$$

where

$$Q(f) = [q(1-q)\sin^2(\pi Tf)][q^2 + (1-2q)\sin^2(\pi Tf)]^{-1}$$

Since $E[c(k)] = \bar{c} = \bar{b} - \bar{b} = 0$, the spectrum has no discrete components, which can be a substantial practical advantage. The spectral shaping factor $Q(f)$, shown in Fig. 5.3, produces spectral nulls at $f=0$ and $f=1/T$. This was used to advantage in early wire-cable PCM systems to mitigate the effects of no low-frequency transmission and the effects of increased crosstalk between wire pairs at the higher frequencies. Note that the spectrum shape is still dependent on data symbol probability but not on the correlation structure of the data.

Another simple line code, found useful in optical and magnetic recording systems, is the *Miller code*, whose power spectrum can be determined with a four-state Markov chain [Proakis and Salehi, 1994].

FIGURE 5.3 Spectral density shaping function for bipolar coding.

5.6 Bandpass Digital Data Signals

In most communication systems, signals are positioned in a frequency band which excludes low frequencies. These are called bandpass signals. For digital data signals, we could simply consider the baseband formats discussed previously, but with data pulse shapes, $g(t)$, which have a bandpass nature. However, it is more common to produce bandpass signals by modulation of a sinusoidal carrier with low-pass (baseband) data signals. Hence, we examine here the correlation and spectral properties of **quadrature amplitude modulation (QAM)** carrier signals. Let $u(t)$ and $v(t)$ be real baseband signal processes, then the QAM signal with a carrier frequency of f_0 is

$$x(t) = u(t) \cos(2\pi f_0 t) - v(t) \sin(2\pi f_0 t) \quad (5.61)$$

which can be more conveniently handled in terms of complex signals

$$x(t) = \Re[w(t)e^{j2\pi f_0 t}]; \quad w(t) = u(t) + jv(t) \quad (5.62)$$

The signals $u(t)$ and $v(t)$ are often called the *in-phase* and *quadrature* components, respectively, of the QAM signal. The autocorrelation function for $x(t)$ becomes

$$R_{xx}(t, \tau) = \frac{1}{2} \Re[R_{ww}(t, \tau)e^{j2\pi f_0 \tau}] + \frac{1}{2} \Re[R_{ww^*}(t, \tau)e^{j2\pi(2f_0)\tau}] \quad (5.63)$$

First we consider the situation where $u(t)$ and $v(t)$ are jointly WSS processes, which might be a good model for some types of analog systems. In this case, there are three cycle frequencies ($0, +2f_0, -2f_0$). We obtain the cyclic autocorrelation functions from Eq. (5.5) by time averaging over a period of $T = 1/f_0$ with the result that

$$\tilde{c}_{xx}(0, \tau) = \frac{1}{2} \Re[R_{ww}(\tau)e^{j2\pi f_0 \tau}] \quad (5.64a)$$

$$\tilde{c}_{xx}(2f_0, \tau) = \frac{1}{4} R_{ww^*}(\tau) = \tilde{c}_{xx}^*(-2f_0, \tau) \quad (5.64b)$$

From the second term in Eq. (5.63), in the WSS case, it is evident that a period of $T = 1/2f_0$ would also work; however, we choose to regard the QAM signal as CS($1/f_0$) since the mean value could have a component at f_0 . The autocorrelation result is the same in either case.

We note that $x(t)$ itself would be WSS under the condition that the cross-correlation, $R_{uv^*}(\tau)$, vanishes, making the second term in Eq. (5.63) disappear. This condition is equivalent to $R_{uu}(\tau) = R_{vv}(\tau)$ and $R_{vu}(\tau) = -R_{uv}(\tau) = -R_{vu}(-\tau)$; in other words, $x(t)$ is WSS if the in-phase and quadrature components have the same autocorrelation and their cross-correlation function is odd. If $u(t)$ and $v(t)$ are independent zero-mean processes, then we require only that their autocorrelations match. This is called *balanced* QAM and its power spectral density is

$$S_{xx}(f) = C_{xx}(0, f) = \frac{1}{2}S_{uu}(f-f_0) + \frac{1}{2}S_{uu}(f+f_0) \quad (5.65)$$

For the case of digital data signals, we examine the QAM/PAM signal where the complex baseband signal is a pair of PAM signals,

$$w(t) = \sum_k c(k)g(t-kT); \quad c(k) = a(k) + jb(k) \quad (5.66)$$

Here we encounter a problem regarding the period of the cyclostationarity, because the PAM signal exhibits a period of T while the carrier modulation introduces a period of $1/f_0$, and these periods are not necessarily commensurate. The problem is easily handled by methods used for almost periodic functions, by extending the integration interval indefinitely

$$R_{xx}(t, \tau) = \sum_i \tilde{c}_{xx}(v_i, \tau) e^{j2\pi v_i t} \quad (5.67a)$$

$$\tilde{c}_{xx}(v_i, \tau) = \lim_{T_0 \rightarrow \infty} \frac{1}{2T_0} \int_{-T_0}^{T_0} R_{xx}(t, \tau) e^{-j2\pi v_i t} dt \quad (5.67b)$$

The values of v_i for which Eq. (5.67b) are nonzero are the cycle frequencies. The process is sometimes called *polycyclostationary*. Now, using Eq. (5.25) for the cyclic autocorrelations of $w(t)$ and Eq. (5.63) for the effect of the modulation, then taking Fourier transforms, we get the following results for the cyclic spectral density functions for $x(t)$:

$$C_{xx}\left(\frac{m}{T}, f\right) = \left(\frac{1}{4T}\right)S_{cc}\left(f-f_0-\frac{m}{2T}\right)K(f-f_0; m) \\ + \left(\frac{1}{4T}\right)S_{cc}\left(-f-f_0+\frac{m}{2T}\right)K(f+f_0; m) \quad (5.68a)$$

$$C_{xx}\left(\frac{m}{T} + 2f_0, f\right) = \left(\frac{1}{4T}\right)S_{cc^*}\left(f-\frac{m}{2T}\right)K(f; m) \quad (5.68b)$$

$$C_{xx}\left(\frac{m}{T} - 2f_0, f\right) = \left(\frac{1}{4T}\right)S_{cc^*}^*\left(-f+\frac{m}{2T}\right)K(f; m) \quad (5.68c)$$

where, for convenience, we have defined the function

$$K(f; m) = G\left(f+\frac{m}{2T}\right)G^*\left(f-\frac{m}{2T}\right) \quad (5.69)$$

The cycle frequencies are $\{m/T, m/T + 2f_0, m/T - 2f_0\}$. For example, if the data pulse $g(t)$ had less than 100% excess bandwidth, then $K(f; m)$ vanishes for $|m| > 2$ and there are a total of nine cycle frequencies. If the QAM is balanced, for example, by making the $a(k)$ and $b(k)$ identically distributed and independent, then the cross-spectral density $S_{cc^*}(f)$ vanishes and only three cycle frequencies remain.

As an illustration, let us assume that the $a(k)$ and $b(k)$ sequences are independent and each sequence has zero-mean, independent data, but with variances, σ_a^2 and σ_b^2 , for in-phase and quadrature data, respectively. Then $S_{cc}(f) = \sigma_a^2 + \sigma_b^2$ and $S_{cc^*}(f) = \sigma_a^2 = \sigma_b^2$, giving the following simple expressions for the cyclic spectral densities:

$$C_{xx}\left(\frac{m}{T}, f\right) = \frac{\sigma_a^2 + \sigma_b^2}{4T} [K(f - f_0; m) + K(f + f_0; m)] \quad (5.70a)$$

$$C_{xx}\left(\frac{m}{T} + 2f_0, f\right) = C_{xx}\left(\frac{m}{T} - 2f_0, f\right) = \frac{\sigma_a^2 - \sigma_b^2}{4T} K(f; m) \quad (5.70b)$$

and the power spectral density is

$$S_{xx}(f) = C_{xx}(0, f) = \frac{\sigma_a^2 + \sigma_b^2}{4T} [|G(f - f_0)|^2 + |G(f + f_0)|^2] \quad (5.71)$$

which is simply a pair of frequency-translated versions of the corresponding baseband PAM spectrum.

The case of *double-sideband amplitude modulation* (DSB-AM/PAM) is covered in the preceding equations simply by making all of the $b(k)$ equal to zero. This can be regarded as extremely unbalanced QAM; hence, the nonzero cyclic components will tend to be greater than in the QAM case. Other modulation formats can be handled by essentially the same methods. For example, *vestigial-sideband modulation* (VSB-AM/PAM) uses a single data stream and a complex data pulse; $w(t) = \sum a(k)[g(t - kT) + j\tilde{g}(t - kT)]$. A more general version of QAM uses a different pulse shape in the in-phase and quadrature channels. Staggered QAM (SQAM) uses time-shifted versions of the same pulse; for example, $w(t) = \sum a(k)g(t - kT) + j\sum b(k)g(t - T/2 - kT)$. *Quaternary phase-shift keying* (QPSK) is a special case of QAM with $a(k), b(k) \in \{+1, -1\}$.

5.7 Appendix: The Poisson Sum Formula

For any time function $g(t)$ having Fourier transform $G(f)$, the following relation is often useful in system analysis:

$$\sum_k g(t - kT) = \frac{1}{T} \sum_m G\left(\frac{m}{T}\right) e^{j2\pi mt/T} \quad (A.5.1)$$

The relation is easily verified by making a Fourier series expansion of the periodic function on the left-hand side of Eq. (A.5.1). The m th Fourier coefficient is

$$c(m) = \frac{1}{T} \int_0^T \sum_k g(t - kT) e^{-j2\pi mt/T} dt \quad (A.5.2)$$

and, by a change of integration variable,

$$c(m) = \frac{1}{T} \int_{-\infty}^{\infty} g(\sigma) e^{-j2\pi m\sigma/T} d\sigma = \frac{1}{T} G\left(\frac{m}{T}\right) \quad (A.5.3)$$

Another useful version of the Poisson sum formula is the time/frequency dual of Eq. (A.5.1).

$$\sum_k g(kT)e^{-j2\pi kTf} = \frac{1}{T} \sum_m G\left(f - \frac{m}{T}\right) \quad (\text{A.5.4})$$

Defining Terms

- Autocorrelation:** The expected value of the product of two elements (time samples) of a single random process. The variables of the autocorrelation function are the two time values indexing the random variables in the product.
- Cross correlation:** The expected value of the product of elements from two distinct random processes.
- Cycle frequency:** The frequency parameter associated with a sinusoidal variation of a component of the autocorrelation of a cyclostationary process.
- Cyclic autocorrelation:** A parameter characterizing the amount of contribution to the overall autocorrelation at a particular cycle frequency.
- Cyclostationary random process (wide-sense):** A random process whose mean and autocorrelation functions vary periodically with time.
- Excess bandwidth:** The amount of bandwidth of a PAM signal that exceeds the minimum bandwidth for no intersymbol interference. It is usually expressed as a fraction of the Nyquist frequency of $1/2T$, where $1/T$ is the PAM symbol rate.
- Poisson sum formula:** A useful identity relating the Fourier series and sum-of-translates representations of a periodic function.
- Power spectral density:** A real, nonnegative function of frequency that characterizes the contribution to the overall mean-squared value (power) of a random process due to components in any specified frequency interval.
- Pulse amplitude modulation (PAM):** A signal format related to a discrete-time sequence by superposing time-translated versions of a single waveform, each scaled by the corresponding element of the sequence.
- Quadrature amplitude modulation (QAM):** A signal format obtained by separately modulating the amplitude of two components of a sinusoidal carrier differing in phase by 90° . In digital communications, the two components (referred to as in-phase and quadrature components) can each be regarded as a PAM signal.
- Time-ambiguity function:** A property of a waveform, similar to convolution of the waveform with itself, which characterizes the degree to which the waveform can be localized in time. The Fourier transform of the time-ambiguity function is the energy spectral density of the waveform.

Further Information

The text by Papoulis [1991] is the third edition of a well known and referenced work on probability and random processes that first appeared in 1965. It is a concise and comprehensive treatment of the topic and is widely regarded as an ideal reference source. Gardner [1989] provides the most complete textbook treatment of cyclostationary processes. He presents a careful development of the theory of such processes as well as several examples of applications relevant to the communications field. Stark and Woods [1986] is a somewhat more advanced textbook. It uses modern notation and viewpoints and gives the reader a good introduction to the related topics of parameter estimation and decision theory.

- 6.4 The M/M/1 Queuing System: Averages and Variances
- 6.5 Averages for the Queue and the Server

6.1 Introduction

Everyone has experienced being in a **queue**: waiting in line at a checkout counter, waiting in traffic as we enter a highway's tollgate, or waiting for a time-sharing computer to run our program. Examples of queues from everyday life and technical experiences are almost endless.

A study of queues is important for the following reasons:

1. From the user's point of view, a queue, that is, waiting in line, is a nuisance and will be tolerated only at some minimal level of inconvenience.
2. From the point of view of a provider of some service, queues are necessary. It is extremely uneconomical to provide a large number of servers to handle the biggest possible rush, only to have many of them idle most of the time.

One motivation to study queues is to find some balance between these two conflicting viewpoints. Probability theory is the tool we use for a study of queues because arrivals and departures from a **queuing system** occur randomly. In Fig 6.1, a **customer** arrives at the input to the queuing system, and if no **server** is free, the customer must wait in a queue until it is his, her, or its turn to be served. A **queue discipline** is the name given to a rule by which a customer is selected from a queue for service.

6.2 Little's Formula

Let the average rate at which customers arrive at a queuing system be the constant λ . Departures from the queuing system occur when a server finishes with a customer. In the steady state, the average rate at which customers depart the queuing system is also λ . Arrivals to a queuing system may be described as a counting process $A(t)$ such as shown in Fig 6.2. We estimate an average rate of arrivals with

$$\bar{\lambda} = \frac{A(t)}{t} \quad (\text{per unit time}) \quad (6.1)$$

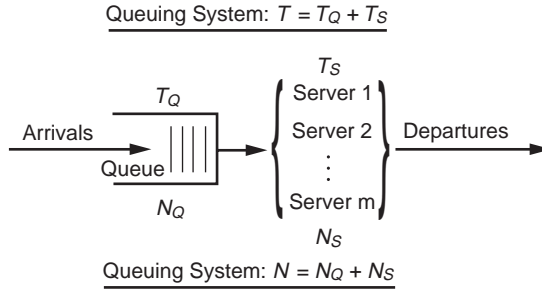

FIGURE 6.1 Illustration of queuing system: Customers arrive at a queue and, after some time, depart from a server that serves the queue.

FIGURE 6.2 Illustration of the arrival and departure counting processes for a queuing system.

where $A(t)$ is the number of arrivals in $[0, t]$. Departures from the system $D(t)$ are also described by a counting process, and an example is also shown in Fig. 6.2. Note that $A(t) \geq D(t)$ must be true at all times. The time that each customer spends in the queuing system is the time difference between the customer's arrival and subsequent departure from a server. The time spent in the queuing system for arrival i is denoted $t_i, i = 1, 2, 3, \dots$

The average time a customer spends waiting in a queuing system is

$$\bar{t} = \frac{1}{A(t)} \sum_{i=1}^{A(t)} t_i \quad (\text{units of time}) \tag{6.2}$$

The average number of customers in a queuing system \bar{n} is, from Eqs. (6.1) and (6.2),

$$\bar{n} = \frac{1}{t} \sum_{i=1}^{A(t)} t_i = \bar{\lambda} \bar{t} \quad (\text{dimensionless}) \tag{6.3}$$

If we assume that, with enough data, sample averages approximate their expected values, then $\bar{\lambda} \rightarrow \lambda$, $\bar{t} \rightarrow E[T]$, and $\bar{n} \rightarrow E[N]$, where N and T are random variables. Also, Eq. (6.3) becomes

$$E[N] = \lambda E[T] \tag{6.4}$$

This relation is known as Little's formula [Williams, 1991]; it has a generality much beyond what one might suppose, given the heuristic demonstration leading to Eq. (6.4).

Example 1

The data in Table 6.1 are the data used to plot $A(t)$ and $D(t)$ in Fig. 6.1. In Table 6.1, the times, given in the units of minutes, are: arrival time t_A , time spent in the queue t_Q , time spent with the server t_S , total time in the queuing system for the i th arrival t_i , and the departure time t_D . For each i we see in Table 6.1, that $t_i = t_Q + t_S$ and that $t_D = t_A + t_i$. These data describe a first-in–first-out (FIFO) queuing discipline: If a customer arrives before the previous customer departs, then the customer must wait his turn in the queue until the server is available. If the previous customer has departed prior to a customer’s arrival, then the waiting time in the queue is $t_Q = 0$.

According to the data in Table 6.1, when $t = 20.7$ then $A(t) = i = 10$. From Eq. (6.1),

$$\bar{\lambda} = \frac{10}{20.7} = 0.48 \quad (\text{min}^{-1})$$

The sum of all the t_i in Table 6.1 is 31.4 min. Therefore, from Eq. (6.2),

$$\bar{t} = \frac{31.4}{10} = 3.14 \quad (\text{min})$$

Finally, using Little’s formula in Eq. (6.3), the sample average number of customers in the queuing system is

$$\bar{n} = \frac{10}{20.7} \times \frac{31.4}{10} = 1.52$$

6.3 The M/M/1 Queuing System: State Probabilities

A generally accepted notation used to name a queuing system is A/S/m: A is a description of the dynamics by which arrivals come to the queuing system; S is a description of the dynamics by which a server processes a customer taken from the queue; and m is the number of servers. The arrivals and the server are independent of each other except that a server cannot serve a customer who has not yet arrived into the queue.

We define the **state** of a queuing system as the total number of customers within it, that is, either within the queue or being served. The only queuing system that we discuss in this chapter is M/M/1: The arrival dynamics are Markov (with rate constant λ), the server dynamics are Markov (with rate constant λ_S), and there is only one server.

There can be, at most, only *one* arrival and, at most, *one* departure in a time interval Δt when $\Delta t \rightarrow 0$. As far as arrivals are concerned, when Δt is a small increment of time, the probability of an arrival into the queuing system in the interval Δt is

$$P(A) = \lambda \Delta t \tag{6.5}$$

Correspondingly, the probability of no arrival in Δt is

$$P(\bar{A}) = 1 - \lambda\Delta t \quad (6.6)$$

The probability of serving (discharging) a customer $P(D)$ is actually conditioned by the event that there is at least one customer in the queuing system. Thus, *given* that the state is at least one,

$$P(D) = \lambda_s\Delta t \quad (6.7)$$

The probability of continuing to serve a customer who is already being served is

$$P(\bar{D}) = 1 - \lambda_s\Delta t \quad (6.8)$$

Suppose that the state of a queuing system is zero at time $t + \Delta t$. This can occur in only one of three mutually exclusive ways. If the state at time t is zero, then either there is no arrival in the increment Δt , or, if there is an arrival in Δt , then there is also a departure within the same Δt . If the state at t is one, then there must be one departure and no arrival within Δt . Let $P_n(t)$ denote the probability of a queuing system being in the state n at time t . Then, with this notation, a summary of the preceding statement is

$$P_0(t + \Delta t) = P_0(t)\{P(\bar{A}) + P(A)P(D)\} + P_1(t)P(\bar{A})P(D)$$

Using Eqs. (6.5–6.8), this may be arranged into

$$\frac{P_0(t + \Delta t) - P_0(t)}{\Delta t} = -\lambda P_0(t)\{1 - \lambda_s\Delta t\} + \lambda_s P_1(t)\{1 - \lambda\Delta t\}$$

Then, taking the limit as $\Delta t \rightarrow 0$, we have the derivative

$$\frac{dP_0(t)}{dt} = \lambda_s P_1(t) - \lambda P_0(t)$$

When a queuing system is in the steady state, the rate of change of the probability $P_0(t)$ with respect to time is zero, and we have

$$\lambda P_0(t) = \lambda_s P_1(t) \quad (6.9)$$

If at time $t + \Delta t$ the state of the queuing system is greater than zero, we have

$$\begin{aligned} P_n(t + \Delta t) &= P_n(t)\{P(\bar{A})P(\bar{D}) + P(A)P(D)\} \\ &\quad + P_{n+1}(t)P(\bar{A})P(D) + P_{n-1}(t)P(A)P(\bar{D}) \end{aligned}$$

The first term on the right of this equation describes two ways for the state to remain the same when time increases from t to $t + \Delta t$: either no arrival and no departure occur, or exactly one arrival occurs and exactly one departure occurs. The second term describes the state $n + 1$ changing to n by exactly one departure with no arrival. The third term describes the change from state $n - 1$ to n by exactly one arrival and no departure. No other combinations of arrivals and departures can happen using our assumptions when $n > 0$. Then, as before, finding the derivative of $P_n(t)$ and setting it equal to zero in the steady-state condition, we find

$$(\lambda + \lambda_s)P_n(t) = \lambda_s P_{n+1}(t) + \lambda P_{n-1}(t) \quad (6.10)$$

We introduce the ratio

$$\rho = \frac{\lambda}{\lambda_s} \quad (6.11)$$

Then, when $n = 0$, we have from Eq. (6.9),

$$P_1(t) = \rho P_0(t)$$

When $n = 1$, Eq. (6.10) becomes

$$(\lambda + \lambda_s)P_1(t) = \lambda_s P_2(t) + \lambda P_0(t)$$

Combining this with $P_1(t)$, we have an expression which, when simplified, becomes

$$P_2(t) = \rho^2 P_0(t)$$

Continuing in this way, it follows that

$$P_n(t) = \rho^n P_0(t) \quad (6.12)$$

Since the queuing system can theoretically be in any state $n = 0, 1, 2, \dots$ (that is, there can be any nonnegative number of customers in the queuing system), we must require that

$$\sum_{n=0}^{\infty} P_n(t) = 1 \quad (6.13)$$

Combining Eqs. (6.12) and (6.13), we have

$$P_0(t) \sum_{n=0}^{\infty} \rho^n = 1$$

By stipulating that $\rho < 1$, we can sum the geometric progression [Beyer, 1987, p. 8]:

$$\sum_{n=0}^{\infty} \rho^n = \frac{1}{1 - \rho} \quad (6.14)$$

Thus, when $n = 0$, we have

$$P_0(t) = 1 - \rho \quad (6.15)$$

Combining Eq. (6.15) with Eq. (6.12) gives the probability of any state n for the M/M/1 queuing system:

$$P_n(t) = (1 - \rho)\rho^n \quad (6.16)$$

As long as the state of a queuing system is greater than zero, then one of the customers must be with the server. Therefore, the probability that the server is busy is $P(N > 0)$. Since $P(N > 0) + P_0(t) = 1$, it follows, using Eq. (6.15), that

$$P(N > 0) = \rho \quad (6.17)$$

The result in Eq. (6.17) is why the ratio ρ is called the **utilization** of an M/M/1 queuing system.

Example 2

A manager of a queuing system wants to know the probability that k or more customers are in the queue waiting to be served by the server; $k = 1, 2, 3, \dots$. If even one customer is in the queue, then there must also be one customer with the server. Therefore, what the manager wants to know is the probability that the state of the queuing system is $k + 1$ or more. Then, with Eq. (6.16),

$$P(N_Q \geq k) = P(N \geq k + 1) = \sum_{n=k+1}^{\infty} (1 - \rho)\rho^n$$

If we use the change of variables $m = n - (k + 1)$, and Eq. (6.14), we then answer the manager's question:

$$P(N_Q \geq k) = (1 - \rho)\rho^{k+1} \sum_{m=0}^{\infty} \rho^m = \rho^{k+1}$$

6.4 The M/M/1 Queuing System: Averages and Variances

The purpose of this section is to find the statistical parameters of mean and variance for both random variables N and T shown in Fig. 6.1 for an M/M/1 queue. In the following, the lower case n and t stand for realizations of the random variables N and T .

If the geometric progression in Eq. (6.14) is differentiated once with respect to ρ , we have

$$\sum_{n=0}^{\infty} n\rho^n = \frac{\rho}{(1 - \rho)^2}$$

Then, differentiating this once again,

$$\sum_{n=0}^{\infty} n^2\rho^n = \frac{\rho(1 + \rho)}{(1 - \rho)^3}$$

The first of these two derivatives can be used along with Eq. (6.16) to show that the mean of N is

$$E[N] = \sum_{n=0}^{\infty} nP_n(t) = \sum_{n=0}^{\infty} n(1 - \rho)\rho^n = \frac{\rho}{1 - \rho} \quad (6.18)$$

The second of these two derivatives is used to express the mean of the square of N ,

$$E[N^2] = \sum_{n=0}^{\infty} n^2P_n(t) = \sum_{n=0}^{\infty} n^2(1 - \rho)\rho^n = \frac{\rho(1 + \rho)}{(1 - \rho)^2} \quad (6.19)$$

Equations (6.18) and (6.19) are used to find the variance of N ,

$$\text{Var}[N] = E[N^2] - (E[N])^2 = \frac{\rho}{(1 - \rho)^2} \quad (6.20)$$

One notes that as $\lambda_s \rightarrow \lambda$, the utilization approaches unity, and both the mean and the variance of N for the M/M/1 queue become unbounded.

Assume that a customer arrives at an M/M/1 queuing system at time $t = 0$. The customer finds that the queuing system is in state n where n could be $0, 1, 2, \dots$. We use the notation T_n to denote the random variable for the total time in the queuing system *given* that the state found by a customer is n . The probability of that customer leaving the queuing system in the interval between t and $t + \Delta t$ is

$$P(t < T_n \leq t + \Delta t) = F_{T_n}(t + \Delta t) - F_{T_n}(t)$$

where $F_{T_n}(t)$ is the probability cumulative distribution function (cdf) for T_n . Another way of expressing this probability is

$$P(t < T_n \leq t + \Delta t) = P(\text{exactly } n \text{ departures from the server between } 0 \text{ and } t) \\ \times P(\text{the customer departs from the server in } \Delta t)$$

The first of the probabilities is Poisson [Williams, 1991] with rate parameter λ_s and time interval t . The second probability is obtained from Eq. (6.7). Thus,

$$P(t < T_n \leq t + \Delta t) = \left\{ \frac{(\lambda_s t)^n}{n!} e^{-\lambda_s t} \right\} \lambda_s \Delta t$$

Combining these two expressions for $P(t < T_n \leq t + \Delta t)$, we have the following:

$$F_{T_n}(t + \Delta t) - F_{T_n}(t) = \left\{ \frac{(\lambda_s t)^n}{n!} e^{-\lambda_s t} \right\} \lambda_s \Delta t$$

We can use this to construct the following derivative:

$$\lim_{\Delta t \rightarrow 0} \frac{F_{T_n}(t + \Delta t) - F_{T_n}(t)}{\Delta t} = \frac{d}{dt} F_{T_n}(t) = f_{T_n}(t)$$

where $f_{T_n}(t)$ is the probability density function (pdf) for T_n ,

$$f_{T_n}(t) = \frac{\lambda_s^{n+1} t^n}{n!} e^{-\lambda_s t}, \quad t \geq 0 \quad (6.21)$$

The random variable T is the time in the queuing system considering all possible states. Then, using Eqs. (6.16), (6.21), and the series expansion for e^x [Beyer, 1987, p. 299],

$$f_T(t) = \sum_{n=0}^{\infty} f_{T_n}(t) P_n(0) \\ = \sum_{n=0}^{\infty} \frac{\lambda_s^{n+1} t^n}{n!} e^{-\lambda_s t} (1 - \rho) \rho^n \\ = (1 - \rho) \lambda_s e^{-\lambda_s t} \sum_{n=0}^{\infty} \frac{\lambda_s^n t^n \rho^n}{n!} \\ = (1 - \rho) \lambda_s e^{-\lambda_s t} e^{\rho \lambda_s t}$$

Using Eq. (6.11), we finally have the result

$$f_T(t) = (\lambda_s - \lambda)e^{(\lambda_s - \lambda)t}, \quad t \geq 0 \quad (6.22)$$

This is recognized as the pdf for an exponential random variable. It is therefore known that [Williams, 1991]

$$E[T] = \frac{1}{\lambda_s - \lambda} = \frac{1/\lambda_s}{1 - \rho} \quad (6.23)$$

$$\text{Var}[T] = \frac{1}{(\lambda_s - \lambda)^2} = \frac{1/\lambda_s^2}{(1 - \rho)^2} \quad (6.24)$$

Example 3

Assume that an M/M/1 queuing system has a utilization of $\rho = 0.6$; this means that the server is idle 40% of the time. The average number of customers in the queuing system is, from Eq. (6.18),

$$E[N] = \frac{\rho}{1 - \rho} = 1.50$$

The standard deviation for this value is, from Eq. (6.20),

$$\sqrt{\text{Var}[N]} = \frac{\sqrt{\rho}}{1 - \rho} = 1.94$$

From Eqs. (6.23) and (6.24),

$$E[T] = \sqrt{\text{Var}[T]} = \left(\frac{1}{1 - \rho}\right) \frac{1}{\lambda_s} = \frac{2.5}{\lambda_s}$$

Thus, the mean and the standard deviation of the time a customer spends in the M/M/1 queuing system are the same.

Realizations of either N and T in an M/M/1 queuing system with $\rho = 0.6$ should be expected to fluctuate markedly about their means because of their relatively large standard deviations. A similar behavior may occur with other values of the utilization.

6.5 Averages for the Queue and the Server

The average number of customers in the server can be calculated using Eq. (6.17):

$$E[N_s] = (1)P(N > 0) + (0)P_0(t) = P(N > 0) = \rho \quad (6.25)$$

Combining Eq. (6.18) with Eq. (6.25), we find the average number of customers in the queue:

$$\begin{aligned} E[N_Q] &= E[N] - E[N_s] \\ &= \frac{\rho}{1 - \rho} - \rho \\ &= \frac{\rho^2}{1 - \rho} \end{aligned} \quad (6.26)$$

The average time a customer spends with the server is the reciprocal of the server's average rate,

$$E[T_S] = 1/\lambda_s \quad (6.27)$$

Therefore, using Eqs. (6.23) and (6.27), the average time spent waiting in the queue before being served is

$$\begin{aligned} E[T_Q] &= E[T] - E[T_S] \\ &= \frac{1/\lambda_s}{1-\rho} - \frac{1}{\lambda_s} \\ &= \frac{\rho/\lambda_s}{1-\rho} \end{aligned} \quad (6.28)$$

Example 4

An M/M/1 queuing system has a utilization of $\rho = 0.6$ and a rate at which the server can work of $\lambda_s = \frac{1}{45}(\text{s}^{-1})$. Using Eq. (6.28), customers should expect to spend the following time in the queue before being served:

$$E[T_Q] = \frac{45\rho}{1-\rho} = 1.13 \quad (\text{min})$$

At any time, the expected number of customers in the queue waiting to be served is, using Eq. (6.26),

$$E[N_Q] = \frac{\rho^2}{1-\rho} = 0.90$$

And, the expected number of customers with the server is its utilization, Eq. (6.25),

$$E[N_S] = \rho = 0.6$$

Defining Terms

Customer: A person or object that is directed to a server.

Queue: A line of people or objects waiting to be served by a server.

Queue discipline: A rule by which a customer is selected from a queue for service by a server.

Queuing system: A combination of a queue, a server, and a queue discipline.

Server: A person, process, or subsystem designed to perform some specific operation on or for a customer.

State: The total number of customers within a queuing system.

Utilization: The percentage of time that the server is busy.

7.1 Introduction

A *channel* is the link between a source and a sink (receiver). In the early days of electrical wire communication, each channel was used to transmit only one signal. If you were to view an early photograph of the streets of New York, you would note that utility poles dominate the scene. Literally hundreds of wires formed a web above the city streets. Some people considered this beautiful, particularly on an icy winter morning. Of course, aside from aesthetic considerations, the proliferation of separate channels could not be permitted to continue as communications expanded.

In many contemporary applications, a variety of signals must be transmitted on a single channel. The channel must, therefore, be shared among the various applications. The process of combining multiple signals for transmission through a single channel is called **multiplexing**.

When multiple signals simultaneously occupy the same channel, the various signals must be separable from each other. In a mathematical sense, the various signals must be *orthogonal*.

The form of multiplexing used in everyday conversation requires time separation. In such situations, the participants try not to speak at the same time. But there are more efficient ways that signals can share a channel without overlapping. This section examines frequency multiplexing, wavelength multiplexing, time multiplexing, space multiplexing, and several *multiple access* schemes.

7.2 Frequency Multiplexing

Frequency-division multiplexing (FDM) is the technique used in traditional analog broadcast systems including AM radio, FM radio, and television. As a simple example, suppose two people in a room wanted to talk simultaneously. A listener would hear a superposition of both speech waveforms and would have difficulty separating one from the other. If, however, one of the speakers spoke in a baritone and the other in soprano, the listener could resolve the two voice signals using an acoustic filter. For example, a lowpass filter would only admit the baritone's voice, thereby blocking the other signal.

Of course, we do not want to restrict the various sources in an unrealistic manner. FDM takes advantage of the observation that all frequencies of a particular message waveform can be easily shifted by a constant amount. The shifting is performed using a sinusoidal carrier signal. The original message

FIGURE 7.1 Frequency-division multiplexing.

FIGURE 7.2 Demultiplexing of FDM.

signal is multiplied by the carrier. This shifts the frequencies of the message signal by the frequency of the carrier. If, for example, the original signal is baseband (composed of relatively low frequencies around DC), multiplication of the signal by a sinusoidal carrier shifts all frequencies to a range centered about the sinusoidal frequency. We are describing *amplitude modulation*. By using multiple sinusoids of differing frequencies, signals can be stacked in frequency in a non-overlapping manner. This is illustrated in Fig. 7.1. The right portion of the figure illustrates typical frequency spectra (Fourier transforms). To be able to separate the signals, the various carriers must be spaced by at least twice the highest frequency of the message signal.

The multiplexed signals can be extracted using bandpass filters (i.e., frequency *gates*). The frequencies can then be shifted back to baseband using demodulators. This is shown in Fig. 7.2.

The demodulator block in Fig. 7.2 takes on various forms. The coherent form simply shifts the signal back down to baseband frequencies using an exact replica of the original sinusoid. If the original modulated signal is modified to explicitly contain the carrier sinusoid, incoherent demodulators (e.g., the envelope detector) may obviate the need for reproducing the original sinusoid.

In designing FDM systems, attention must be given to the minimum separation between carriers. Although the minimum spacing is twice the highest signal frequency, using this exact value would place unrealistic constraints on the bandpass filters of Fig. 7.2. For this reason, a *guard slot* is often included between multiplexed frequency components. The larger the guard band, the easier it is to design the separation filters. However, the price being paid is a reduction in the number of channels that can be multiplexed within a given bandwidth. Note that this is not the approach used by broadcast multiplex systems. Instead, there is no guard slot and the FCC avoids assigning adjacent frequency slots to two strong signal sources.

Frequency-division multiplexing is sometimes used to create a composite baseband signal. For example, in FM stereo, the two audio signals are frequency multiplexed to produce a new baseband signal. One of the audio signals occupies the band of frequencies between DC and 15 kHz, whereas the second audio signal is shifted by 38 kHz. It then occupies a band between 23 and 53 kHz. The composite sum signal can then be considered as a new baseband waveform with frequencies between DC and 53 kHz. The composite baseband waveform frequency modulates a carrier and is frequency multiplexed a second time, this time with other modulated composite signals.

When frequency-division multiplexing is used on fiber-optic channels, it is sometimes referred to as **wavelength-division multiplexing (WDM)**. WDM systems encode each signal on a different carrier frequency. For relatively short distances, WDM is often more complex (i.e., expensive) than running multiple fiber cables, but this may change in time.

7.3 Time Multiplexing

There is a complete duality between the time domain and the frequency domain. Therefore, the discussion of FDM of the preceding section can be extended to **time-division multiplexing (TDM)**. This form of multiplexing is common to pulse modulation systems.

An analog signal can be transmitted by first sampling the waveform. In accordance with the *sampling theorem*, the number of samples required each second is at least twice the highest frequency of the waveform. For example, a speech waveform with an upper frequency of 4 kHz can be fully represented by samples taken at a rate of 8000 samples/s. If each sample value modulates the height of a pulse, as in PAM, the signal can be sent using 8000 varying-height pulses each second. If each pulse occupies only a fraction of the time spacing between samples, the time axis can be shared with other sampled signals. Figure 7.3 shows an example for three signals. The notation used designates s_{ij} as the i th time sample of the j th signal. Thus, for example, s_{23} is the second sample of the third signal. The three signals are said to be time-division multiplexed. If the pulses are made narrower, additional signals can be multiplexed. Of course, the narrower the pulses, the wider the bandwidth of the multiplexed signal. Once you are given the bandwidth of the channel, the minimum pulse width is set. In using TDM, one must also be sensitive to channel distortion, which widens the pulses before they arrive at the receiver. Pulses that do not overlap at the transmitter may, therefore, overlap at the receiver, thus causing *intersymbol interference (ISI)*. Equalizers can be used to reduce the ISI.

If the transmission is (binary) digital rather than analog, each sample is coded into a binary number. Instead of sending a single pulse, multiple binary pulses are sent for each sample. This leads to *pulse code modulation*, or PCM. TDM can still be used, but the number of pulses in each sampling interval increases by a factor equal to the number of bits of A/D conversion.

The **T-1 carrier** transmission system has historical significance and also forms the basis of many contemporary multiplexing systems. It was developed by Bell Systems (before divestiture) in the early 1960s.

The T-1 carrier system develops a 1.544-Mb/s pulsed digital signal by multiplexing 24 voice channels. Each channel is sampled at a rate of 8000 samples/s. Each sample is then converted into 8 bits using compressed PCM. Although all 8 bits corresponding to a particular sample can be available for sending that sample value, one of the bits is sometimes devoted to signaling, which includes bookkeeping needed

FIGURE 7.3 Time-division multiplexing of PAM signals.

FIGURE 7.4 Multiplexing structure of T-1 carrier.

to set up the call and keep track of billing. The 24 channels are then time-division multiplexed, as shown in Fig. 7.4.

Each frame, which corresponds to one sampling period, contains 192 bits (8 times 24), plus a 193rd bit for **frame synchronization**. Since frames occur 8000 times/s, the system transmits 1.544 Mb/s.

Need for Frame Synchronization

When a receiver captures and demodulates a TDM signal, the result is a continuous sequence of numbers (usually binary). These numbers must be sorted to associate the correct numbers with the correct signal. This sorting process is known as demultiplexing. To perform this function, the receiver needs to know when each frame begins. If nothing is known about the value of the signals, frame synchronization must be performed using overhead. A known synchronizing signal is transmitted along with the multiplexed signals. This synchronizing signal can be sent as one of the multiplexed signals, or it can be a framing bit as in the case of T-1 carrier. The receiver searches for the known pattern and locks on to it. Of course, there is some probability that one of the actual signals will resemble the synchronizing signal, and false sync lock can result. The probability of false lock decreases as the synchronizing signal is made longer.

Dissimilar Channels

The examples given so far in this section assume that the signals to be multiplexed are of the same form. For example, in the T-1 carrier system, each of the 24 signals is sampled at the same rate (8 kHz) and converted to the same number of bits.

Dissimilar signals must sometimes be multiplexed. In the general case, we refer to this as *asynchronous multiplexing*. We present two examples. In the first example, the data rates of the various channels are rationally related. In the second example, they are not rationally related.

Suppose first that we had to multiplex three channels, A, B, and C. Assume further that the data rates for both channels B and C are one-half that of A. That is, A is producing symbols at twice the rate of B or C. A simple multiplexing scheme would include two symbols of signal A for each symbol of B or C. Thus, the transmitted sequence could be

$$A B A C A B A C A B A C A B A C \circ$$

This is known as *supercommutation*. It can be visualized as a rotating switch with one contact each for signal B and C and two contacts for signal A. This is shown in Fig. 7.5.

Supercommutation can be combined with *subcommutation* to yield greater flexibility. Suppose, in the preceding example, the signal C were replaced by four signals, C1, C2, C3, and C4, each of which produces symbols at 1/4 the rate of C. Thus, every time the **commutator** of Fig. 7.5 reaches the C contact, we wish to feed a sample of one of the lower rate signals. This is accomplished using subcommutation, as shown in Fig. 7.6.

If the rational relationships needed to do sub- and supercommutation are not present, we need to use a completely asynchronous multiplexing approach. Symbols from the various sources are stored in a buffer and the buffer sorts things out and transmits the interleaved symbols at the appropriate rate.

FIGURE 7.5 Supercommutation.

FIGURE 7.6 Combination of sub- and supercommutation.

FIGURE 7.7 Typical frame for fixed-assignment TDMA.

This is a variation of the **statistical multiplexer (stat-MUX)** commonly used in packet switching and other asynchronous applications. If the individual channels are not synchronous, the symbols arrive at varying rates and times. Consider, for example, the output of a workstation connected to a network. The human operator certainly does not create symbols at a synchronous rate. The buffer in the multiplexer, therefore, must be carefully sized. If it is too small, it could become overloaded and lose information. At the other extreme, if symbols exit the MUX too rapidly, then the buffer could become empty and stuffing symbols must be added.

Time Multiplexing at Higher Layers

We have been talking about interleaving at the sample or symbol (bit) level. There are many contemporary systems that share a channel at the signal level. Thus, each source has the resources of the channel for a segment of time. This is particularly suited to bursty signals.

In **time-division multiple access (TDMA)**, the channel is shared among multiple users by assigning time slots to each user. Each source, therefore, must transmit its signal in bursts that occur only during the time allocated to that source.

In *fixed-assignment TDMA*, the time axis is divided into frames. Each frame is composed of time slots assigned to various users. [Figure 7.7\(a\)](#) shows a typical frame structure for N users. Two consecutive frames are illustrated. If a particular user generates a signal with a high symbol rate, that user could be assigned more than one time slot within the frame. [Figure 7.7\(b\)](#) shows a representative time slot.

Note that the transmission begins with a preamble which contains addressing information. Each slot must be self-synchronizing (i.e., an individual receiver needs to be able to establish symbol synchronization), and so the preamble might also contain a unique waveform to help establish synchronization. In some systems, the preamble also contains error control data (e.g., parity bits).

Sources sharing the channel need not be in the same geographical location. Therefore, as the signals line up in the channel as a frame, they experience varying time delays depending on the length of the transmission path. For this reason, guard time slots are included in the frame structure to assure that the delayed signals do not overlap in time.

Interleaving at the signal burst level includes such concepts as packet switching and asynchronous transfer mode (ATM).

7.4 Space Multiplexing

Time and frequency are the traditional domains used for multiplexing. However, there are other forms of multiplexing that force the signals to be orthogonal to each other. Among these are space and polarization multiplexing.

When terrestrial multipoint communication became popular, the general approach was to maximize the distance over which signals could be transmitted. In broadcast commercial systems, advertising revenue is related to the number of households the signal reaches. Obviously, higher powers and greater distances translate into more revenue. However, with the proliferation of high-power signal sources, frequency and time separation became increasingly difficult. Mobile radio was the driving force for a reversal of philosophy. The **cellular radio** concept is based on intentionally reducing the signal coverage area. With signal power low enough to limit range, signals that overlap in all other domains (e.g., time and frequency) can be transmitted simultaneously and separated by concentrating on the limited geographical area of coverage. To achieve communication over a distance, these low-frequency wireless techniques must be combined with more traditional long distance communication systems. The practicality of this approach had to wait for developments in electronics and computing that permitted reliable handing off among antennas as the location of the transmitter and/or receiver changes.

Space-division multiplexing can also be accomplished with highly directional antennas. Spot beam antennas can focus a signal along a particular direction, and multiple signals can be transmitted using slightly different headings. Some satellite systems (e.g., INTELSAT) divide the earth into regions and do simultaneous transmission of different signals to these regions using directional antennas.

Polarization multiplexing is yet another way to simultaneously send multiple signals on the same channel. If two signals occupy the same frequency band on the same channel yet are polarized in different planes, they can be separated at the receiver. The receiving antenna must be polarized in the same direction as the desired signal.

7.5 Techniques for Multiplexing in Spread Spectrum

We have examined three areas of nonoverlapping signals: time, frequency, and space. There are hybrid variations of these in which the signals appear to overlap in all three domains, yet are still separable. The proliferation of spread spectrum systems has opened up the domain of **code-division multiple access (CDMA)**. Spread spectrum is a transmission method that intentionally widens the signal bandwidth by modulating the bandlimited message with a wideband noiselike signal. Since the spreading function is pseudorandom (i.e., completely known although possessing noiselike properties), different widening functions can be made orthogonal to each other.

One way to visualize this is by considering the **frequency hopping** form of spread spectrum. This is a form of spread spectrum where the bandlimited message modulates a carrier whose frequency jumps around over a very wide range. The pattern of this jumping follows a noiselike sequence. However, since the jumping is completely specified, a second signal could occupy the same frequency band but jump across carrier frequencies that are always different from the first. The signals can be demodulated using

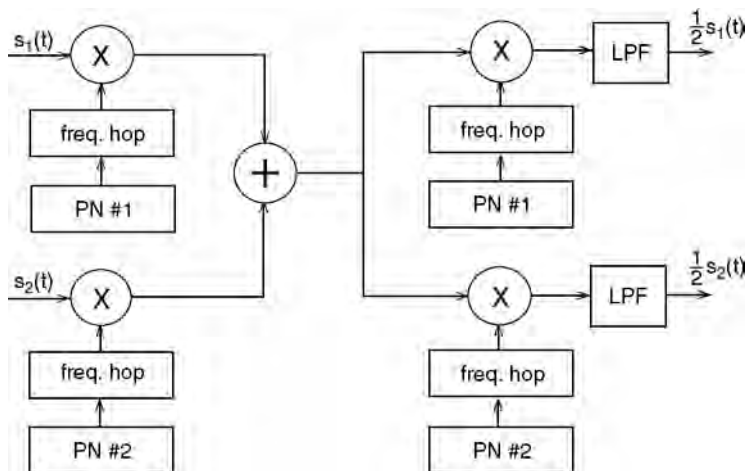

FIGURE 7.8 Code-division multiple access.

the same jumped carrier that was used in the transmitter. This is illustrated in Fig. 7.8. A pseudonoise sequence generator (labeled PN in the figure) produces a noiselike sequence. This sequence controls the frequency of an oscillator (known as a frequency hopper). The two pseudonoise sequences, PN1 and PN2, result from different initiating sequences, so their resulting frequency patterns appear unrelated.

7.6 Concluding Remarks

We have seen that signals can be forced to be nonoverlapping in a variety of domains. As it becomes possible to implement increasingly complex hardware and/or software systems, we can expect additional forms of multiplexing to be developed. The expanding applications of wireless communication are significantly increasing the volume of signals being transmitted. As competition for channel use expands at an accelerating pace, the ingenuity and imagination of engineers will be continually challenged.

Defining Terms

Asynchronous multiplexing: A technique for combining the output of various sources when those sources are producing information at unrelated rates.

Cellular radio: Each transmitting antenna uses a sufficiently low power so that the transmission range is relatively short (within a cell).

Code-division multiple access (CDMA): A technique for simultaneous transmission of wideband signals (spread spectrum) that occupy the same band of frequencies.

Commutation: Interspersing of signal pulses using the equivalent of a rotating multi-contact switch.

Frame synchronization: In time-division multiplexing, frame synchronization allows the receiver to associate pulses with the correct original sources.

Frequency-division multiplexing (FDM): Multiplexing technique that requires that signals be confined to assigned, nonoverlapping frequency bands.

Frequency hopping: Spread spectrum technique that uses carriers whose frequencies hop around in a prescribed way to create a wideband modulated signal.

Interleaving: Putting signals together in a defined sequence. Similar to shuffling a deck of cards.

Multiplexing: The process of combining signals for transmission on a single channel.

Polarization multiplexing: More than one signal can share a channel if the signals are polarized to different planes.

Space-division multiplexing: Sharing of a channel by concentrating individual signals in non-overlapping narrow beams.

Statistical multiplexer (Stat-MUX): Multiplexer that can accept asynchronous inputs and produce a synchronous output signal.

T-1 carrier: Time-division multiplexing technique for combining 24 voice channels.

Time-division multiple access (TDMA): A channel is shared among various users by assigning time slots to each user. Transmissions are bursts within the assigned time slots.

Time-division multiplexing (TDM): Multiplexing technique which requires that signal symbols be confined to assigned, non-overlapping portions of the time axis.

Wavelength-division multiplexing: Optical multiplexing systems where each signal is modulated on a different carrier frequency.

Further Information

The basics of multiplexing are covered in any general communications textbook. The more recent state-of-the-art information can be found in the technical literature, primarily that of the IEEE. In particular, the *IEEE Transactions on Communications* and *IEEE Selected Papers on Communications* contain articles on advances in research areas. Other *IEEE Transactions* often contain related articles (e.g., the *IEEE Transactions on Vehicular Technology* contain articles related to multiplexing in mobile radio systems). The *IEEE Communications Magazine* is a highly readable periodical that covers the broad spectrum of communications in the form of tutorial papers. *IEEE Spectrum Magazine* occasionally contains articles of interest related to communications, and special issues of *IEEE Proceedings* cover communications topics.

8.1 Introduction

Pseudonoise sequences (PN sequences), also referred to as pseudorandom sequences, are sequences that are deterministically generated and yet possess some properties that one would expect to find in randomly generated sequences. Applications of PN sequences include signal synchronization, navigation, radar ranging, random number generation, spread-spectrum communications, multipath resolution, cryptography, and signal identification in multiple-access communication systems. The *correlation* between two sequences $\{x(t)\}$ and $\{y(t)\}$ is the complex inner product of the first sequence with a shifted version of the second sequence. The correlation is called (1) an autocorrelation if the two sequences are the same, (2) a crosscorrelation if they are distinct, (3) a periodic correlation if the shift is a cyclic shift, (4) an aperiodic correlation if the shift is not cyclic, and (5) a partial-period correlation if the inner product involves only a partial segment of the two sequences. More precise definitions are given subsequently.

Binary **m sequences**, defined in the next section, are perhaps the best-known family of PN sequences. The balance, run-distribution, and autocorrelation properties of these sequences mimic those of random sequences. It is perhaps the random-like correlation properties of PN sequences that make them most attractive in a communications system, and it is common to refer to any collection of low-correlation sequences as a family of PN sequences.

Section 8.2 begins by discussing m sequences. Thereafter, the discussion continues with a description of sequences satisfying various correlation constraints along the lines of the accompanying self-explanatory figure, **Fig. 8.1**. Expanded tutorial discussions on pseudorandom sequences may be found in [14], in [15, **Chapter 5**], and in [6].

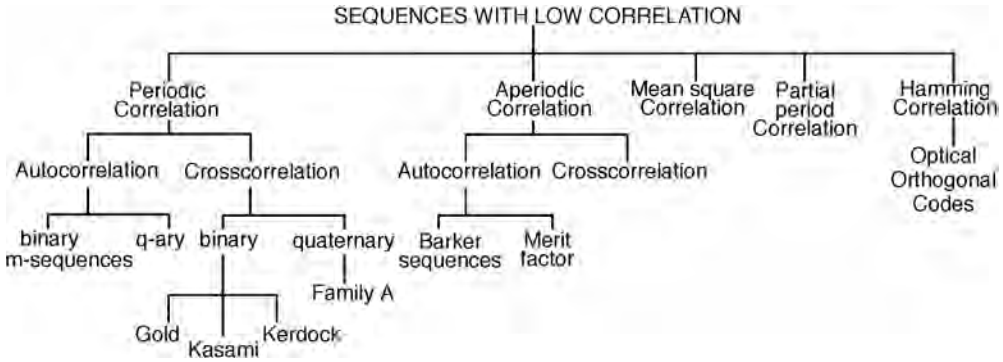

FIGURE 8.1 Overview of pseudonoise sequences.

FIGURE 8.2 An example Gold sequence generator. Here $\{a(t)\}$ and $\{b(t)\}$ are m sequences of length 7.

8.2 m Sequences

A binary $\{0, 1\}$ **shift-register sequence** $\{s(t)\}$ is a sequence that satisfies a linear recurrence relation of the form

$$\sum_{i=0}^r f_i s(t+i) = 0, \quad \text{for all } t \geq 0 \quad (8.1)$$

where $r \geq 1$ is the *degree* of the recursion; the coefficients f_i belong to the finite field $GF(2) = \{0, 1\}$ where the leading coefficient $f_r = 1$. Thus, both sequences $\{a(t)\}$ and $\{b(t)\}$ appearing in Fig. 8.2 are shift-register sequences. A sequence satisfying a recursion of the form in Eq. (8.1) is said to have *characteristic polynomial* $f(x) = \sum_{i=0}^r f_i x^i$. Thus, $\{a(t)\}$ and $\{b(t)\}$ have characteristic polynomials given by $f(x) = x^3 + x + 1$ and $f(x) = x^3 + x^2 + 1$, respectively.

Since an r -bit binary shift register can assume a maximum of 2^r different states, it follows that every shift-register sequence $\{s(t)\}$ is eventually periodic with period $n \leq 2^r$, i.e.,

$$s(t) = s(t+n), \quad \text{for all } t \geq N$$

for some integer N . In fact, the maximum period of a shift-register sequence is $2^r - 1$, since a shift register that enters the all-zero state will remain forever in that state. The upper shift register in Fig. 8.2, when initialized with starting state 0 0 1, generates the periodic sequence $\{a(t)\}$ given by

$$0010111 \quad 0010111 \quad 0010111 \quad \dots \quad (8.2)$$

of period $n = 7$. It follows then that this shift register generates sequences of maximal period starting from any nonzero initial state.

An m sequence is simply a binary shift-register sequence having maximal period. For every $r \geq 1$, m sequences are known to exist. The periodic **autocorrelation** function θ_s of a binary $\{0, 1\}$ sequence $\{s(t)\}$ of period n is defined by

$$\theta_s(\tau) = \sum_{t=0}^{n-1} (-1)^{s(t+\tau)-s(t)}, \quad 0 \leq \tau \leq n-1$$

An m sequence of length $2^r - 1$ has the following attributes: (1) *Balance property*: in each period of the m sequence there are 2^{r-1} ones and $2^{r-1} - 1$ zeros, (2) *Run property*: every nonzero binary s -tuple, $s \leq r$ occurs 2^{r-s} times, the all-zero s -tuple occurs $2^{r-s} - 1$ times, and (3) *Two-level autocorrelation function*:

$$\theta_s(\tau) = \begin{cases} n & \text{if } \tau = 0 \\ -1 & \text{if } \tau \neq 0 \end{cases} \quad (8.3)$$

The first two properties follow immediately from the observation that every nonzero r -tuple occurs precisely once in each period of the m sequence. For the third property, consider the difference sequence $\{s(t + \tau) - s(t)\}$ for $\tau \neq 0$. This sequence satisfies the same recursion as the m sequence $\{s(t)\}$ and is clearly not the all-zero sequence. It follows, therefore, that $\{s(t + \tau) - s(t)\} \equiv \{s(t + \tau')\}$ for some τ' , $0 \leq \tau' \leq n - 1$, i.e., is a different cyclic shift of the m sequence $\{s(t)\}$. The balance property of the sequence $\{s(t + \tau')\}$ then gives us attribute 3. The m sequence $\{a(t)\}$ in Eq. (8.2) can be seen to have the three listed properties.

If $\{s(t)\}$ is any sequence of period n and d is an integer, $1 \leq d \leq n$, then the mapping $\{s(t)\} \rightarrow \{s(dt)\}$ is referred to as a *decimation* of $\{s(t)\}$ by the integer d . If $\{s(t)\}$ is an m sequence of period $n = 2^r - 1$ and d is an integer relatively prime to $2^r - 1$, then the decimated sequence $\{s(dt)\}$ clearly also has period n . Interestingly, it turns out that the sequence $\{s(dt)\}$ is always also an m sequence of the same period. For example, when $\{a(t)\}$ is the sequence in Eq. (8.2), then

$$a(3t) = 0011101 \quad 0011101 \quad 0011101 \quad \dots \quad (8.4)$$

and

$$a(2t) = 0111001 \quad 0111001 \quad 0111001 \quad \dots \quad (8.5)$$

The sequence $\{a(3t)\}$ is also an m sequence of period 7, since it satisfies the recursion

$$s(t + 3) + s(t + 2) + s(t) = 0 \quad \text{for all } t$$

of degree $r = 3$. In fact $\{a(3t)\}$ is precisely the sequence labeled $\{b(t)\}$ in Fig. 8.2. The sequence $\{a(2t)\}$ is simply a cyclically shifted version of $\{a(t)\}$ itself; this property holds in general. If $\{s(t)\}$ is any m sequence of period $2^r - 1$, then $\{s(2t)\}$ will always be a shifted version of the same m sequence. Clearly, the same is true for decimations by any power of 2.

Starting from an m sequence of period $2^r - 1$, one can generate all m sequences of the same period through decimations by integers d relatively prime to $2^r - 1$. The set of integers d , $1 \leq d \leq 2^r - 1$, satisfying $(d, 2^r - 1) = 1$ forms a group under multiplication modulo $2^r - 1$, with the powers $\{2^i \mid 0 \leq i \leq r - 1\}$ of 2 forming a subgroup of order r . Since decimation by a power of 2 yields a shifted version of the same m sequence, it follows that the number of distinct m sequences of period $2^r - 1$ is $[\phi(2^r - 1)/r]$ where $\phi(n)$ denotes the number of integers d , $1 \leq d \leq n$, relatively prime to n . For example, when $r = 3$, there are just two cyclically distinct m sequences of period 7, and these are precisely the sequences $\{a(t)\}$ and $\{b(t)\}$

discussed in the preceding paragraph. Tables provided in [12] can be used to determine the characteristic polynomial of the various m sequences obtainable through the decimation of a single given m sequence. The classical reference on m sequences is [4].

If one obtains a sequence of some large length n by repeatedly tossing an unbiased coin, then such a sequence will very likely satisfy the balance, run, and autocorrelation properties of an m sequence of comparable length. For this reason, it is customary to regard the extent to which a given sequence possesses these properties as a measure of randomness of the sequence. Quite apart from this, in many applications such as signal synchronization and radar ranging, it is desirable to have sequences $\{s(t)\}$ with low autocorrelation sidelobes, i.e., $|\theta_s(\tau)|$ is small for $\tau \neq 0$. Whereas m sequences are a prime example, there exist other methods of constructing binary sequences with low out-of-phase autocorrelation.

Sequences $\{s(t)\}$ of period n having an autocorrelation function identical to that of an m sequence, i.e., having θ_s satisfying Eq. (8.3), correspond to well-studied combinatorial objects known as *cyclic Hadamard difference sets*. Known infinite families fall into three classes: (1) Singer and Gordon, Mills and Welch, (2) quadratic residue, and (3) twin-prime difference sets. These correspond, respectively, to sequences of period n of the form $n = 2^r - 1$, $r \geq 1$; n prime; and $n = p(p + 2)$ with both p and $p + 2$ being prime in the last case. For a detailed treatment of cyclic difference sets, see [2]. A recent observation by Maschietti in [9] provides additional families of cyclic Hadamard difference sets that also correspond to sequences of period $n = 2^r - 1$.

8.3 The q -ary Sequences with Low Autocorrelation

As defined earlier, the autocorrelation of a binary $\{0, 1\}$ sequence $\{s(t)\}$ leads to the computation of the inner product of an $\{-1, +1\}$ sequence $\{(-1)^{s(t)}\}$ with a cyclically shifted version $\{(-1)^{s(t+\tau)}\}$ of itself. The $\{-1, +1\}$ sequence is transmitted as a phase shift by either 0° and 180° of a radio-frequency carrier, i.e., using binary phase-shift keying (PSK) modulation. If the modulation is q -ary PSK, then one is led to consider sequences $\{s(t)\}$ with symbols in the set Z_q , i.e., the set of integers modulo q . The relevant autocorrelation function $\theta_s(\tau)$ is now defined by

$$\theta_s(\tau) = \sum_{t=0}^{n-1} \omega^{s(t+\tau)-s(t)}$$

where n is the period of $\{s(t)\}$ and ω is a complex primitive q th root of unity. It is possible to construct sequences $\{s(t)\}$ over Z_q whose autocorrelation function satisfies

$$\theta_s(\tau) = \begin{cases} n & \text{if } \tau = 0 \\ 0 & \text{if } \tau \neq 0 \end{cases}$$

For obvious reasons, such sequences are said to have an *ideal autocorrelation function*.

We provide without proof two sample constructions. The sequences in the first construction are given by

$$s(t) = \begin{cases} t^2/2 & \pmod{n} & \text{when } n \text{ is even} \\ t(t+1)/2 & \pmod{n} & \text{when } n \text{ is odd} \end{cases}$$

Thus, this construction provides sequences with ideal autocorrelation for any period n . Note that the size q of the sequence symbol alphabet equals n when n is odd and $2n$ when n is even.

The second construction also provides sequences over Z_q of period n but requires that n be a perfect square. Let $n = r^2$ and let π be an arbitrary permutation of the elements in the subset $\{0, 1, 2, \dots, (r-1)\}$

of Z_n ; Let g be an arbitrary function defined on the subset $\{0, 1, 2, \dots, r-1\}$ of Z_n . Then any sequence of the form

$$s(t) = rt_1\pi(t_2) + g(t_2) \pmod{n}$$

where $t = rt_1 + t_2$ with $0 \leq t_1, t_2 \leq r-1$ is the base- r decomposition of t and has an ideal autocorrelation function. When the alphabet size q equals or divides the period n of the sequence, ideal-autocorrelation sequences also go by the name *generalized bent functions*. For details, see [6].

8.4 Families of Sequences with Low Crosscorrelation

Given two sequences $\{s_1(t)\}$ and $\{s_2(t)\}$ over Z_q of period n , their **crosscorrelation** function $\theta_{1,2}(\tau)$ is defined by

$$\theta_{1,2}(\tau) = \sum_{t=0}^{n-1} \omega^{s_1(t+\tau) - s_2(t)}$$

where ω is a primitive q th root of unity. The crosscorrelation function is important in code-division multiple-access (CDMA) communication systems. Here, each user is assigned a distinct signature sequence, and to minimize interference due to the other users, it is desirable that the signature sequences have pairwise, low values of crosscorrelation function. To provide the system in addition with a self-synchronizing capability, it is desirable that the signature sequences have low values of the autocorrelation function as well.

Let $\mathcal{F} = \{\{s_i(t)\} | 1 \leq i \leq M\}$ be a family of M sequences $\{s_i(t)\}$ over Z_q , each of period n . Let $\theta_{i,j}(\tau)$ denote the crosscorrelation between the i th and j th sequence at shift τ , i.e.,

$$\theta_{i,j}(\tau) = \sum_{t=0}^{n-1} \omega^{s_i(t+\tau) - s_j(t)}, \quad 0 \leq \tau \leq n-1$$

The classical goal in sequence design for CDMA systems has been minimization of the parameter

$$\theta_{\max} = \max\{|\theta_{i,j}(\tau)| \mid \text{either } i \neq j \text{ or } \tau \neq 0\}$$

for fixed n and M . It should be noted though that, in practice, because of data modulation, the correlations that one runs into are typically of an aperiodic rather than a periodic nature (see Section 8.5). The problem of designing for low aperiodic correlation, however, is a more difficult one. A typical approach, therefore, has been to design based on periodic correlation and then analyze the resulting design for its aperiodic correlation properties. Again, in many practical systems, the mean square correlation properties are of greater interest than the worst-case correlation represented by a parameter such as θ_{\max} . The mean square correlation is discussed in Section 8.6.

Bounds on the minimum possible value of θ_{\max} for given period n , family size M , and alphabet size q are available that can be used to judge the merits of a particular sequence design. The most efficient bounds are those due to Welch, Sidelnikov, and Levenshtein, see [6]. In CDMA systems, there is greatest interest in designs in which the parameter θ_{\max} is in the range $\sqrt{n} \leq \theta_{\max} \leq 2\sqrt{n}$. Accordingly, Table 8.1 uses the Welch, Sidelnikov, and Levenshtein bounds to provide an order-of-magnitude upper bound on the family size M for certain θ_{\max} in the cited range.

Practical considerations dictate that q be small. The bit-oriented nature of electronic hardware makes it preferable to have q a power of 2. With this in mind, a description of some efficient sequence families having low auto- and crosscorrelation values and alphabet sizes $q = 2$ and $q = 4$ are described next.

TABLE 8.1 Bounds on Family Size M for Given n, θ_{\max}

θ_{\max}	Upper bound on M	Upper Bound on M
	$q = 2$	$q > 2$
\sqrt{n}	$n/2$	n
$\sqrt{2n}$	n	$n^2/2$
$2\sqrt{n}$	$3n^2/10$	$n^3/2$

Gold and Kasami Sequences

Given the low autocorrelation sidelobes of an m sequence, it is natural to attempt to construct families of low correlation sequences starting from m sequences. Two of the better known constructions of this type are the families of Gold and Kasami sequences.

Let r be odd and $d = 2^k + 1$, where $k, 1 \leq k \leq r - 1$, is an integer satisfying $(k, r) = 1$. Let $\{s(t)\}$ be a cyclic shift of an m sequence of period $n = 2^r - 1$ that satisfies $S(dt) \neq 0$ and let \mathcal{G} be the *Gold* family of $2^r + 1$ sequences given by

$$\mathcal{G} = \{s(t)\} \cup \{s(dt)\} \cup \{\{s(t) + s(d[t + \tau])\} | 0 \leq \tau \leq n - 1\}$$

Then, each sequence in \mathcal{G} has period $2^r - 1$ and the maximum-correlation parameter θ_{\max} of \mathcal{G} satisfies

$$\theta_{\max} \leq \sqrt{2^{r+1}} + 1$$

An application of the Sidelnikov bound coupled with the information that θ_{\max} must be an odd integer yields that for the family \mathcal{G} , θ_{\max} is as small as it can possibly be. In this sense, the family \mathcal{G} is an optimal family. We remark that these comments remain true even when d is replaced by the integer $d = 2^{2k} - 2^k + 1$ with the conditions on k remaining unchanged.

The Gold family remains the best-known family of m sequences having low crosscorrelation. Applications include the Navstar Global Positioning System whose signals are based on Gold sequences.

The family of Kasami sequences has a similar description. Let $r = 2v$ and $d = 2^v + 1$. Let $\{s(t)\}$ be a cyclic shift of an m sequence of period $n = 2^r - 1$ that satisfies $s(dt) \neq 0$, and consider the family of Kasami sequences given by

$$\mathcal{K} = \{s(t)\} \cup \{\{s(t) + s(d[t + \tau])\} | 0 \leq \tau \leq 2^v - 2\}$$

Then the Kasami family \mathcal{K} contains 2^v sequences of period $2^r - 1$. It can be shown that in this case

$$\theta_{\max} = 1 + 2^v$$

This time an application of the Welch bound and the fact that θ_{\max} is an integer shows that the Kasami family is optimal in terms of having the smallest possible value of θ_{\max} for given n and M .

Quaternary Sequences with Low Crosscorrelation

The entries in [Table 8.1](#) suggest that nonbinary (i.e., $q > 2$) designs may be used for improved performance. A family of quaternary sequences that outperform the Gold and Kasami sequences is discussed next.

Let $f(x)$ be the characteristic polynomial of a binary m sequence of length $2^r - 1$ for some integer r . The coefficients of $f(x)$ are either 0 or 1. Now, regard $f(x)$ as a polynomial over Z_4 and form the product $(-1)^r f(x) f(-x)$. This can be seen to be a polynomial in x^2 . Define the polynomial $g(x)$ of degree r by

FIGURE 8.3 Shift register that generates family \mathcal{A} quaternary sequences $\{s(t)\}$ of period 7.

setting $g(x^2) = (-1)^r f(x)f(-x)$. Let $g(x) = \sum_{i=0}^r g_i x^i$ and consider the set of all quaternary sequences $\{a(t)\}$ satisfying the recursion $\sum_{i=0}^r g_i a(t+i) = 0$ for all t .

It turns out that with the exception of the all-zero sequence, all of the sequences generated in this way have period $2^r - 1$. Thus, the recursion generates a family \mathcal{A} of $2^r - 1$ cyclically distinct quaternary sequences. Closer study reveals that the maximum correlation parameter θ_{\max} of this family satisfies $\theta_{\max} \leq 1 + \sqrt{2^r}$. Thus, in comparison to the family of Gold sequences, the family \mathcal{A} offers a lower value of θ_{\max} (by a factor of $\sqrt{2}$) for the same family size. In comparison to the set of Kasami sequences, it offers a much larger family size for the same bound on θ_{\max} . Family \mathcal{A} sequences may be found discussed in [16, 3].

We illustrate with an example. Let $f(x) = x^3 + x + 1$ be the characteristic polynomial of the m sequence $\{a(t)\}$ in Eq. (8.1). Then over Z_4

$$g(x^2) = (-1)^3 f(x)f(-x) = x^6 + 2x^4 + x^2 + 3$$

so that $g(x) = x^3 + 2x^2 + x + 3$. Thus, the sequences in family \mathcal{A} are generated by the recursion $s(t+3) + 2s(t+2) + s(t+1) + 3s(t) = 0 \pmod{4}$. The corresponding shift register is shown in Fig. 8.3. By varying initial conditions, this shift register can be made to generate nine cyclically distinct sequences, each of length 7. In this case $\theta_{\max} \leq 1 + \sqrt{8}$.

Binary Kerdock Sequences

The Gold and Kasami families of sequences are closely related to binary linear cyclic codes. It is well known in coding theory that there exist nonlinear binary codes whose performance exceeds that of the best possible linear code. Surprisingly, some of these examples come from binary codes, which are images of *linear quaternary* ($q = 4$) *codes* under the Gray map: $0 \rightarrow 00, 1 \rightarrow 01, 2 \rightarrow 11, 3 \rightarrow 10$. A prime example of this is the Kerdock code, which recently has been shown to be the Gray image of a quaternary linear code. Thus, it is not surprising that the Kerdock code yields binary sequences that significantly outperform the family of Kasami sequences.

The Kerdock sequences may be constructed as follows: let $f(x)$ be the characteristic polynomial of an m sequence of period $2^r - 1$, r odd. As before, regarding $f(x)$ as a polynomial over Z_4 (which happens to have $\{0, 1\}$ coefficients), let the polynomial $g(x)$ over Z_4 be defined via $g(x^2) = -f(x)f(-x)$. [Thus, $g(x)$ is the characteristic polynomial of a family \mathcal{A} sequence set of period $2^r - 1$.] Set $h(x) = -g(-x) = \sum_{i=0}^r h_i x^i$, and let S be the set of all Z_4 sequences satisfying the recursion $\sum_{i=0}^r h_i s(t+i) = 0$. Then S contains 4^r -distinct sequences corresponding to all possible distinct initializations of the shift register.

Let T denote the subset S of size 2^r consisting of those sequences corresponding to initializations of the shift register only using the symbols 0 and 2 in Z_4 . Then the set $S - T$ of size $4^r - 2^r$ contains a set \mathcal{U} of 2^{r-1} cyclically distinct sequences each of period $2(2^r - 1)$. Given $x = a + 2b \in Z_4$ with $a, b \in \{0, 1\}$, let μ denote the most significant bit (MSB) map $\mu(x) = b$. Let \mathcal{K}_E denote the family of 2^{r-1} binary sequences obtained by applying the map μ to each sequence in \mathcal{U} . It turns out that each sequence in \mathcal{U} also has period $2(2^r - 1)$ and that, furthermore, for the family \mathcal{K}_E , $\theta_{\max} \leq 2 + \sqrt{2^{r+1}}$. Thus, \mathcal{K}_E is a much larger family than the Kasami family, while having almost exactly the same value of θ_{\max} .

For example, taking $r = 3$ and $f(x) = x^3 + x + 1$, we have from the previous family \mathcal{A} example that $g(x) = x^3 + 2x^2 + x + 3$, so that $h(x) = -g(-x) = x^3 + 2x^2 + x + 1$. Applying the MSB map to the head of

the shift register and discarding initializations of the shift register involving only 0's and 2's yields a family of four cyclically distinct binary sequences of period 14. Kerdock sequences are discussed in [6,11,1,17].

8.5 Aperiodic Correlation

Let $\{x(t)\}$ and $\{y(t)\}$ be complex-valued sequences of length (or period) n , not necessarily distinct. Their *aperiodic correlation* values $\{\rho_{x,y}(\tau) \mid -(n-1) \leq \tau \leq n-1\}$ are given by

$$\rho_{x,y}(\tau) = \sum_{t=\max\{0,-\tau\}}^{\min\{n-1,n-1-\tau\}} x(t+\tau)y^*(t)$$

where $y^*(t)$ denotes the complex conjugate of $y(t)$. When $x \equiv y$, we will abbreviate and write ρ_x in place of $\rho_{x,y}$. The sequences described next are perhaps the most famous example of sequences with low-aperiodic autocorrelation values.

Barker Sequences

A binary $\{-1, +1\}$ sequence $\{s(t)\}$ of length n is said to be a *Barker sequence* if the aperiodic autocorrelation values $\rho_s(\tau)$ satisfy $|\rho_s(\tau)| \leq 1$ for all τ , $-(n-1) \leq \tau \leq n-1$. The Barker property is preserved under the following transformations:

$$s(t) \rightarrow -s(t), \quad s(t) \rightarrow (-1)^t s(t) \quad \text{and} \quad s(t) \rightarrow s(n-1-t)$$

as well as under compositions of the preceding transformations. Only the following Barker sequences are known:

$$\begin{aligned} n = 2 & \quad ++ \\ n = 3 & \quad +++ \\ n = 4 & \quad +++- \\ n = 5 & \quad +++-+ \\ n = 7 & \quad +++--+- \\ n = 11 & \quad +++--+-+-- \\ n = 13 & \quad ++++-+--+-+-- \end{aligned}$$

where $+$ denotes $+1$ and $-$ denotes -1 and sequences are generated from these via the transformations already discussed. It is known that if any other Barker sequence exists, it must have length $n > 1,898,884$, a multiple of 4.

For an upper bound to the maximum out-of-phase aperiodic autocorrelation of an m sequence, see [13].

Sequences with High Merit Factor

The *merit factor* F of a $\{-1, +1\}$ sequence $\{s(t)\}$ is defined by

$$F = \frac{n^2}{2 \sum_{\tau=1}^{n-1} \rho_s^2(\tau)}$$

Since $\rho_s(\tau) = \rho_s(-\tau)$ for $1 \leq |\tau| \leq n - 1$ and $\rho_s(0) = n$, factor F may be regarded as the ratio of the square of the in-phase autocorrelation to the sum of the squares of the out-of-phase aperiodic autocorrelation values. Thus, the merit factor is one measure of the aperiodic autocorrelation properties of a binary $\{-1, +1\}$ sequence. It is also closely connected with the signal to self-generated noise ratio of a communication system in which coded pulses are transmitted and received.

Let F_n denote the largest merit factor of any binary $\{-1, +1\}$ sequence of length n . For example, at length $n = 13$, the Barker sequence of length 13 has a merit factor $F = F_{13} = 14.08$. Assuming a certain ergodicity postulate it was established by Golay that $\lim_{n \rightarrow \infty} F_n = 12.32$. Exhaustive computer searches carried out for $n \leq 40$ have revealed the following.

1. For $1 \leq n \leq 40$, $n \neq 11, 13$,

$$3.3 \leq F_n \leq 9.85,$$

2. $F_{11} = 12.1$, $F_{13} = 14.08$.

The value F_{11} is also achieved by a Barker sequence. From partial searches, for lengths up to 117, the highest known merit factor is between 8 and 9.56; for lengths from 118 to 200, the best-known factor is close to 6. For lengths >200 , statistical search methods have failed to yield a sequence having merit factor exceeding 5.

An *offset sequence* is one in which a fraction θ of the elements of a sequence of length n are chopped off at one end and appended to the other end, i.e., an offset sequence is a cyclic shift of the original sequence by $n\theta$ symbols. It turns out that the asymptotic merit factor of m sequences is equal to 3 and is independent of the particular offset of the m sequence. There exist offsets of sequences associated with quadratic-residue and twin-prime difference sets that achieve a larger merit factor of 6. Details may be found in [7].

Sequences with Low Aperiodic Crosscorrelation

If $\{u(t)\}$ and $\{v(t)\}$ are sequences of length $2n - 1$ defined by

$$u(t) = \begin{cases} x(t) & \text{if } 0 \leq t \leq n - 1 \\ 0 & \text{if } n \leq t \leq 2n - 2 \end{cases}$$

and

$$v(t) = \begin{cases} y(t) & \text{if } 0 \leq t \leq n - 1 \\ 0 & \text{if } n \leq t \leq 2n - 2 \end{cases}$$

then

$$\{\rho_{x,y}(\tau) \mid -(n-1) \leq \tau \leq n-1\} = \{\theta_{u,v}(\tau) \mid 0 \leq \tau \leq 2n-2\} \quad (8.6)$$

Given a collection

$$U = \{\{x_i(t)\} \mid 1 \leq i \leq M\}$$

of sequences of length n over Z_q , let us define

$$\rho_{\max} = \max\{|\rho_{a,b}(\tau)| \mid a, b \in U, \text{ either } a \neq b \text{ or } \tau \neq 0\}$$

It is clear from Eq. (8.6) how bounds on the *periodic* correlation parameter θ_{\max} can be adapted to give bounds on ρ_{\max} . Translation of the Welch bound gives that for every integer $k \geq 1$,

$$\rho_{\max}^{2k} \geq \left(\frac{n^{2k}}{M(2n-1)-1} \right) \left\{ \frac{M(2n-1)-1}{\binom{2n+k-2}{k}} - 1 \right\}$$

Setting $k = 1$ in the preceding bound gives

$$\rho_{\max} \geq n \sqrt{\frac{M-1}{M(2n-1)-1}}$$

Thus, for fixed M and large n , Welch's bound gives

$$\rho_{\max} \geq \mathcal{O}(n^{1/2})$$

There exist sequence families which asymptotically achieve $\rho_{\max} \approx \mathcal{O}(n^{1/2})$, [10].

8.6 Other Correlation Measures

Partial-Period Correlation

The *partial-period (p-p) correlation* between the sequences $\{u(t)\}$ and $\{v(t)\}$ is the collection $\{\Delta_{u,v}(l, \tau, t_0) \mid 1 \leq l \leq n, 0 \leq \tau \leq n-1, 0 \leq t_0 \leq n-1\}$ of inner products

$$\Delta_{u,v}(l, \tau, t_0) = \sum_{t=t_0}^{t_0+l-1} u(t+\tau)v^*(t)$$

where l is the length of the partial period and the sum $t + \tau$ is again computed modulo n .

In direct-sequence CDMA systems, the pseudorandom signature sequences used by the various users are often very long for reasons of data security. In such situations, to minimize receiver hardware complexity, correlation over a partial period of the signature sequence is often used to demodulate data, as well as to achieve synchronization. For this reason, the p-p correlation properties of a sequence are of interest.

Researchers have attempted to determine the moments of the p-p correlation. Here the main tool is the application of the Pless power-moment identities of coding theory [8]. The identities often allow the first and second p-p correlation moments to be completely determined. For example, this is true in the case of m sequences (the remaining moments turn out to depend upon the specific characteristic polynomial of the m sequence). Further details may be found in [15].

Mean Square Correlation

Frequently in practice, there is a greater interest in the mean-square correlation distribution of a sequence family than in the parameter θ_{\max} . Quite often in sequence design, the sequence family is derived from a linear, binary cyclic code of length n by picking a set of cyclically distinct sequences of period n . The families of Gold and Kasami sequences are so constructed. In this case, as pointed out by Massey, the mean square correlation of the family can be shown to be either optimum or close to optimum, under certain easily satisfied conditions, imposed on the minimum distance of the dual code. A similar situation holds even when the sequence family does not come from a linear cyclic code. In this sense, mean square

correlation is not a very discriminating measure of the correlation properties of a family of sequences. An expanded discussion of this issue may be found in [5].

Optical Orthogonal Codes

Given a pair of $\{0, 1\}$ sequences $\{s_1(t)\}$ and $\{s_2(t)\}$ each having period n , we define the *Hamming correlation* function $\theta_{12}(\tau)$, $0 \leq \tau \leq n - 1$, by

$$\theta_{12}(\tau) = \sum_{t=0}^{n-1} s_1(t + \tau) s_2(t)$$

Such correlations are of interest, for instance, in optical communication systems where the 1s and 0s in a sequence correspond to the presence or absence of pulses of transmitted light.

An (n, w, λ) optical orthogonal code (OOC) is a family $\mathcal{F} = \{\{s_i(t)\} \mid i = 1, 2, \dots, M\}$, of M $\{0, 1\}$ sequences of period n and constant Hamming weight w , where w is an integer lying between 1 and $n - 1$ satisfying $\theta_{ij}(\tau) \leq \lambda$ whenever either $i \neq j$ or $\tau \neq 0$.

Note that the Hamming distance $d_{a,b}$ between a period of the corresponding codewords $\{a(t)\}$, $\{b(t)\}$, $0 \leq t \leq n - 1$, in an (n, w, λ) OOC having Hamming correlation ρ , $0 \leq \rho \leq \lambda$, is given by $d_{a,b} = 2(w - \rho)$, and, thus, OOCs are closely related to constant-weight error correcting codes. Given an (n, w, λ) OOC, by enlarging the OOC to include every cyclic shift of each sequence in the code, one obtains a constant-weight, minimum distance $d_{\min} \geq 2(w - \lambda)$ code. Conversely, given a constant-weight cyclic code of length n , weight w , and minimum distance d_{\min} , one can derive an (n, w, λ) OOC code with $\lambda \leq w - d_{\min}/2$ by partitioning the code into cyclic equivalence classes and then picking precisely one representative from each equivalence class of size n .

By making use of this connection, one can derive bounds on the size of an OOC from known bounds on the size of constant-weight codes. The bound given next follows directly from the Johnson bound for constant weight codes [8]. The number $M(n, w, \lambda)$ of codewords in a (n, w, λ) OOC satisfies

$$M(n, w, \lambda) \leq \frac{1}{w} \left\lfloor \frac{n-1}{w-1} \dots \left\lfloor \frac{n-\lambda+1}{w-\lambda+1} \left\lfloor \frac{n-\lambda}{w-\lambda} \right\rfloor \dots \right\rfloor \right\rfloor$$

An OOC code that achieves the Johnson bound is said to be optimal. A family $\{\mathcal{F}_n\}$ of OOCs indexed by the parameter n and arising from a common construction is said to be asymptotically optimum if

$$\lim_{n \rightarrow \infty} \frac{|\mathcal{F}_n|}{M(n, w, \lambda)} = 1$$

Constructions for optical orthogonal codes are available for the cases when $\lambda = 1$ and $\lambda = 2$. For larger values of λ , there exist constructions which are asymptotically optimum. Further details may be found in [6].

Defining Terms

Autocorrelation of a sequence: The complex inner product of the sequence with a shifted version itself.

Crosscorrelation of two sequences: The complex inner product of the first sequence with a shifted version of the second sequence.

m Sequence: A periodic binary $\{0, 1\}$ sequence that is generated by a shift register with linear feedback and which has maximal possible period given the number of stages in the shift register.

Pseudonoise sequences: Also referred to as pseudorandom sequences (PN), these are sequences that are deterministically generated and yet possess some properties that one would expect to find in randomly generated sequences.

Shift-register sequence: A sequence with symbols drawn from a field, which satisfies a linear-recurrence relation and which can be implemented using a shift register.

Purdue University

Digital-to-analog (D/A) conversion is the process of converting digital codes into a continuous range of analog signals. *Analog-to-digital (A/D) conversion* is the complementary process of converting a continuous range of analog signals into digital codes. Such conversion processes are necessary to interface real-world systems, which typically monitor continuously varying analog signals, with digital systems that process, store, interpret, and manipulate the analog values.

D/A and A/D applications have evolved from predominately military-driven applications to consumer-oriented applications. Up to the mid-1980s, the military applications determined the design of many D/A and A/D devices. The military applications required very high performance coupled with hermetic packaging, radiation hardening, shock and vibration testing, and military specification and record keeping. Cost was of little concern, and “low power” applications required approximately 2.8 W. The major applications up to the mid-1980s included military radar warning and guidance systems, digital oscilloscopes, medical imaging, infrared systems, and professional video.

The applications currently requiring D/A and A/D circuits have different performance criteria from those of earlier years. In particular, low power and high speed applications are driving the development of D/A and A/D circuits, as the devices are used extensively in battery-operated consumer products. The predominant applications include cellular telephones, hand-held camcorders, portable computers, and set-top cable TV boxes. These applications generally have low power and long battery life requirements, or they may have high speed and high resolution requirements, as is the case with the set-top cable TV boxes.

9.1 D/A and A/D Circuits

D/A and A/D conversion circuits are available as integrated circuits (ICs) from many manufacturers. A huge array of ICs exists, consisting of not only the D/A or A/D conversion circuits, but also closely related circuits such as sample-and-hold amplifiers, analog multiplexers, voltage-to-frequency and frequency-to-voltage converters, voltage references, calibrators, operation amplifiers, isolation amplifiers, instrumentation amplifiers, active filters, DC-to-DC converters, analog interfaces to digital signal processing systems, and data acquisition subsystems. Data books from the IC manufacturers contain an enormous amount of information about these devices and their applications to assist the design engineer.

TABLE 9.1 D/A and A/D Integrated Circuits

D/A Converter ICs	Resolution, b	Multiplying vs Fixed Reference	Settling Time, ms	Input Data Format
Analog devices AD558	8	Fixed reference	3	Parallel
Analog devices AD7524	8	Multiplying	0.400	Parallel
Analog devices AD390	Quad, 12	Fixed reference	8	Parallel

TI 2914 PCM codec and filter	8	Yes	8	Serial

The ICs discussed in this chapter will be strictly the D/A and A/D conversion circuits. [Table 9.1](#) lists a small sample of the variety of the D/A and A/D converters currently available. The ICs usually perform either D/A or A/D conversion. There are serial interface ICs, however, typically for high-performance audio and digital signal processing applications, that perform both A/D and D/A processes.

D/A and A/D Converter Performance Criteria

The major factors that determine the quality of performance of D/A and A/D converters are *resolution*, *sampling rate*, *speed*, and *linearity*.

The *resolution* of a D/A circuit is the smallest change in the output analog signal. In an A/D system, the resolution is the smallest change in voltage that can be detected by the system and that can produce a change in the digital code. The resolution determines the total number of digital codes, or *quantization levels*, that will be recognized or produced by the circuit.

The *resolution* of a D/A or A/D IC is usually specified in terms of the bits in the digital code or in terms of the least significant bit (LSB) of the system. An n -bit code allows for 2^n quantization levels, or $2^n - 1$ steps between quantization levels. As the number of bits increases, the step size between quantization levels decreases, therefore increasing the accuracy of the system when a conversion is made between an analog and digital signal. The system resolution can be specified also as the voltage step size between quantization levels. For A/D circuits, the resolution is the smallest input voltage that is detected by the system.

The *speed* of a D/A or A/D converter is determined by the time it takes to perform the conversion process. For D/A converters, the speed is specified as the *settling time*. For A/D converters, the speed is specified as the *conversion time*. The settling time for D/A converters will vary with supply voltage and transition in the digital code; thus, it is specified in the data sheet with the appropriate conditions stated.

A/D converters have a maximum *sampling rate* that limits the speed at which they can perform continuous conversions. The sampling rate is the number of times per second that the analog signal can be sampled and converted into a digital code. For proper A/D conversion, the minimum sampling rate must be at least two times the highest frequency of the analog signal being sampled to satisfy the Nyquist sampling criterion. The conversion speed and other timing factors must be taken into consideration to determine the maximum sampling rate of an A/D converter. **Nyquist A/D converters** use a sampling rate that is slightly more than twice the highest frequency in the analog signal. **Oversampling A/D converters** use sampling rates of N times rate, where N typically ranges from 2 to 64.

Both D/A and A/D converters require a voltage reference in order to achieve absolute conversion accuracy. Some conversion ICs have internal voltage references, whereas others accept external voltage references. For high-performance systems, an external precision reference is needed to ensure long-term stability, load regulation, and control over temperature fluctuations. External precision voltage reference ICs can be found in manufacturers' data books.

Measurement accuracy is specified by the converter's *linearity*. *Integral linearity* is a measure of linearity over the entire conversion range. It is often defined as the deviation from a straight line drawn between the endpoints and through zero (or the offset value) of the conversion range. Integral linearity is also referred to as *relative accuracy*. The *offset* value is the reference level required to establish the zero or midpoint of the conversion range. *Differential linearity* is the linearity between code transitions. Differential linearity is a measure of the *monotonicity* of the converter. A converter is said to be monotonic if increasing input values result in increasing output values.

The accuracy and linearity values of a converter are specified in the data sheet in units of the LSB of the code. The linearity can vary with temperature, and so the values are often specified at +25°C as well as over the entire temperature range of the device.

D/A Conversion Processes

Digital codes are typically converted to analog voltages by assigning a voltage weight to each bit in the digital code and then summing the voltage weights of the entire code. A general D/A converter consists of a network of precision resistors, input switches, and level shifters to activate the switches to convert a digital code to an analog current or voltage. D/A ICs that produce an analog current output usually have a faster settling time and better linearity than those that produce a voltage output. When the output current is available, the designer can convert this to a voltage through the selection of an appropriate output amplifier to achieve the necessary response speed for the given application.

D/A converters commonly have a fixed or variable reference level. The reference level determines the switching threshold of the precision switches that form a controlled impedance network, which in turn controls the value of the output signal. **Fixed reference D/A converters** produce an output signal that is proportional to the digital input. **Multiplying D/A converters** produce an output signal that is proportional to the product of a varying reference level times a digital code.

D/A converters can produce bipolar, positive, or negative polarity signals. A four-quadrant multiplying D/A converter allows both the reference signal and the value of the binary code to have a positive or negative polarity. The four-quadrant multiplying D/A converter produces bipolar output signals.

D/A Converter ICs

Most D/A converters are designed for general-purpose control applications. Some D/A converters, however, are designed for special applications, such as video or graphic outputs, high-definition video displays, ultra high-speed signal processing, digital video tape recording, digital attenuators, or high-speed function generators.

D/A converter ICs often include special features that enable them to be interfaced easily to microprocessors or other systems. Microprocessor control inputs, input latches, buffers, input registers, and compatibility to standard logic families are features that are readily available in D/A ICs. In addition, the ICs usually have laser-trimmed precision resistors to eliminate the need for user trimming to achieve full-scale performance.

A/D Conversion Processes

Analog signals can be converted to digital codes by many methods, including integration, **successive approximation**, parallel (flash) conversion, **delta modulation**, **pulse code modulation**, and **sigma-delta conversion**. Two of the most common A/D conversion processes are successive approximation A/D conversion and parallel or **flash A/D** conversion. Very high-resolution digital audio or video systems require specialized A/D techniques that often incorporate one of these general techniques as well as specialized A/D conversion processes. Examples of specialized A/D conversion techniques are pulse code modulation (PCM) and sigma-delta conversion. PCM is a common voice encoding scheme used not only by the audio industry in digital audio recordings but also by the telecommunications industry for voice encoding and multiplexing. Sigma-delta conversion is an oversampling A/D conversion where signals are sampled at very high frequencies. It has very high resolution and low distortion and is being used in the digital audio recording industry.

Successive approximation A/D conversion is a technique that is commonly used in medium- to high-speed data acquisition applications. It is one of the fastest A/D conversion techniques that requires a minimum amount of circuitry. The conversion times for successive approximation A/D conversion typically range from 10 to 300 ms for 8-b systems.

The successive approximation A/D converter can approximate the analog signal to form an n -bit digital code in n steps. The successive approximation register (SAR) individually compares an analog input voltage to the midpoint of one of n ranges to determine the value of 1 b. This process is repeated a total of n times, using n ranges, to determine the n bits in the code. The comparison is accomplished as follows. The SAR determines if the analog input is above or below the midpoint and sets the bit of the digital code accordingly. The SAR assigns the bits beginning with the most significant bit. The bit is set to a 1 if the analog input is greater than the midpoint voltage, or it is set to a 0 if it is less than the midpoint voltage. The SAR then moves to the next bit and sets it to a 1 or a 0 based on the results of comparing the analog input with the midpoint of the next allowed range. Because the SAR must perform one approximation for each bit in the digital code, an n -bit code requires n approximations.

A successive approximation A/D converter consists of four functional blocks, as shown in Fig. 9.1: the SAR, the analog comparator, a D/A converter, and a clock.

Parallel or flash A/D conversion is used in high-speed applications such as video signal processing, medical imaging, and radar detection systems. A flash A/D converter simultaneously compares the input analog voltage to $2^n - 1$ threshold voltages to produce an n -bit digital code representing the analog voltage. Typical flash A/D converters with 8-b resolution operate at 20–100 MHz.

The functional blocks of a flash A/D converter are shown in Fig. 9.2. The circuitry consists of a precision resistor ladder network, $2^n - 1$ analog comparators, and a digital priority encoder. The resistor network establishes threshold voltages for each allowed quantization level. The analog comparators indicate whether the input analog voltage is above or below the threshold at each level. The output of the analog comparators is input to the digital priority encoder. The priority encoder produces the final digital output code that is stored in an output latch.

An 8-b flash A/D converter requires 255 comparators. The cost of high-resolution A/D comparators escalates as the circuit complexity increases and as the number of analog converters rises by $2^n - 1$. As a low-cost alternative, some manufacturers produce modified flash A/D converters that perform the A/D conversion in two steps to reduce the amount of circuitry required. These modified flash A/D converters are also referred to as *half-flash* A/D converters, since they perform only half of the conversion simultaneously.

A/D Converter ICs

A/D converter ICs can be classified as general-purpose, high-speed, flash, and sampling A/D converters. The *general-purpose A/D converters* are typically low speed and low cost, with conversion times ranging from 2 ms to 33 ms. A/D conversion techniques used by these devices typically include successive approximation, tracking, and integrating. The general-purpose A/D converters often have control signals for simplified microprocessor interfacing. These ICs are appropriate for many process control, industrial, and instrumentation applications, as well as for environmental monitoring such as seismology, oceanography, meteorology, and pollution monitoring.

High-speed A/D converters have conversion times typically ranging from 400 ns to 3 ms. The higher speed performance of these devices is achieved by using the successive approximation technique, modified flash techniques, and statistically derived A/D conversion techniques. Applications appropriate for these A/D ICs include fast Fourier transform (FFT) analysis, radar digitization, medical instrumentation, and multiplexed data acquisition. Some ICs have been manufactured with an extremely high degree of linearity to be appropriate for specialized applications in digital spectrum analysis, vibration analysis, geological research, sonar digitizing, and medical imaging.

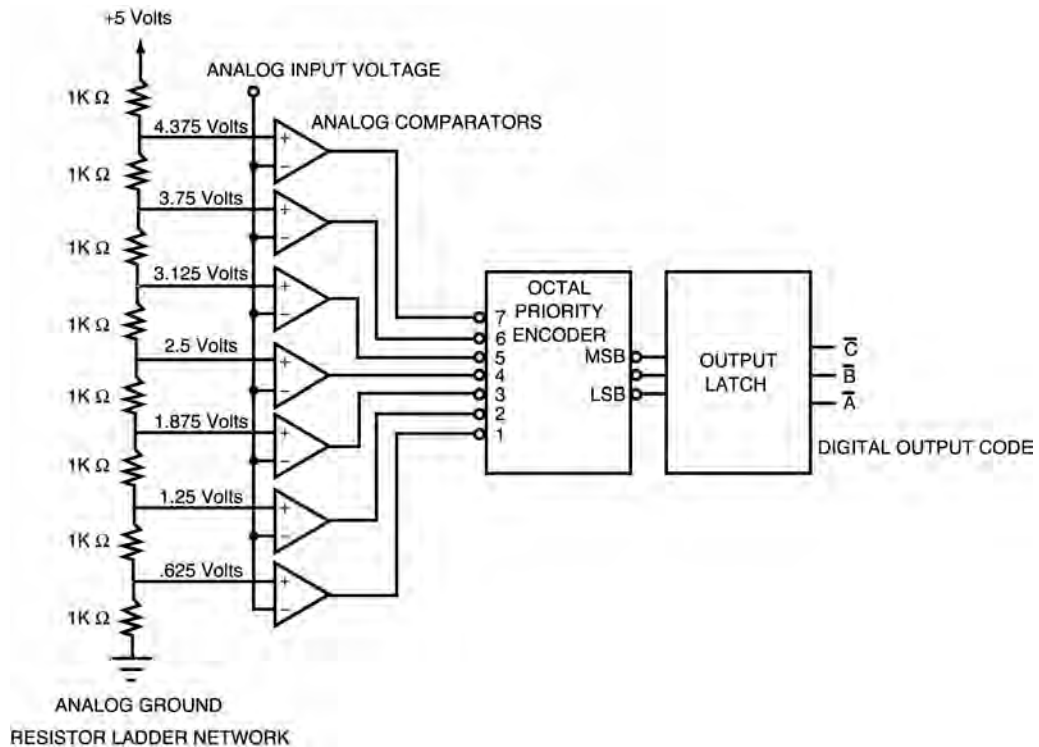

FIGURE 9.2 Flash A/D converter block diagram. (Source: Garrod, S. and Borns, R., *Digital Logic: Analysis, Application, and Design*, p. 928. Copyright © 1991 by Saunders College Publishing, Philadelphia, PA. Reprinted with permission of the publisher.)

Flash A/D converters have conversion times ranging typically from 10 to 50 ns. Flash A/D conversion techniques enable these ICs to be used in many specialized high-speed data acquisition applications such as TV-video digitizing (encoding), radar analysis, transient analysis, high-speed digital oscilloscopes, medical ultrasound imaging, high-energy physics, and robotic vision applications.

Sampling A/D converters have a sample-and-hold amplifier circuit built into the IC. This eliminates the need for an external sample-and-hold circuit. The throughput of these A/D converter ICs ranges typically from 35 kHz to 100 MHz. The speed of the system is dependent on the A/D technique used by the sampling A/D converter.

A/D converter ICs produce digital codes in a serial or parallel format, and some ICs offer the designer both formats. The digital outputs are compatible with standard logic families to facilitate interfacing to other digital systems. In addition, some A/D converter ICs have a built-in analog multiplexer and therefore can accept more than one analog input signal.

Pulse code modulation (PCM) ICs are high-precision A/D converters. The PCM IC is often referred to as a PCM *codec* with both encoder and decoder functions. The encoder portion of the codec performs the A/D conversion, and the decoder portion of the codec performs the D/A conversion. The digital code is usually formatted as a serial data stream for ease of interfacing to digital transmission and multiplexing systems.

PCM is a technique whereby an analog signal is sampled, quantized, and then encoded as a digital word. The PCM IC can include successive approximation techniques or other techniques to accomplish the PCM encoding. In addition, the PCM codec may employ nonlinear data compression techniques, such as *companding*, if it is necessary to minimize the number of bits in the output digital code. *Companding* is a logarithmic technique used to compress a code to fewer bits before transmission. The inverse

logarithmic function is then used to expand the code to its original number of bits before converting it to the analog signal. Companding is typically used in telecommunications transmission systems to minimize data transmission rates without degrading the resolution of low-amplitude signals. Two standardized companding techniques are used extensively: A-law and μ -law. The A-law companding is used in Europe, whereas the μ -law is used predominantly in the United States and Japan. Linear PCM conversion is used in high-fidelity audio systems to preserve the integrity of the audio signal throughout the entire analog range.

Digital signal processing (DSP) techniques provide another type of A/D conversion ICs. Specialized A/D conversion such as *adaptive differential pulse code modulation* (ADPCM), sigma–delta modulation, *speech subband encoding*, *adaptive predictive speech encoding*, and *speech recognition* can be accomplished through the use of DSP systems. Some DSP systems require analog front ends that employ traditional PCM codec ICs or DSP interface ICs. These ICs can interface to a digital signal processor for advanced A/D applications. Some manufacturers have incorporated DSP techniques on board the single-chip A/D IC, as in the case of the DSP56ACD16 sigma–delta modulation IC by Motorola.

Integrating A/D converters are used for conversions that must take place over a long period of time, such as digital voltmeter applications or sensor applications such as thermocouples. The integrating A/D converter produces a digital code that represents the average of the signal over time. Noise is reduced by means of signal averaging, or integration. Dual-lope integration is accomplished by a counter that advances while an input voltage charges a capacitor in a specified time interval, T . This is compared to another count sequence that advances while a reference voltage is discharging across the same capacitor in a time interval, Δt . The ratio of the charging count value to the discharging count value is proportional to the ratio of the input voltage to the reference voltage. Hence, the integrating converter provides a digital code that is a measure of the input voltage averaged over time. The conversion accuracy is independent of the capacitor and the clock frequency since they affect both the charging and discharging operations. The charging period, T , is selected to be the period of the fundamental frequency to be rejected. The maximum conversion rate is slightly less than $1/(2T)$ conversions per second. While this limits the conversion rate to be too slow for high-speed data acquisition applications, it is appropriate for long-duration applications of slowly varying input signals.

Grounding and Bypassing on D/A and A/D ICs

D/A and A/D converter ICs require correct grounding and capacitive bypassing in order to operate according to performance specifications. The digital signals can severely impair analog signals. To combat the electromagnetic interference induced by the digital signals, the analog and digital grounds should be kept separate and should have only one common point on the circuit board. If possible, this common point should be the connection to the power supply.

Bypass capacitors are required at the power connections to the IC, the reference signal inputs, and the analog inputs to minimize noise that is induced by the digital signals. Each manufacturer specifies the recommended bypass capacitor locations and values in the data sheet. The 1-mF tantalum capacitors are commonly recommended, with additional high-frequency power supply decoupling sometimes being recommended through the use of ceramic disc shunt capacitors. The manufacturers' recommendations should be followed to ensure proper performance.

Selection Criteria for D/A and A/D Converter ICs

Hundreds of D/A and A/D converter ICs are available, with prices ranging from a few dollars to several hundred dollars each. The selection of the appropriate type of converter is based on the application requirements of the system, the performance requirements, and cost. The following issues should be considered in order to select the appropriate converter.

1. What are the input and output requirements of the system? Specify all signal current and voltage ranges, logic levels, input and output impedances, digital codes, data rates, and data formats.

2. What level of accuracy is required? Determine the resolution needed throughout the analog voltage range, the dynamic response, the degree of linearity, and the number of bits encoding.
3. What speed is required? Determine the maximum analog input frequency for sampling in an A/D system, the number of bits for encoding each analog signal, and the rate of change of input digital codes in a D/A system.
4. What is the operating environment of the system? Obtain information on the temperature range and power supply to select a converter that is accurate over the operating range.

Final selection of D/A and A/D converter ICs should be made by consulting manufacturers to obtain their technical specifications of the devices. Major manufacturers of D/A and A/D converters include Analog Devices, Burr–Brown, DATEL, Maxim, National, Phillips Components, Precision Monolithics, Signetics, Sony, Texas Instruments, Ultra Analog, and Yamaha. Information on contacting these manufacturers and others can be found in an IC *Master Catalog*.

Defining Terms

Companding: A process designed to minimize the transmission bit rate of a signal by compressing it prior to transmission and expanding it upon reception. It is a rudimentary “data compression” technique that requires minimal processing.

Delta modulation: An A/D conversion process where the digital output code represents the change, or slope, of the analog input signal, rather than the absolute value of the analog input signal. A 1 indicates a rising slope of the input signal. A 0 indicates a falling slope of the input signal. The sampling rate is dependent on the derivative of the signal, since a rapidly changing signal would require a rapid sampling rate for acceptable performance.

Fixed reference D/A converter: The analog output is proportional to a fixed (nonvarying) reference signal.

Flash A/D: The fastest A/D conversion process available to date, also referred to as parallel A/D conversion. The analog signal is simultaneously evaluated by $2^n - 1$ comparators to produce an n -bit digital code in one step. Because of the large number of comparators required, the circuitry for flash A/D converters can be very expensive. This technique is commonly used in digital video systems.

Integrating A/D: The analog input signal is integrated over time to produce a digital signal that represents the area under the curve, or the integral.

Multiplying D/A: A D/A conversion process where the output signal is the product of a digital code multiplied by an analog input reference signal. This allows the analog reference signal to be scaled by a digital code.

Nyquist A/D converters: A/D converters that sample analog signals that have a maximum frequency that is less than the Nyquist frequency. The Nyquist frequency is defined as one-half of the sampling frequency. If a signal has frequencies above the Nyquist frequency, a distortion called *aliasing* occurs. To prevent aliasing, an *antialiasing filter* with a flat passband and very sharp rolloff is required.

Oversampling converters: A/D converters that sample frequencies at a rate much higher than the Nyquist frequency. Typical oversampling rates are 32 and 64 times the sampling rate that would be required with the Nyquist converters.

Pulse code modulation (PCM): An A/D conversion process requiring three steps: the analog signal is sampled, quantized, and encoded into a fixed length digital code. This technique is used in many digital voice and audio systems. The reverse process reconstructs an analog signal from the PCM code. The operation is very similar to other A/D techniques, but specific PCM circuits are optimized for the particular voice or audio application.

Sigma–delta A/D conversion: An *oversampling* A/D conversion process where the analog signal is sampled at rates much higher (typically 64 times) than the sampling rates that would be required with a Nyquist converter. Sigma–delta modulators integrate the analog signal before performing

the delta modulation. The integral of the analog signal is encoded rather than the change in the analog signal, as is the case for traditional delta modulation. A digital sample rate reduction filter (also called a digital decimation filter) is used to provide an output sampling rate at twice the Nyquist frequency of the signal. The overall result of oversampling and digital sample rate reduction is greater resolution and less distortion compared to a Nyquist converter process.

Successive approximation: An A/D conversion process that systematically evaluates the analog signal in n steps to produce an n -bit digital code. The analog signal is successively compared to determine the digital code, beginning with the determination of the most significant bit of the code.

Wavelet Transforms • Mean Square Estimation—the Orthogonality Principle

10.1 Introduction

Signal space concepts have their roots in the mathematical theory of inner product spaces known as **Hilbert spaces** [Stakgold, 1967]. Many books on linear systems touch on the subject of signal spaces in the context of Fourier series and transforms [Ziemer, Tranter, and Fannin, 1998]. The applications of signal space concepts in communication theory find their power in the representation of signal detection and estimation problems in geometrical terms, which provides much insight into signalling techniques and communication system design. The first person to have apparently exploited the power of signal space concepts in communication theory was the Russian Kotel'nikov [1968], who presented his doctoral dissertation in January, 1947. Wozencraft and Jacobs [1965] expanded on this approach and their work is still today widely referenced. Arthurs and Dym [1962] made use of signal space concepts in the performance analysis of several digital modulation schemes. A one-chapter summary of the use of signal space methods in signal detection and estimation is provided in Ziemer and Tranter [2002]. Another application of signal space concepts is in signal and image compression. Wavelet theory [Rioul and Vetterli, 1991] is currently finding use in these application areas. In the next section, the fundamentals of generalized vector spaces are summarized, followed by an overview of several applications to signal representations.

10.2 Fundamentals

A linear space or **vector space** (signal space) [Stakgold, 1967] is a collection of elements (called **vectors**) \mathbf{x} , \mathbf{y} , \mathbf{z} , ..., for which the following axioms are satisfied:

1. To every pair of vectors \mathbf{x} and \mathbf{y} there corresponds a vector $\mathbf{x} + \mathbf{y}$, with the properties:
 - a. $\mathbf{x} + \mathbf{y} = \mathbf{y} + \mathbf{x}$
 - b. $\mathbf{x} + (\mathbf{y} + \mathbf{z}) = (\mathbf{x} + \mathbf{y}) + \mathbf{z}$
 - c. There exists a unique element $\mathbf{0}$ such that $\mathbf{x} + \mathbf{0} = \mathbf{x}$ for every \mathbf{x}
 - d. To every \mathbf{x} , there exists a unique vector labeled $-\mathbf{x}$ such that $\mathbf{x} + (-\mathbf{x}) = \mathbf{0}$
2. To all vectors \mathbf{x} and \mathbf{y} , and all numbers a and b (in general, complex), the following commutative and associative rules hold:

- a. $\alpha(\beta\mathbf{x}) = (\alpha\beta)\mathbf{x}$
- b. $(\alpha + \beta)\mathbf{x} = \alpha\mathbf{x} + \beta\mathbf{x}$
- c. $\alpha(\mathbf{x} + \mathbf{y}) = \alpha\mathbf{x} + \alpha\mathbf{y}$
- d. $1\mathbf{x} = \mathbf{x}$, where 1 is the **identity element**

A vector is said to be a **linear combination** of the vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k$ in a vector space if there exist numbers (in general, complex) $\alpha_1, \alpha_2, \dots, \alpha_k$ such that

$$\mathbf{x} = \sum_{i=1}^k \alpha_i \mathbf{x}_i \quad (10.1)$$

The vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k$ are said to be **linearly dependent** (or form a dependent set) if there exist complex numbers $\alpha_1, \alpha_2, \dots, \alpha_k$, not all zero, such that

$$\alpha_1 \mathbf{x}_1 + \alpha_2 \mathbf{x}_2 + \dots + \alpha_k \mathbf{x}_k = 0 \quad (10.2)$$

If Eq. (10.2) can be satisfied only for $\alpha_1 = \alpha_2 = \dots = \alpha_k = 0$, the vectors are **linearly independent**.

One is tempted to use the infinite-sum version of Eq. (10.2) in defining the notion of independence for an infinite set of vectors. This is not true in general; one needs the notion of convergence, which is based on the concept of distance between vectors.

With the idea of linear independence firmly in mind, the concept of **dimension** of a vector space readily follows. A vector space is *n-dimensional* if it possesses a set of *n* **independent vectors**, but every set of *n* + 1 vectors is a dependent set. If for every positive integer *k*, a set of *k* independent vectors in the space can be found, the space is said to be infinite dimensional. A **basis** for a vector space means a finite set of vectors $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_k$ with the following attributes:

1. They are linearly independent.
2. Every vector \mathbf{x} in the space can be written as a linear combination of the basis vectors; that is

$$\mathbf{x} = \sum_{i=1}^k \xi_i \mathbf{e}_i \quad (10.3)$$

It can be proved that the representation (10.3) is unique and that if the space is *n*-dimensional, any set of *n* independent vectors $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n$ forms a basis.

The next concept to be developed is that of a **metric space**. In addition to the addition of vectors and multiplication of vectors by scalars, as is true of ordinary three-dimensional vectors, it is important to have the notions of length and direction of a vector imposed. In other words, a metric structure must be added to the algebraic structure already defined. A collection of elements $\mathbf{x}, \mathbf{y}, \mathbf{z}, \dots$ in a space will be called a metric space if to each pair of elements \mathbf{x}, \mathbf{y} there corresponds a real number $d(\mathbf{x}, \mathbf{y})$ satisfying the properties:

1. $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{y}, \mathbf{x})$
2. $d(\mathbf{x}, \mathbf{y}) \geq 0$ with equality if and only if $\mathbf{x} = \mathbf{y}$
3. $d(\mathbf{x}, \mathbf{z}) \leq d(\mathbf{x}, \mathbf{y}) + d(\mathbf{y}, \mathbf{z})$ (called the **triangle inequality**)

The function $d(\mathbf{x}, \mathbf{y})$ is called a **metric** (or distance function). Note that the definition of $d(\mathbf{x}, \mathbf{y})$ *does not require that the elements be vectors*; there may not be any way of adding elements or multiplying them by scalars as required for a vector space.

With the definition of a metric, one can now discuss the idea of convergence of a sequence $\{\mathbf{x}_k\}$ of elements in the space. Note that $d(\mathbf{x}_k, \mathbf{x})$ is a sequence of real numbers. Therefore, it is sensible to write that

$$\lim_{k \rightarrow \infty} \mathbf{x}_k = \mathbf{x} \quad (10.4)$$

if the sequence of numbers $d(\mathbf{x}_k, \mathbf{x})$ converges to 0 in the ordinary sense of convergence of sequences of real numbers. If

$$\lim_{m,p \rightarrow \infty} d(\mathbf{x}_m, \mathbf{x}_p) = 0 \quad (10.5)$$

the sequence $\{\mathbf{x}_k\}$ is said to be a **Cauchy sequence**. It can be shown that if a sequence $\{\mathbf{x}_k\}$ converges, it is a Cauchy sequence. The converse is not necessarily true, for the limit may have carelessly been excluded from the space. If the converse is true, then the metric space is said to be **complete**.

The next vector space concept to be defined is that of length or norm of a vector. A **normed vector space** (or linear space) is a vector space in which a real-valued function $\|\mathbf{x}\|$ (known as the *norm* of \mathbf{x}) is defined, with the properties

1. $\|\mathbf{x}\| \geq 0$ with equality if and only if $\mathbf{x} = 0$
2. $\|\alpha\mathbf{x}\| = |\alpha| \|\mathbf{x}\|$
3. $\|\mathbf{x}_1 + \mathbf{x}_2\| \leq \|\mathbf{x}_1\| + \|\mathbf{x}_2\|$

A normed vector space is automatically a metric space if the metric is defined as

$$d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\| = \langle \mathbf{x} - \mathbf{y}, \mathbf{x} - \mathbf{y} \rangle^{1/2} \quad (10.6)$$

(see definition below) which is called the natural metric for the space. A normed vector space may be viewed either as a linear space, a metric space, or both. Its elements may be interpreted as *vectors* or *points*.

The structure of a normed vector space will now be refined further with the definition of the notion of angle between two vectors. In particular, it will be possible to tell whether two vectors are perpendicular. The notion of angle between two vectors will be obtained by defining the **inner product** (also known as a scalar or dot product). In general, an inner product in a vector space is a complex-valued function of ordered pairs \mathbf{x}, \mathbf{y} with the properties

1. $\langle \mathbf{x}, \mathbf{y} \rangle = \langle \mathbf{y}, \mathbf{x} \rangle^*$ (the asterisk denotes complex conjugate)
2. $\langle \alpha\mathbf{x}, \mathbf{y} \rangle = \alpha \langle \mathbf{x}, \mathbf{y} \rangle$
3. $\langle \mathbf{x}_1 + \mathbf{x}_2, \mathbf{y} \rangle = \langle \mathbf{x}_1, \mathbf{y} \rangle + \langle \mathbf{x}_2, \mathbf{y} \rangle$
4. $\langle \mathbf{x}, \mathbf{x} \rangle \geq 0$ with equality if and only if $\mathbf{x} = 0$

From the first two properties, it follows that

$$\langle \mathbf{x}, \alpha\mathbf{y} \rangle = \alpha^* \langle \mathbf{x}, \mathbf{y} \rangle \quad (10.7)$$

Also, **Schwarz's inequality** can be proved and is given by

$$|\langle \mathbf{x}, \mathbf{y} \rangle| \leq \langle \mathbf{x}, \mathbf{x} \rangle^{1/2} \langle \mathbf{y}, \mathbf{y} \rangle^{1/2} \quad (10.8)$$

with equality if and only if $\mathbf{x} = \alpha\mathbf{y}$. The real, nonnegative quantity $\langle \mathbf{x}, \mathbf{x} \rangle^{1/2}$ satisfies all of the properties of a norm. Therefore, it is adopted as the definition of the norm, and Schwarz's inequality assumes the form

$$|\langle \mathbf{x}, \mathbf{y} \rangle| \leq \|\mathbf{x}\| \|\mathbf{y}\| \quad (10.9)$$

The natural metric in the space is given by Eq. (10.6). An inner product space, which is complete in its natural metric, is called a Hilbert space.

Example 10.1

Consider the space of all complex-valued functions $\mathbf{x}(t)$ defined on $a \leq t \leq b$ for which the integral

$$E_x = \int_a^b |\mathbf{x}(t)|^2 dt \quad (10.10)$$

exists (i.e., the space of all finite-energy signals in the interval $[a, b]$). The inner product may be defined as

$$\langle \mathbf{x}, \mathbf{y} \rangle = \int_a^b \mathbf{x}(t) \mathbf{y}^*(t) dt \quad (10.11)$$

The natural norm is

$$\|\mathbf{x}\| = \left[\int_a^b |\mathbf{x}(t)|^2 dt \right]^{1/2} \quad (10.12)$$

and the metric is

$$d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\| = \left[\int_a^b |\mathbf{x}(t) - \mathbf{y}(t)|^2 dt \right]^{1/2} \quad (10.13)$$

respectively. Schwarz's inequality becomes

$$\left| \int_a^b \mathbf{x}(t) \mathbf{y}^*(t) dt \right| \leq \left[\int_a^b |\mathbf{x}(t)|^2 dt \right]^{1/2} \left[\int_a^b |\mathbf{y}(t)|^2 dt \right]^{1/2} \quad (10.14)$$

It can be shown that this space is complete and, hence, is a Hilbert space.

An additional requirement that can be imposed on a Hilbert space is separability, which, roughly speaking, restricts the number of elements in the space. A Hilbert space \mathcal{H} is **separable** if there exists a **countable** (i.e., can be put in one-to-one correspondence with the positive integers) set of elements $(\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_n, \dots)$ whose finite linear combinations are such that for any element \mathbf{f} in \mathcal{H} there exist an index N and constants $\alpha_1, \alpha_2, \dots, \alpha_N$ such that

$$\left\| \mathbf{f} - \sum_{k=1}^N \alpha_k \mathbf{f}_k \right\| < \epsilon, \quad \epsilon > 0 \quad (10.15)$$

The set $(\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_n, \dots)$ is called a **spanning set**. The discussions from here on are limited to separable Hilbert spaces.

Any finite-dimensional Hilbert space E_n is separable. In fact, there exists a set of n vectors $(\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_n)$ such that each vector \mathbf{x} in E_n has the representation

$$\mathbf{x} = \sum_{k=1}^n \alpha_k \mathbf{f}_k \quad (10.16)$$

It can be shown that the spaces consisting of square-integrable functions on the intervals $[a, b]$, $(-\infty, b]$, $[a, \infty)$, and $(-\infty, \infty)$ are all separable, where a and b are finite, and spanning sets exist for each of these spaces. For example, a spanning set for the space of square-integrable functions on $[a, b]$ is the set $(1, t, t^2, \dots)$, which is clearly countable.

The concepts of convergence and Cauchy sequences carry over to Hilbert spaces, with *convergence in the mean* defined as

$$\lim_{k \rightarrow \infty} \int_a^b |\mathbf{x}_k(t) - \mathbf{x}(t)|^2 dt = 0 \quad (10.17)$$

Similarly, the ideas of independence and basis sets apply to Hilbert spaces in infinite-dimensional form.

It is necessary to distinguish between the concepts of a *basis* and a *spanning* set consisting of independent vectors. As ϵ is reduced in Eq. (10.15), it is expected that N must be increased, and it may also be

necessary to change the previously found coefficients $\alpha_1, \dots, \alpha_N$. Hence, there might not exist a fixed sequence of constants $\xi_1, \xi_2, \dots, \xi_n, \dots$ with the property

$$\mathbf{x} = \sum_{k=1}^{\infty} \xi_k f_k \quad (10.18)$$

as would be required if the set $\{f_k\}$ were a basis. For example, on the space of square-integrable functions on $[-1, 1]$, the independent set $f_0 = 1, f_1 = t, f_2 = t^2, \dots$, is a spanning set, but not a basis, since there are many square-integrable functions on $[-1, 1]$ that cannot be expanded in a series like Eq. (10.18) (an example is $|t|$). Odd as it may seem at first, it is possible if the powers of t in this spanning set are regrouped into the set of polynomials known as the Legendre polynomials, $P_k(t)$.

Two vectors \mathbf{x}, \mathbf{y} are **orthogonal** or perpendicular if $\langle \mathbf{x}, \mathbf{y} \rangle = 0$. A finite or countably infinite set of vectors $\{\phi_1, \phi_2, \dots, \phi_k, \dots\}$ is said to be an *orthogonal set* if $\langle \phi_i, \phi_j \rangle = 0, i \neq j$. A *proper orthogonal set* is an orthogonal set none of whose elements is the zero vector. A proper orthogonal set is an independent set. A set is **orthonormal** if

$$\langle \phi_i, \phi_j \rangle = \begin{cases} 0, & i \neq j \\ 1, & i = j \end{cases} \quad (10.19)$$

An important concept is that of a **linear manifold** in a Hilbert space. A set M is said to be a linear manifold if, for \mathbf{x} and \mathbf{y} belonging to M , so does $\alpha\mathbf{x} + \beta\mathbf{y}$ for arbitrary complex numbers α and β ; thus, M is itself a linear space. If a linear manifold is a closed set, it is called a closed linear manifold (i.e., every Cauchy sequence has a limit in the space) and is itself a Hilbert space. In three-dimensional Euclidean space, linear manifolds are simply lines and planes containing the origin. In a finite-dimensional space, every linear manifold is necessarily closed.

Let M be a linear manifold, closed or not. Consider the set M^\perp of all vectors which are orthogonal to every vector in M . It is a linear manifold, which can be shown to be closed. If M is closed, M and M^\perp are known as **orthogonal complements**. Given a linear manifold M , each vector in the space can be decomposed in a unique manner, as a sum $\mathbf{x}_p + \mathbf{z}$, where \mathbf{x}_p is in M and \mathbf{z} is in M^\perp .

Given an infinite orthonormal set $\{\phi_1, \phi_2, \dots, \phi_n, \dots\}$ in the space of all square-integrable functions on the interval $[a, b]$, let $\{a_n\}$ be a sequence of complex numbers. The **Riesz–Fischer theorem** tells how to represent an element in the space and states:

1. If

$$\sum_{n=1}^{\infty} |a_n|^2 \quad (10.20)$$

diverges, then

$$\sum_{n=1}^{\infty} a_n \phi_n \quad (10.21)$$

diverges.

2. If Eq. (10.20) converges, then Eq. (10.21) also converges to some element \mathbf{g} in the space and

$$a_n = \langle \mathbf{g}, \phi_n \rangle \quad (10.22)$$

The next question that arises is how to construct an orthonormal set from an independent set $\{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_k, \dots\}$. A way to do this is known as the **Gram–Schmidt procedure**. The construction is as follows:

1. Pick a function from the set $\{e_k\}$, say e_1 . Let

$$\phi_1 = \frac{e_1}{\langle e_1, e_1 \rangle^{1/2}} \quad (10.23)$$

2. Remove from a second function in the set $\{e_k\}$, say e_2 , its projection on ϕ_1 . This yields

$$g_2 = e_2 - \langle e_2, \phi_1 \rangle \phi_1 \quad (10.24)$$

The vector g_2 is a linear combination of e_1 and e_2 , and is orthogonal to ϕ_1 . To normalize it, form

$$\phi_2 = \frac{g_2}{\langle g_2, g_2 \rangle^{1/2}} \quad (10.25)$$

3. Pick another function from the set $\{e_k\}$, say e_3 , and form

$$g_3 = e_3 - \langle e_3, \phi_2 \rangle \phi_2 - \langle e_3, \phi_1 \rangle \phi_1 \quad (10.26)$$

Normalize g_3 in a manner similar to that used for g_2 .

4. Continue until all functions in the set $\{e_k\}$ have been used.

Note that the sets $\{e_k\}$, $\{g_k\}$, and $\{\phi_k\}$ all generate the same linear manifold.

A basis consisting of orthonormal vectors is known as an **orthonormal basis**. If the basis vectors are not normalized, it is simply an *orthogonal basis*.

Example 10.2

Consider the interval $[-1, 1]$ and the independent set $e_0 = 1, e_2 = t, \dots, e_k = t^k, \dots$. The Gram–Schmidt procedure applied to this set without normalization, but with the requirement that all orthogonal functions take on the value 1 at $t = 1$, gives the set of *Legendre polynomials*, which is

$$\psi_0(t) = 1, \quad \psi_1(t) = t, \quad \psi_2(t) = \frac{1}{2}(3t^2 - 1), \quad \psi_3(t) = \frac{1}{2}(5t^3 - 3t), \dots \quad (10.27)$$

It is next desired to approximate an arbitrary vector x in a Hilbert space in terms of a linear combination of the independent set $\{e_1, \dots, e_k\}$, where $k \leq n$ if the space is an n -dimensional Euclidean space, and k is an arbitrary integer if the space is infinite-dimensional. First, the orthonormal set $\{\phi_1, \dots, \phi_k\}$ is constructed from $\{e_1, \dots, e_k\}$. The unique, best approximation to x is the **Fourier sum**

$$\sum_{i=1}^k \langle x, \phi_i \rangle \phi_i \quad (10.28)$$

which is geometrically the projection of x onto the linear manifold generated by $\{\phi_1, \dots, \phi_k\}$, or equivalently, the sum of the projections along the individual axes defined by $\phi_1, \phi_2, \dots, \phi_k$. The square of the distance between x and its projection is

$$\left\| x - \sum_{i=1}^k \langle x, \phi_i \rangle \phi_i \right\|^2 = \|x\|^2 - \sum_{i=1}^k |\langle x, \phi_i \rangle|^2 \quad (10.29)$$

Since the left-hand side is nonnegative, Eq. (10.29) gives **Bessel's inequality**, which is

$$\|\mathbf{x}\|^2 \geq \sum_{i=1}^k |\langle \mathbf{x}, \phi_i \rangle|^2 \tag{10.30}$$

A convenient feature of the Fourier sum is the following: If another vector ϕ_{k+1} is added to the orthonormal approximating set of vectors, the best approximation now becomes

$$\sum_{i=1}^{k+1} \langle \mathbf{x}, \phi_i \rangle \phi_i \tag{10.31}$$

Thus, an additional term is added to the series expansion without changing previously computed coefficients, which makes the extension to a countably infinite orthonormal approximating set simple to envision. In the case of an infinite orthonormal approximating set, Bessel's inequality (10.30) now has an infinite limit on the sum. Does the approximating sum (10.31) converge to \mathbf{x} ? The answer is that convergence can be guaranteed only if the set $\{\phi_k\}$ is extensive enough, that is, if it is a *basis* or a *complete orthonormal set*. In such cases, Eq. (10.30) becomes an equality. In fact, a number of equivalent criteria can be stated to determine whether an orthonormal set $\{\phi_k\}$ is a basis or not [Stakgold, 1967]. These are:

1. In finite n -dimensional Euclidean space, $\{\phi_k\}$ has exactly n elements for completeness.
2. For every \mathbf{x} in the space of square-integrable functions,

$$\mathbf{x} = \sum_i \langle \mathbf{x}, \phi_i \rangle \phi_i \tag{10.32}$$

3. For every \mathbf{x} in the space of square-integrable functions,

$$\|\mathbf{x}\|^2 = \sum_{i=1}^k |\langle \mathbf{x}, \phi_i \rangle|^2 \tag{10.33}$$

(known as **Parseval's equality**).

4. The only \mathbf{x} in the space of square-integrable functions for which all of the Fourier coefficients vanish is the 0 function.
5. There exists no function $\phi(t)$ in the space of square-integrable functions such that $\{\phi_1, \phi_2, \dots, \phi_k, \dots\}$ is an orthonormal set.

Examples of complete orthonormal sets of trigonometric functions over the interval $[0, T]$ are as follows: (1) The complex exponentials with frequencies equal to the harmonics of the fundamental frequency $\omega_0 = 2\pi/T$, or

$$\frac{1}{\sqrt{T}}, \frac{e^{j\omega_0 t}}{\sqrt{T}}, \frac{e^{-j\omega_0 t}}{\sqrt{T}}, \frac{e^{j2\omega_0 t}}{\sqrt{T}}, \frac{e^{-j2\omega_0 t}}{\sqrt{T}}, \dots \tag{10.34}$$

The factor $(T)^{1/2}$ in the denominator is necessary to normalize the functions and is often not included in the definition of the complex exponential Fourier series. (2) The sines and cosines with frequencies equal to harmonics of the fundamental frequency $\omega_0 = 2\pi/T$, or

$$\frac{1}{\sqrt{T}}, \frac{\cos \omega_0 t}{\sqrt{T/2}}, \frac{\sin \omega_0 t}{\sqrt{T/2}}, \frac{\cos 2\omega_0 t}{\sqrt{T/2}}, \frac{\sin 2\omega_0 t}{\sqrt{T/2}}, \dots \tag{10.35}$$

Note that if any function is left out of these sets, the basis is incomplete.

10.3 Application of Signal Space Representation to Signal Detection

The M -ary signal detection problem is as follows: given M signals, $s_0(t), s_1(t), \dots, s_M(t)$, defined over $0 \leq t \leq T$. One is chosen at random and sent each T -second interval through a channel that adds white, Gaussian noise of power spectral density $N_0/2$ to it. The challenge is to design a receiver that will decide which signal was sent through the channel during each T -second interval with minimum probability of making an error.

An approach to this problem, as expanded upon in greater detail by Wozencraft and Jacobs [1965, Chap. 4] and Ziemer and Tranter [2002, Chap. 9], is to construct a linear manifold, called the signal space, using the Gram–Schmidt procedure on the M signals. Suppose that this results in the orthonormal basis set $\{\phi_1, \phi_2, \dots, \phi_K\}$ where $K \leq M$. The received signal plus noise is represented in this signal space as vectors with coordinates (note that they depend on the signal transmitted)

$$Z_{ij} = A_{ij} + N_j, \quad \begin{array}{l} j = 1, 2, \dots, K, \\ i = 1, 2, \dots, M, \end{array} \quad (10.36)$$

where

$$A_{ij} = \int_0^T s_i(t) \phi_j(t) dt \quad (10.37)$$

The numbers Z_{ij} are components of vectors referred to as the **signal vectors**, and the space of all signal vectors is called the **observation space**. An apparent problem with this approach is that not all possible noise waveforms added to the signal can be represented as vectors in this K -dimensional observation space. The part of the noise that is represented is

$$n_1(t) = \sum_{j=1}^K N_j \phi_j(t) \quad (10.38)$$

where

$$N_j = \int_0^T n(t) \phi_j(t) dt \quad (10.39)$$

In terms of Hilbert space terminology, Eq. (10.38) is the projection of the noise waveform onto the observation space (i.e., a linear manifold). The unrepresented part of the noise is

$$n_{\perp}(t) = n(t) - n_1(t) \quad (10.40)$$

and is the part of the noise that must be represented in the orthogonal complement of the observation space. The question is, will the decision process be harmed by ignoring this part of the noise? It can be shown that $n_{\perp}(t)$ is uncorrelated with $n_1(t)$. Thus, since $n(t)$ is Gaussian they are statistically independent and $n_{\perp}(t)$ has no bearing on the decision process; nothing is lost by ignoring $n_{\perp}(t)$.

The decision process can be shown to reduce to choosing the signal $s_{\ell}(t)$, which minimizes the distance to the data vector; that is,

$$d(\mathbf{z}, s_{\ell}) = \|\mathbf{z} - s_{\ell}\| = \left[\sum_{j=1}^K (Z_{ij} - A_{\ell j})^2 \right]^{1/2} = \text{minimum}, \quad \ell = 1, 2, \dots, M \quad (10.41)$$

FIGURE 10.1 Observation space in two dimensions, showing five signal points with boundaries for decision regions providing the minimum distance decision in each case.

where

$$\mathbf{z}(t) = \sum_{j=1}^K Z_{ij} \phi_j(t) \quad (10.42)$$

and

$$s_\ell(t) = \sum_{j=1}^K A_{\ell j} \phi_j(t) \quad (10.43)$$

Thus, the signal detection problem is reduced to a geometrical one, where the observation space is subdivided into decision regions in order to make a decision, as shown in Fig. 10.1.

10.4 Application of Signal Space Representation to Parameter Estimation

The procedure used in applying signal space concepts to estimation is similar to that used for signal detection. Consider the observed waveform consisting of additive signal and noise of the form

$$y(t) = s(t, A) + n(t), \quad 0 \leq t \leq T \quad (10.44)$$

where A is a parameter to be estimated and the noise is white as before. Let $\{\phi_k(t)\}$, $k = 1, 2, \dots$, be a complete orthonormal basis set. The observed waveform can be represented as

$$y(t) = \sum_{k=1}^{\infty} S_k(A) \phi_k(t) + \sum_{k=1}^{\infty} N_k \phi_k(t) \quad (10.45)$$

where

$$S_k(A) = \langle s, \phi_k \rangle = \int_0^T s(t, A) \phi_k(t) dt \quad (10.46)$$

and N_j is defined by Eq. (10.39). Hence, an estimate can be made on the basis of the set of coefficients

$$Z_k = S_k(A) + N_k \quad (10.47)$$

or on the basis of a vector in the signal space with these coordinates. A reasonable criterion for estimating A is to maximize the likelihood ratio, or a monotonic function thereof. Its logarithm, for $n(t)$ Gaussian, can be shown to reduce to

$$\ell(A) = \lim_{K \rightarrow \infty} L_K(A) = \lim_{K \rightarrow \infty} \left[\frac{2}{N_0} \sum_{k=1}^K Z_k S_k(A) - \frac{1}{N_0} \sum_{k=1}^K S_k^2(A) \right] \quad (10.48)$$

In the limit as $k \rightarrow \infty$, this becomes

$$\ell(A) = \frac{2}{N_0} \int_0^T z(t) s(t, A) dt - \frac{1}{N_0} \int_0^T s^2(t, A) dt \quad (10.49)$$

A necessary condition for the value of A that maximizes Eq. (10.49) is

$$\frac{\partial \ell(A)}{\partial A} = \frac{2}{N_0} \int_0^T [z(t) - s(t, A)] \frac{\partial s(t, A)}{\partial A} dt \Big|_{A=\hat{A}} = 0 \quad (10.50)$$

The value of A that maximizes Eq. (10.49), denoted \hat{A} , is called the **maximum likelihood estimate**.

Wavelet Transforms

Wavelet transforms can be continuous time or discrete time. They find applications in speech and image compression, signal and image classification, and pattern recognition. Wavelet representations have been adopted by the U.S. Federal Bureau of Investigation for fingerprint compression.

The continuous-time **wavelet transform** of a signal $x(t)$ takes the form [Rioul and Vetterli, 1991]

$$W_x(\tau, a) = \int_{-\infty}^{\infty} x(t) h_{a, \tau}^*(t) dt \quad (10.51)$$

where

$$h_{a, \tau}(t) = \frac{1}{\sqrt{a}} h\left(\frac{t - \tau}{a}\right) \quad (10.52)$$

are basis functions called **wavelets**. Thus, the wavelets defined in Eq. (10.52) are scaled and translated versions of the basic wavelet prototype $h(t)$ (also known as the *mother wavelet*), and the wavelet transform is seen to be a convolution of the conjugate of a wavelet with the signal $x(t)$. Substitution of Eq. (10.52) into Eq. (10.51) yields

$$W_x(\tau, a) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} x(t) h^*\left(\frac{t - \tau}{a}\right) dt \quad (10.53)$$

Note that $h(t/a)$ is contracted if $a < 1$ and expanded if $a > 1$. Thus, an interpretation of Eq. (10.53) is that as a increases, the function $h(t/a)$ becomes spread out over time and takes the long-term behavior

of $\mathbf{x}(t)$ into account; as a decreases the short-time behavior of $\mathbf{x}(t)$ is taken into account. A change of variables in Eq. (10.53) gives

$$W_x(\tau, a) = \sqrt{a} \int_{-\infty}^{\infty} x(at) h^* \left(t - \frac{\tau}{a} \right) dt \quad (10.54)$$

Now the interpretation of Eq. (10.54) is as the scale increases ($a < 1$), an increasingly contracted version of the signal is seen through a constant-length sifting function, $h(t)$. This is only the barest of introductions to wavelets, and the reader is urged to consult the references to learn more about wavelets and their applications, particularly their discrete-time implementation.

Mean Square Estimation—The Orthogonality Principle

Given n random variables, X_1, X_2, \dots, X_n , it is desired to find n constants a_1, a_2, \dots, a_n such that when another random variable S is estimated by the sum

$$\hat{S} = \sum_{i=1}^n a_i X_i \quad (10.55)$$

then the mean square error

$$\text{MSE} = E \left\{ \left| S - \sum_{i=1}^n a_i X_i \right|^2 \right\} \quad (10.56)$$

is a minimum, where $E\{\}$ denotes expectation or statistical average. It is shown in [Papoulis, 1984] that the **mean square estimate** (MSE) is minimized when the error is orthogonal to the data, or when

$$E \left\{ \left[S - \sum_{i=1}^n a_i X_i \right] X_j^* \right\} = 0, \quad j = 1, 2, \dots, n \quad (10.57)$$

This is known as the **orthogonality principle** or **projection theorem** and can be interpreted as stating that the MSE is minimized when the error vector $\mathbf{S} - \hat{\mathbf{S}}$ is orthogonal to the subspace (linear manifold) spanned by the vectors $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_n$, as shown in Fig. 10.2. The projection theorem has many applications including MSE filtering of noisy signals, known as Wiener filtering.

FIGURE 10.2 Schematic representation of mean square estimation in three dimensions with the estimate expressed in terms of a linear combination of two random variables, X_1 and X_2 , which lie in the $\phi_1 - \phi_2$ plane.

Defining Terms

- Basis (basis functions):** An independent set of vectors in a linear space in terms of which any vector in the space can be represented as a linear combination.
- Bessel's inequality:** The statement that the norm squared of any vector in a vector space is greater or equal to the sum of the squares of the projections onto a set of orthonormal basis vectors.
- Cauchy sequence:** A convergent sequence whose members become progressively closer as the limit is approached.
- Complete:** The idea that a basis set is extensive enough to represent any vector in the space as a Fourier sum.
- Countable:** A set that can be put in one-to-one correspondence with the positive integers.
- Dimension:** A vector space is n -dimensional if it possesses a set of n independent vectors, but every set of $n + 1$ vectors is linearly dependent.
- Fourier sum:** An approximation of a vector in a Hilbert space as a linear combination of orthonormal basis functions where the coefficient of each basis function is the projection of the vector onto the respective basis function.
- Gram–Schmidt procedure:** An algorithm that produces a set of orthonormal vectors from an arbitrary set of vectors.
- Hilbert space:** A normed linear space complete in its natural metric.
- Identity element:** An element in a vector space that when multiplied by any vector reproduces that vector.
- Independent vectors:** A set of vectors is independent if any one of them cannot be expressed as a linear combination of the others.
- Inner product:** A function of ordered pairs of vectors in a vector space, which is analogous to the dot product in ordinary Euclidean vector space.
- Linear combination:** A linear sum of a set of vectors in a vector space with each member in the sum, in general, multiplied by a different scalar.
- Linear manifold:** A subspace of a Hilbert space that contains the origin.
- Linearly dependent (dependent):** A set of vectors that is not linearly independent.
- Linearly independent (independent):** A set of vectors, none of which can be expressed as a linear combination of the others.
- Maximum likelihood estimate:** An estimate for a parameter that maximizes the likelihood function.
- Mean square estimation:** Estimation of a random variable by a linear combination of n other random variables that minimizes the expectation of the squared difference between the random variable to be estimated and the approximating linear combination.
- Metric:** A real-valued function of two vectors in a vector space that is analogous to the distance between them in the ordinary Euclidean sense.
- Metric space:** A vector space in which a metric is defined.
- Norm:** A function of a single vector in a vector space that is analogous to the length of a vector in ordinary Euclidean vector space.
- Normed vector space:** A vector space in which a norm has been defined.
- Observation space:** The space of all possible received data vectors in a signal detection or estimation problem.
- Orthogonal:** The property of two vectors expressed by their inner product being zero.
- Orthogonal complement:** The space of vectors that are orthogonal to a linear manifold or subspace.
- Orthogonality principle:** The theorem that states that the minimum mean-square estimate of a random variable in terms of a linear combination of n other random variables requires the difference between the random variable and linear combination, or error, to be statistically orthogonal to each random variable in the linear combination (i.e., the expectation of the product of the error and each random variable is zero). Also called the *projection theorem*.
- Orthonormal:** Orthogonal vectors that have unit norm.
- Orthonormal basis:** A basis set for which the basis vectors are orthonormal.

Parseval's equality: The statement that the norm squared of a vector in a complete Hilbert space equals the sum of the squares of the vector's projections onto an orthonormal basis set in the space.

Projection theorem: See **orthogonality principle**.

Riesz–Fischer theorem: A theorem that states the conditions under which an element of a space of square-integrable functions can be represented in terms of an infinite orthonormal set.

Schwarz's inequality: An inequality expressing the fact that the absolute value of the inner product of any pair of vectors in a Hilbert space is less than or equal to the product of their respective norms.

Separable: A Hilbert space in which a countable set of elements exists that can be used to represent any element in the space to any degree of accuracy desired as a linear combination of the members of the set.

Signal vector: A vector representing a received signal in a signal detection or estimation problem.

Spanning set: The set of elements of a separable Hilbert space used to represent an arbitrary element with any degree of accuracy desired.

Triangle inequality: An inequality of a normed linear space that is analogous to the fact that the length of the sum of any two sides of a triangle is less than or equal to the sum of their respective lengths.

Vector: An element of a linear, or vector, space.

Vector space: A space of elements, called vectors, which obey certain laws of associativity and commutativity and have identity elements for scalar multiplication and element addition defined.

Wavelet: See **wavelet transform**.

Wavelet transform: Resolution of a signal into a set of basis functions called wavelets. As a parameter of the wavelet is changed, the behavior of the signal over progressively shorter time intervals is resolved.

Further Information

Very readable expositions of signal space concepts as applied to signal detection and estimation are found in Chapter 4 of the classic book by Wozencraft and Jacobs. The paper by Arthurs and Dym listed in the references is also very readable. A treatment of signal space concepts and applications to signal detection and parameter estimation is given in Chapter 9 of the book by Ziemer and Tranter. For the mathematical theory behind signal space concepts, the book by Stakgold is recommended. For those interested in wavelet transforms and their relationship to signal spaces, the April 1992 issue of the *IEEE Signal Processing Magazine* provides a tutorial article on wavelet transforms.

11.1 Introduction

Early channel models used in conjunction with analysis of communication systems assumed a binary symmetric channel (BSC) [Wozencraft and Jacobs, 1967]. In this case, the probability of bit error is assumed constant. This channel is memoryless, that is, the presence or absence of an error for a particular symbol has no influence on past or future symbols. Few transmission paths can be characterized as a BSC; most channels of interest are subject to some degree of fading and dispersion which introduce memory (correlation) between symbol errors. Therefore, it is necessary that a fading dispersive channel model be described to allow complete characterization of communication systems for typical applications.

Modeling of the fading dispersive channel is based on the use of mathematics to describe the physical or observed properties of the channel. Stein, Schwartz, and Bennett [1966] and Kennedy [1969] first used a deterministic characterization of the channel and then introduced dynamics into the model to account for the time-varying nature of a fading channel. Bello [1963] described a channel model using a tapped delay line representation, which is based on knowledge of the correlation properties of the channel.

The fading dispersive channel is described in [Section 11.2](#) as a linear time-varying filter. Mobile and scatter channels produce a received signal consisting of the sum of multiple time-variant paths. Such channels are assumed to impart zero mean Gaussian statistics on a transmitted signal. Characterization of the channel then reduces to the specification of a correlation function or power spectral density. Many radio channels are adequately modeled by making these assumptions, including tropospheric scatter, high-frequency (HF) skywave, VHF/UHF mobile channels, and lunar reflection channels. Line-of-sight (LOS) channels, however, consist of a direct ray plus multiple indirect rays. The LOS channel, therefore, is assumed to impart nonzero mean Gaussian statistics on the transmitted signal. Modeling of the LOS channel can be somewhat simplified as compared to the general fading dispersive channel model, as shown in [Section 11.3](#).

Digital communication channels introduce errors in bursts, which invalidates the use of the BSC. To characterize error clustering effects, various error models have been proposed, which can be divided into two basic categories, *descriptive* and *generative*. Descriptive models attempt to characterize channels by use of statistics that describe the general behavior of the channel. The Neyman type A distribution [Neyman, 1939] is an example of a descriptive model; here channel errors are modeled as a compound Poisson distribution in which error clusters have a Poisson distribution and errors within a cluster also

have a Poisson distribution. Such models have been shown to apply to channels that have relatively few error-causing mechanisms, such as cable transmission [Becam et al., 1984], but have not been effectively used with more complex channels such as digital radio. Generative models, however, are able to match channel data by iteratively expanding the size of the model to fit the data. The generative model allows error statistics to be generated from a model made up of a finite-state Markov chain, using the states and transitions to represent the error behavior in the communications channel. These error models are usually developed to represent empirical results, but extensions are often made to more general cases.

11.2 Fading Dispersive Channel Model

Fading arises from destructive interference among multiple propagation paths, hence the term *multipath fading*. These paths arise due to reflection, refraction, or diffraction in the channel. The amplitude and phase of each path vary in time due to changes in the structure of the medium. The resultant signal at a receiver will experience fading, defined as changes in the received signal level in time, where resulting destructive or constructive interference depends on the relative amplitudes and phases of the multiple paths. The received signal may also experience dispersion, defined as spreading of the signal in time or frequency. Channels may be characterized as having multiple, randomly behaving paths or as having a dominant path in addition to multiple secondary paths. Forward scatter and mobile channels tend to have a large number of indirect paths, whereas line-of-sight channels tend to have a direct path that predominates over a few indirect paths.

The fading dispersive channel model may be best presented by using complex representation of the transmitted and received waveforms. Let us define $s(t)$ to be the transmitted signal and $y(t)$ to be the received signal. Assuming both $s(t)$ and $y(t)$ are narrowband signals, we can represent them as

$$s(t) = \text{Re}[z(t)e^{j2\pi f_c t}] \quad (11.1)$$

$$y(t) = \text{Re}[w(t)e^{j2\pi f_c t}] \quad (11.2)$$

where f_c is the carrier frequency and $z(t)$ and $w(t)$ are the complex envelopes of $s(t)$ and $y(t)$, respectively. The complex envelope notation carries information about the amplitude and phase of the signal waveforms. The magnitude of the complex envelope is the conventional envelope of the signal, and the angle of the complex envelope is the phase of the signal with respect to the carrier frequency f_c .

The first assumption made in characterizing the fading dispersive channel is that a large number of paths exist, and so the central limit theorem can be applied. We then can represent the channel impulse response as a complex Gaussian process, $g(t, \xi)$, which displays the time-varying nature of the channel. Assuming a linear channel,

$$w(t) = \int_{-\infty}^{\infty} z(t - \xi)g(t, \xi) d\xi \quad (11.3)$$

We also need to define the time-varying transfer function of the channel, which is the Fourier transform dual of the channel impulse response

$$G(f, t) = \int_{-\infty}^{\infty} g(t, \xi)e^{-j2\pi f\xi} d\xi \quad (11.4)$$

In this section, we will further assume that no direct or dominant path is present in the channel and that the scatterers behave as a random process, so that the statistics are Gaussian with zero mean. The received envelope then displays Rayleigh law statistics. Mobile and scatter communication systems are examples of such channels.

The final assumption required for characterization of the channel model involves the stationarity of the channel impulse response. Although the fluctuations in the channel are due to non-stationary statistical phenomena, on a short enough time scale and for small enough bandwidth, the fluctuations in time and frequency can be characterized as approximately stationary. This approximate stationarity is often called quasistationarity. Since our interest here is in short-term fading, it is reasonable to assume that $g(t, \xi)$ is stationary in a time sense. Channels displaying stationarity in time are called *wide-sense stationary* (WSS). For most scatter and mobile channels, the channel may be modeled as a continuum of uncorrelated scatters. If the channel impulse response $g(t, \xi)$ is independent for different values of delay (ξ), the channel is said to exhibit *uncorrelated scattering* (US). When the time-varying impulse response is assumed to have stationary fluctuations in time and frequency, the channel is said to be wide-sense stationary with uncorrelated scattering (WSSUS).

A WSSUS complex Gaussian process is completely determined statistically by specifying its autocorrelation function or its power spectral density. Because of the dual (time and frequency) nature of the channel, there exist several correlation functions and power spectral densities that are used to characterize the channel, and the most applicable of these are defined and briefly described as follows:

1. The *time-frequency correlation function* (sometimes called the two-frequency correlation function) is defined as

$$R(\Omega, \tau) = E[G^*(f, t)G(f + \Omega, t + \tau)] \quad (11.5)$$

Note that the complex character of $G(f, t)$ requires a slightly altered definition of autocorrelation, with the asterisk denoting the complex conjugate operation. $R(\Omega, \tau)$ represents the cross-correlation function between the complex envelopes of received carriers transmitted Ω Hz apart. Since the transfer function is assumed stationary with uncorrelated scattering, $R(\Omega, \tau)$ is dependent only on the frequency separation Ω and time delay τ .

2. The *tap gain correlation function* (sometimes called the path gain correlation function) is defined as

$$Q(\tau, \xi)\delta(\Delta\xi) = E[g^*(t, \xi)g(t + \tau, \xi + \Delta\xi)] \quad (11.6)$$

where $\delta(\bullet)$ is the unit impulse function and $Q(\tau, \xi)$ is the Fourier transform of $R(\Omega, \tau)$ on the Ω variable. $Q(\tau, \xi)$ represents the autocorrelation function of the gain fluctuations for paths providing delays in the interval $(\xi, \xi + \Delta\xi)$. The form of Eq. (11.6) implies that the fluctuations of the complex gains at different delays are uncorrelated, which is a result of the uncorrelated scattering assumption.

3. The *scattering function* is defined as the power spectrum of the complex gain fluctuations at delay ξ and is obtained from $Q(\tau, \xi)$ by applying the Fourier transform on the τ variable,

$$S(\xi, \nu) = \int_{-\infty}^{\infty} Q(\tau, \xi)e^{-j2\pi f\nu} d\tau \quad (11.7)$$

The scattering function directly exhibits the delay and Doppler spreading characteristics of the dispersive channel. The power spectral density associated with values of time delay ξ and Doppler frequency ν in this interval ξ to $\xi + \Delta\xi$ and ν to $\nu + \Delta\nu$, respectively, is then $S(\xi, \nu) \Delta\xi \Delta\nu$. The scattering function is also seen to be the double Fourier transform of the time-frequency correlation function.

Special cases of the described channel model that are of interest include the frequency-selective channel, time-selective channel, time- and frequency-selective channel, and nonselective channel. These cases are described by first showing how the general model is simplified and then showing the physical conditions for which these special cases arise.

Frequency-Selective Channel

The frequency-selective channel is characterized by a transfer function that varies in a more or less random fashion with frequency. An approximately constant amplitude and phase can only be observed over a frequency interval sufficiently small. The fading, which occurs at each frequency, will be very nearly the same, that is, highly correlated, for closely spaced frequencies and essentially independent, that is, no correlation for frequencies sufficiently far apart. The lack of correlation in fading of spaced frequencies is thus called **frequency-selective fading**.

A fading channel which is selective only in frequency is then implicitly also a nontime selective or *time-flat* channel. This time-flat channel is characterized by a channel impulse response that is time invariant. When the fading rate is so slow that little change in the channel impulse response occurs over the duration of a transmitted pulse, that channel may be approximated as a time-flat channel. Assuming the channel impulse response to be time invariant, the input–output relationship (11.3) may be simplified to the usual convolution integral

$$w(t) = \int_{-\infty}^{\infty} z(t - \xi)g(\xi) d\xi \quad (11.8)$$

in which $g(\xi)$ is now the time-invariant channel impulse response. With the time-invariance assumption, the complex correlation function of $g(\xi)$ becomes

$$E[g^*(\xi)g(\xi + \Delta\xi)] = Q(\xi)\delta(\Delta\xi) \quad (11.9)$$

where the function

$$Q(\xi) = Q(O, \xi) \quad (11.10)$$

is called the *delay power spectrum*. The *frequency correlation function*, which is the Fourier transform of the delay power spectrum, is given by

$$q(\Omega) = R(\Omega, \xi) = E[G^*(f)G(f + \Omega)] \quad (11.11)$$

where $G(f)$ is the time-invariant channel transfer function. A sufficient characterization of this channel is provided by either the delay power spectrum $Q(\xi)$ or the frequency correlation function $q(\Omega)$.

The frequency correlation function $q(\Omega)$ would be determined experimentally by transmitting two sine waves of different frequency and measuring the correlation between the complex envelopes as a function of frequency separation of the sine waves. When the frequency separation Ω is such that the correlation function $q(\Omega)$ is very near the maximum value $q(O)$ for all $\Omega < B_c$, all transmitted frequencies less than B_c will be received fading in a highly correlated fashion. For this reason B_c is called the **coherence bandwidth**, where B_c has been defined as the frequency separation for which $q(\Omega)$ equals $1/e$, or alternatively, $1/2$.

The delay power spectrum $Q(\xi)$ is the average power at time delay ξ in the multipath structure of the channel. One may define a **multipath** or **delay spread** parameter L as the width of $Q(\xi)$. Two measures of L that occur frequently are *total* and 2σ . The total delay spread L_T is meant to define the spread of $Q(\xi)$ for values of ξ where $Q(\xi)$ is significantly different from zero. The 2σ delay spread $L_{2\sigma}$ is defined as twice the standard deviation of $Q(\xi)$ when it has been normalized to unit area and regarded as a probability density function. Note that the coherence bandwidth and delay spread are reciprocals of one another, due to the Fourier transform relationship between $q(\Omega)$ and $Q(\xi)$.

If we assume that the received signal consists of scattered components ranging over a delay interval L , then the received signal corresponding to a transmitted symbol of duration T will be spread over $T + L$. As long as $L > T$, the received signal is spread in time, and the corresponding channel is said to be *time dispersive*. In a digital communications system, the effect of time dispersion is to cause intersymbol interference and a corresponding degradation in probability of symbol error.

A channel exhibits frequency selectivity when the transmitted bandwidth of the signal is sufficiently larger than the coherence bandwidth of the channel. Stated another way, frequency selectivity is observed if the delay spread L of the channel is sufficiently larger than the transmitted signal duration T . This channel is simultaneously time flat since the duration of a transmitted pulse is sufficiently small compared to the fading correlation time. For example, a high-speed troposcatter channel (in the range of megabits per second) often exhibits frequency selectivity since the transmitted bandwidth is larger than the channel coherence bandwidth.

Time-Selective Channel

The time-selective channel has the property that the impulse response is time variant. An approximately constant amplitude and phase can only be observed over a time interval sufficiently small. The fading which occurs at some frequency will be very nearly the same, that is, highly correlated, for closely spaced times, and essentially independent for times sufficiently far apart. The lack of correlation in fading of a given frequency over time intervals is thus called **time-selective fading**.

A fading channel that is selective only in time is then implicitly also a nonfrequency selective or *frequency-flat* channel. Such a channel has the property that the amplitude and phase fluctuations observed on the channel response to a given frequency are the same for any frequency. The frequency-flat fading channel is observed when the signal bandwidth is smaller than the correlation bandwidth of the channel. Low-speed data transmission over an HF channel (in the range of kilobits per second) is an example of time selectivity wherein the transmitted pulse width is greater than the average fade duration.

For the frequency-flat fading channel the channel impulse response is independent of the frequency variable, so that the input–output relationship (11.3) becomes

$$w(t) = z(t)g(t) \quad (11.12)$$

in which $g(t)$ is the time-varying, frequency-invariant, impulse response. The complex correlation function of $g(t)$ then becomes

$$E[g^*(t)g(t + \tau)] = p(\tau) = R(0, \tau) \quad (11.13)$$

where the function $p(\tau)$ is the *time (fading) correlation function*. A sufficient characterization of this channel is provided by either the time correlation function $p(\tau)$, or its Fourier transform $P(\nu)$, the *Doppler power spectrum*.

To make an experimental determination of $p(\tau)$, one could simply transmit a sine wave and evaluate the autocorrelation function of the received process. Here one may define a **coherence time** parameter (also called *fading time constant*) T_c in terms of $p(\tau)$ in the same way as B_c was defined in terms of $q(\Omega)$. The channel parameter T_c is then a measure of the average fade duration and is particularly useful in predicting the occurrence of time-selective fading in the channel, just as B_c is useful in predicting the occurrence of frequency-selective fading.

The Fourier transform of the time-correlation function is the Doppler power spectrum $P(\nu)$, which yields signal power as a function of Doppler shift. The total **Doppler spread** B_T and 2σ Doppler spread $B_{2\sigma}$ parameters are defined analogous to delay spread L_T and $L_{2\sigma}$, respectively, and have analogous utilities. Note that the coherence time and Doppler spread are reciprocals of one another, due to the Fourier transform relationship between $p(\tau)$ and $P(\nu)$. If the Doppler spread B is greater than the transmitted signal bandwidth W , then the received signal will be spread over $W + B$. For the case $B > W$, the received signal is spread in frequency and the corresponding channel is said to be *frequency dispersive*.

Observation of Doppler effects is evidence that the channel is behaving as a time-varying filter. These time variations in the channel can be related directly to motion in the medium or motion by the communications device. In the case of a troposcatter channel, fluctuations caused by motion in the scatterers within the medium cause Doppler effects. Motion of the user or vehicle in a mobile communications channel likewise gives rise to Doppler effects.

Time- and Frequency-Selective Channel

Channels that exhibit both time and frequency selectivity are called doubly dispersive. Such channels are neither time flat nor frequency flat. In general, real channels do not exhibit time and frequency selectivity simultaneously. To simultaneously exhibit time and frequency selectivity, the coherence bandwidth must simultaneously be both larger and smaller than the transmitted bandwidth, or alternatively, the multipath spread must simultaneously be both larger and smaller than the signal duration. In view of this contradiction, we assume that either time or frequency selectivity effects can occur with this channel but not simultaneously. For this channel we then can make the often used approximation

$$S(\xi, \nu) = P(\nu)Q(\xi) \quad (11.14)$$

which thus separates the frequency and time selectivity effects on the channel. Equation (11.14) points out the fact that time and frequency selectivity are independent phenomena.

Nonselective Channel

The nonselective fading channel exhibits neither frequency nor time selectivity. This channel is also called *time flat*, *frequency flat*, or just flat-flat. This channel is then the random-phase Rayleigh fading channel. For a transmitted signal given by Eq. (11.1), the received signal is

$$y(t) = A \operatorname{Re}[z(t)e^{j(2\pi f_c t - \theta)}] \quad (11.15)$$

where A and θ are statistically independent random variables that are time invariant, the former being Rayleigh distributed and the latter being uniformly distributed in the interval $-\pi$ to π .

The flat-flat fading model can closely approximate the behavior of a channel if the bandwidth of the transmitted signal is much less than the correlation bandwidth of the channel and if the transmitted pulse width is very much less than the correlation time of the fading. However, these two requirements are usually incompatible since the time-bandwidth product of the transmitted signal has a lower bound.

11.3 Line-of-Sight Channel Models

Multipath channel models for line-of-sight (LOS) radio systems assume a direct path in addition to one or more secondary paths observed at the receiver. The channel impulse response is modeled as a nonzero mean, complex Gaussian process, where the envelope has a Ricean distribution and the channel is known as a *Ricean fading channel*. Both multipath and polynomial transfer functions have been used to model the LOS channel.

Several multipath transfer function models have been developed, usually based on the presence of two [Jakes, 1978] or three [Rummler, 1979] rays. In general, the multipath channel transfer function can be written as

$$H(\omega) = 1 + \sum_{i=1}^n \beta_i e^{j\omega\tau_i} \quad (11.16)$$

where the direct ray has been normalized to unity and the β_i and τ_i are amplitude and delay of the interfering rays relative to the direct ray. The two-ray model can thus be characterized by two parameters, β and τ . In this case, the amplitude of the resultant signal is

$$R = (1 + \beta^2 + 2\beta\cos\omega\tau)^{1/2} \quad (11.17)$$

and the phase of the resultant is

$$\phi = \arctan\left(\frac{\beta \sin \omega \tau}{1 + \beta \cos \omega \tau}\right) \quad (11.18)$$

The group delay is then

$$T(\omega) = \frac{d\phi}{d\omega} = \beta \tau \left(\frac{\beta + \cos \omega \tau}{1 + 2\beta \cos \omega \tau + \beta^2} \right) \quad (11.19)$$

The deepest fade occurs with

$$\omega_d \tau = \pi(2n - 1) \quad (n = 1, 2, 3, \dots) \quad (11.20)$$

where both R and T are at a minimum, with

$$R_{\min} = 1 - \beta \quad (11.21)$$

$$T_{\min} = \frac{\beta \tau}{1 - \beta} \quad (11.22)$$

The frequency defined by ω_d is known as the notch frequency and is related to the carrier frequency ω_c by

$$\omega_d = \omega_c + \omega_0 \quad (11.23)$$

where ω_0 is referred to as the offset frequency.

Although the two-ray model described here is easy to understand and apply, most multipath propagation research points toward the presence of three (or more) rays during fading conditions. Out of this research, Rummler's three-ray model is the most widely accepted [Rummler, 1979].

Experiments conducted to develop or verify multipath channel models are limited by the narrowband channels available in existing radio systems. These limited channel bandwidths are generally insufficient to resolve parameters of a two- or three-ray multipath model. One alternative is to use polynomial functions of frequency to analytically fit measured data. Such polynomials have been used to describe amplitude and group delay distortion. Curve fits can be made to individual records of amplitude and group delay distortion using an M th-order polynomial,

$$p(\omega) = C_0 + C_1 \omega + C_2 \omega^2 + \dots + C_M \omega^M \quad (11.24)$$

To obtain the coefficients $\{C_1, C_2, \dots, C_M\}$, a least squares fit has been used with polynomials typically of order $M = 2, 4,$ and 6 . For fades that are frequency selective, the most suitable order has been found to be $M = 4$. During periods of nonfading or flat fading, polynomials of order $M = 0$ or 2 have provided acceptable accuracy [Smith and Cormack, 1982]. As shown by Greenstein and Czekaj [1980] these polynomial coefficients can be related to a power series model of the channel transfer function

$$H(\omega) = A_0 + \sum_{k=1}^n (A_k + jB_k)(j\omega)^k \quad (11.25)$$

Studies have shown that at least a first-order polynomial, with three coefficients $\{A_0, A_1,$ and $B_1\}$, is required for LOS channels, and that a second-order polynomial with five coefficients may be required for highly dispersive channels [Greenstein and Czekaj, 1980].

11.4 Digital Channel Models

For digital communications channels, one must be able to relate probability of (symbol, bit) error to the behavior of real channels, which tend to introduce errors in bursts. Two approaches may be taken. The classical method relates signal level variation to error rate statistics. Here, an equation for probability of error for a particular modulation technique is used to develop error statistics such as outage probability, outage rate, and outage duration for a given probability density function of signal level representing a certain channel. The drawback to this approach is the limitation of the results to only classical channels, such as Gaussian or Rayleigh, for which the signal statistics are known. As shown earlier, real channels tend to exhibit complex and time-varying behavior not easily represented by known statistics. For example, radio channels may experience time-selective fading, frequency-selective fading, rain attenuation, interference, and other forms of degradation at one time or another.

The second approach uses error models for channels with memory, that is, for channels where errors occur in bursts. If based on actual channel data, error models have the advantage of exactly reflecting the vagaries of the channel and, depending on the model, allowing various error statistics to be represented as a function of the model's parameters. The chief problem with error modeling is the selection of the model and its parameters to provide a good fit to the data and to the channel(s) in general. The Gilbert model focused on the use of a Markov chain composed of a good state G , which is error free, and a bad state B , with a certain probability of error [Gilbert, 1960]. Subsequent applications used a larger number of states in the Markov chain to better simulate error distributions in real channels. Fritchman [1967] first introduced the simple partitioned Markov chain with k error-free states and $N - k$ error states, which has shown good agreement with experimental results [Knowles and Drukarev, 1988; Semmar et al., 1991].

The single-error partitioned Fritchman model, in which the N states are divided into $N - 1$ error-free states and one error state, with transition probabilities P_{ij} , $i, j = 1$ to N , has been popularly used to characterize sequences of error-free and errored events (e.g., bits or symbols), known as gaps and clusters, respectively. For a binary error sequence where the presence or absence of a bit error is represented by 1 and 0, the error gap distribution $P(0^m|1)$ is the probability that at least m error-free bits will follow given that an errored bit has occurred. Similarly, the error cluster distribution $P(1^m|0)$ is the probability that at least m errored bits will follow given that an error-free bit has occurred. For the single-error Fritchman model [1967],

$$P(0^m|1) = \sum_{i=1}^k \frac{P_{N,i}}{P_{i,i}} (P_{i,i})^m \quad (11.26)$$

or

$$P(0^m|1) = \sum_{i=1}^k \alpha_i \beta_i^m \quad (11.27)$$

where the values α_i or β_i are the Fritchman model parameters. For $i = 1$ to k and $N - k = 1$, the transition probabilities are related to Fritchman's parameters by

$$P_{i,i} = \beta_i \quad (11.28)$$

$$P_{i,N} = 1 - \beta_i \quad (11.29)$$

$$P_{N,i} = \alpha_i \beta_i \quad (11.30)$$

$$P_{N,N} = 1 - \sum_{i=1}^k \alpha_i \beta_i \quad (11.31)$$

After obtaining $P(0^m|1)$ empirically for a given channel, curve fitting techniques can be employed to represent $P(0^m|1)$ as the sum of $(N - 1)$ exponentials, with coefficients α_i and β_i . Even simpler, for the single error state model, the error cluster distribution can be described with a single exponential with suitable coefficients α_N and β_N . Fritchman [1967] and others have found that a model with $k = 2$ or 3 exponential functions is generally sufficient. For high error rate sequences, a model with up to four exponential functions is required [Semmar et al., 1991].

Defining Terms

Coherence bandwidth: Bandwidth of a received signal for which fading is highly correlated.

Coherence time: Time interval of a received signal for which fading is highly correlated.

Doppler spread: Range of frequency over which the Doppler power spectrum is significantly different from zero.

Frequency-selective fading: Fading with high correlation for closely spaced frequencies and no correlation for widely spaced frequencies.

Multipath spread or delay spread: Range of time over which the delay power spectrum is significantly different from zero.

Time-selective fading: Fading with high correlation for closely spaced times and no correlation for widely spaced times.

12.1 Introduction

Every engineer strives for optimality in design. This is particularly true for communications engineers since in many cases implementing suboptimal receivers and sources can result in dramatic losses in performance. As such, this chapter focuses on design principles leading to the implementation of optimum receivers for the most common communication environments.

The main objective in digital communications is to transmit a sequence of bits to a remote location with the highest degree of accuracy. This is accomplished by first representing bits (or more generally short bit sequences) by distinct waveforms of finite time duration. These time-limited waveforms are then transmitted (broadcasted) to the remote sites in accordance with the data sequence.

Unfortunately, because of the nature of the **communication channel**, the remote location receives a corrupted version of the concatenated signal waveforms. The most widely accepted model for the communication channel is the so-called **additive white Gaussian noise¹ channel (AWGN channel)**. Mathematical arguments based upon the central limit theorem [7], together with supporting empirical evidence, demonstrate that many common communication channels are accurately modeled by this abstraction. Moreover, from the design perspective, this is quite fortuitous since design and analysis with respect to this channel model is relatively straightforward.

¹For those unfamiliar with AWGN, a random process (waveform) is formally said to be white Gaussian noise if all collections of instantaneous observations of the process are jointly Gaussian and mutually independent. An important consequence of this property is that the power spectral density of the process is a constant with respect to frequency variation (spectrally flat). For more on AWGN, see Papoulis [4].

12.2 Preliminaries

To better describe the digital communications process, we shall first elaborate on so-called binary communications. In this case, when the source wishes to transmit a bit value of 0, the transmitter broadcasts a specified waveform $s_0(t)$ over the **bit interval** $t \in [0, T]$. Conversely, if the source seeks to transmit the bit value of 1, the transmitter alternatively broadcasts the signal $s_1(t)$ over the same bit interval. The received waveform $R(t)$ corresponding to the first bit is then appropriately described by the following hypotheses testing problem:

$$\begin{aligned} H_0: R(t) &= s_0(t) + \eta(t) & 0 \leq t \leq T \\ H_1: R(t) &= s_1(t) + \eta(t) \end{aligned} \quad (12.1)$$

where, as stated previously, $\eta(t)$ corresponds to AWGN with spectral height nominally given by $N_0/2$. It is the objective of the receiver to determine the bit value, i.e., the most accurate hypothesis from the received waveform $R(t)$.

The optimality criterion of choice in digital communication applications is the **total probability of error** normally denoted as P_e . This scalar quantity is expressed as

$$\begin{aligned} P_e &= Pr(\text{declaring } 1|0 \text{ transmitted})Pr(0 \text{ transmitted}) \\ &\quad + Pr(\text{declaring } 0|1 \text{ transmitted})Pr(1 \text{ transmitted}) \end{aligned} \quad (12.2)$$

The problem of determining the optimal binary receiver with respect to the probability of error is solved by applying stochastic representation theory [10] to detection theory [5, 9]. The specific waveform representation of relevance in this application is the **Karhunen–Loève (KL) expansion**.

12.3 Karhunen–Loève Expansion

The Karhunen–Loève expansion is a generalization of the Fourier series designed to represent a random process in terms of deterministic basis functions and uncorrelated random variables derived from the process. Whereas the Fourier series allows one to model or represent deterministic time-limited energy signals in terms of linear combinations of complex exponential waveforms, the Karhunen–Loève expansion allows us to represent a second-order random process in terms of a set of **orthonormal** basis functions scaled by a sequence of random variables. The objective in this representation is to choose the basis of time functions so that the coefficients in the expansion are mutually uncorrelated random variables.

To be more precise, if $R(t)$ is a zero mean second-order random process defined over $[0, T]$ with covariance function $K_R(t, s)$, then so long as the basis of deterministic functions satisfy certain integral constraints [9], one may write $R(t)$ as

$$R(t) = \sum_{i=1}^{\infty} R_i \phi_i(t) \quad 0 \leq t \leq T \quad (12.3)$$

where

$$R_i = \int_0^T R(t) \phi_i(t) dt$$

In this case the R_i will be mutually uncorrelated random variables with the ϕ_i being deterministic basis functions that are complete in the space of square integrable time functions over $[0, T]$. Importantly, in this case, equality is to be interpreted as **mean-square equivalence**, i.e.,

$$\lim_{N \rightarrow \infty} E \left[\left(R(t) - \sum_{i=1}^N R_i \phi_i(t) \right)^2 \right] = 0$$

for all $0 \leq t \leq T$.

FACT 12.1 *If $R(t)$ is AWGN, then any basis of the vector space of square integrable signals over $[0, T]$ results in uncorrelated and therefore independent Gaussian random variables.*

The use of Fact 12.1 allows for a conversion of a continuous time detection problem into a finite-dimensional detection problem. Proceeding, to derive the optimal binary receiver, we first construct our set of basis functions as the set of functions defined over $t \in [0, T]$ beginning with the signals of interest $s_0(t)$ and $s_1(t)$. That is,

$\{s_0(t), s_1(t), \text{ plus a countable number of functions which complete the basis } \}$

In order to ensure that the basis is orthonormal, we must apply the Gramm–Schmidt procedure* [6] to the full set of functions beginning with $s_0(t)$ and $s_1(t)$ to arrive at our final choice of basis $\{\phi_i(t)\}$.

FACT 12.2 *Let $\{\phi_i(t)\}$ be the resultant set of basis functions.*

Then for all $i > 2$, the $\phi_i(t)$ are orthogonal to $s_0(t)$ and $s_1(t)$. That is,

$$\int_0^T \phi_i(t) s_j(t) dt = 0$$

for all $i > 2$ and $j = 0, 1$.

Using this fact in conjunction with Eq. (12.3), one may recognize that only the coefficients R_1 and R_2 are functions of our signals of interest. Moreover, since the R_i are mutually independent, the optimal receiver will, therefore, only be a function of these two values.

Thus, through the application of the KL expansion, we arrive at an equivalent hypothesis testing problem to that given in Eq. (12.1),

$$\begin{aligned} H_0: \mathbf{R} &= \begin{bmatrix} \int_0^T \phi_1(t) s_0(t) dt \\ \int_0^T \phi_2(t) s_0(t) dt \end{bmatrix} + \begin{bmatrix} \eta_1 \\ \eta_2 \end{bmatrix} \\ H_1: \mathbf{R} &= \begin{bmatrix} \int_0^T \phi_1(t) s_1(t) dt \\ \int_0^T \phi_2(t) s_1(t) dt \end{bmatrix} + \begin{bmatrix} \eta_1 \\ \eta_2 \end{bmatrix} \end{aligned} \tag{12.4}$$

where it is easily shown that η_1 and η_2 are mutually independent, zero-mean, Gaussian random variables with variance given by $N_0/2$, and where ϕ_1 and ϕ_2 are the first two functions from our orthonormal set of basis functions. Thus, the design of the optimal binary receiver reduces to a simple two-dimensional detection problem that is readily solved through the application of detection theory.

*The Gramm-Schmidt procedure is a deterministic algorithm that simply converts an arbitrary set of basis functions (vectors) into an equivalent set of orthonormal basis functions (vectors).

12.4 Detection Theory

It is well known from detection theory [5] that under the minimum P_e criterion, the optimal detector is given by the *maximum a posteriori rule (MAP)*,

$$\text{choose}_i \text{ largest } p_{H_i|\mathbf{R}}(H_i | \mathbf{R} = \mathbf{r}) \quad (12.5)$$

i.e., determine the hypothesis that is most likely, given that our observation vector is \mathbf{r} . By a simple application of Bayes theorem [4], we immediately arrive at the central result in detection theory: the optimal binary detector is given by the likelihood ratio test (LRT),

$$L(\mathbf{R}) = \frac{p_{\mathbf{R}|H_1}(\mathbf{R})}{p_{\mathbf{R}|H_0}(\mathbf{R})} \underset{H_0}{\overset{H_1}{>}} \frac{\pi_0}{\pi_1} \quad (12.6)$$

where the π_i are the *a priori* probabilities of the hypotheses H_i being true. Since in this case we have assumed that the noise is white and Gaussian, the LRT can be written as

$$L(\mathbf{R}) = \frac{\prod_1^2 \frac{1}{\sqrt{\pi N_0}} \exp\left(-\frac{1}{2} \frac{(R_i - s_{1,i})^2}{N_0/2}\right)}{\prod_1^2 \frac{1}{\sqrt{\pi N_0}} \exp\left(-\frac{1}{2} \frac{(R_i - s_{0,i})^2}{N_0/2}\right)} \underset{H_0}{\overset{H_1}{>}} \frac{\pi_0}{\pi_1} \quad (12.7)$$

where

$$s_{j,i} = \int_0^T \phi_i(t) s_j(t) dt$$

By taking the logarithm and cancelling common terms, it is easily shown that the optimum binary receiver can be written as

$$\frac{2}{N_0} \sum_1^2 R_i (s_{1,i} - s_{0,i}) - \frac{1}{N_0} \sum_1^2 (s_{1,i}^2 - s_{0,i}^2) \underset{H_0}{\overset{H_1}{>}} \ln \frac{\pi_0}{\pi_1} \quad (12.8)$$

This finite-dimensional version of the optimal receiver can be converted back into a continuous time receiver by the direct application of Parseval's theorem [4] where it is easily shown that

$$\begin{aligned} \sum_{i=1}^2 R_i s_{k,i} &= \int_0^T R(t) s_k(t) dt \\ \sum_{i=1}^2 s_{k,i}^2 &= \int_0^T s_k^2(t) dt \end{aligned} \quad (12.9)$$

By applying Eq. (12.9) to Eq. (12.8) the final receiver structure is then given by

$$\int_0^T R(t) [s_1(t) - s_0(t)] dt - \frac{1}{2} (E_1 - E_0) \underset{H_0}{\overset{H_1}{>}} \frac{N_0}{2} \ln \frac{\pi_0}{\pi_1} \quad (12.10)$$

FIGURE 12.1 Optimal correlation receiver structure for binary communications.

FIGURE 12.2 Optimal matched filter receiver structure for binary communications. In this case $h(t) = s_1(T - t) - s_0(T - t)$.

where E_1 and E_0 are the energies of signals $s_1(t)$ and $s_0(t)$, respectively. (See Fig. 12.1 for a block diagram.) Importantly, if the signals are equally likely ($\pi_0 = \pi_1$), the optimal receiver is independent of the typically unknown spectral height of the background noise.

One can readily observe that the optimal binary communication receiver correlates the received waveform with the difference signal $s_1(t) - s_0(t)$ and then compares the statistic to a threshold. This operation can be interpreted as identifying the signal waveform $s_i(t)$ that best correlates with the received signal $R(t)$. Based on this interpretation, the receiver is often referred to as the **correlation receiver**.

As an alternate means of implementing the correlation receiver, we may reformulate the computation of the left-hand side of Eq. (12.10) in terms of standard concepts in filtering. Let $h(t)$ be the impulse response of a linear, time-invariant (LTI) system. By letting $h(t) = s_1(T - t) - s_0(T - t)$, then it is easily verified that the output of $R(t)$ to a LTI system with impulse response given by $h(t)$ and then sampled at time $t = T$ gives the desired result. (See Fig. 12.2 for a block diagram.) Since the impulse response is matched to the signal waveforms, this implementation is often referred to as the **matched filter receiver**.

12.5 Performance

Because of the nature of the statistics of the channel and the relative simplicity of the receiver, performance analysis of the optimal binary receiver in AWGN is a straightforward task. Since the conditional statistics of the log likelihood ratio are Gaussian random variables, the probability of error can be computed directly in terms of Marcum Q functions* as

$$P_e = Q\left(\frac{\|\mathbf{s}_0 - \mathbf{s}_1\|}{\sqrt{2N_0}}\right)$$

where the \mathbf{s}_i are the two-dimensional signal vectors obtained from Eq. (12.4), and where $\|\mathbf{x}\|$ denotes the Euclidean length of the vector \mathbf{x} . Thus, $\|\mathbf{s}_0 - \mathbf{s}_1\|$ is best interpreted as the distance between the respective signal representations. Since the Q function is monotonically decreasing with an increasing argument,

*The Q function is the probability that a standard normal random variable exceeds a specified constant, i.e., $Q(x) = \int_x^\infty \frac{1}{\sqrt{2\pi}} \exp(-z^2/2) dz$.

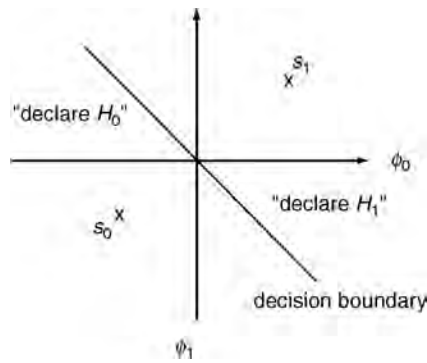

FIGURE 12.3 Signal space and decision boundary for optimal binary receiver.

one may recognize that the probability of error for the optimal receiver decreases with an increasing separation between the signal representations, i.e., the more dissimilar the signals, the lower the P_e .

12.6 Signal Space

The concept of a **signal space** allows one to view the signal classification problem (receiver design) within a geometrical framework. This offers two primary benefits: first, it supplies an often more intuitive perspective on the receiver characteristics (e.g., performance) and second, it allows for a straightforward generalization to standard M -ary signalling schemes.

To demonstrate this, in Fig. 12.3 we have plotted an arbitrary signal space for the binary signal classification problem. The axes are given in terms of the basis functions $\phi_1(t)$ and $\phi_2(t)$. Thus, every point in the signal space is a time function constructed as a linear combination of the two basis functions. By Fact 12.2 we recall that both signals $s_0(t)$ and $s_1(t)$ can be constructed as a linear combination of $\phi_1(t)$ and $\phi_2(t)$ and as such we may identify these two signals in this figure as two points.

Since the decision statistic given in Eq. (12.8) is a linear function of the observed vector \mathbf{R} which is also located in the signal space, it is easily shown that the set of vectors under which the receiver declares hypothesis H_i is bounded by a line in the signal space. This so-called **decision boundary** is obtained by solving the equation $\ln[L(\mathbf{R})] = 0$. (Here again we have assumed equally likely hypotheses.) In the case under current discussion, this decision boundary is simply the hyperplane separating the two signals in signal space. Because of the generality of this formulation, many problems in communication system design are best cast in terms of the signal space, that is, signal locations and decision boundaries.

12.7 Standard Binary Signalling Schemes

The framework just described allows us to readily analyze the most popular signalling schemes in binary communications: amplitude-shift keying (ASK), frequency-shift keying (FSK), and phase-shift keying (PSK). Each of these examples simply constitutes a different selection for signals $s_0(t)$ and $s_1(t)$.

In the case of ASK, $s_0(t) = 0$, while $s_1(t) = \sqrt{2E/T} \sin(2\pi f_c t)$, where E denotes the energy of the waveform and f_c denotes the frequency of the carrier wave with $f_c T$ being an integer. Because $s_0(t)$ is the null signal, the signal space is a one-dimensional vector space with $\phi_1(t) = \sqrt{2/T} \sin(2\pi f_c t)$. This, in turn, implies that $\|s_0 - s_1\| = \sqrt{E}$. Thus, the corresponding probability of error for ASK is

$$P_e(\text{ASK}) = Q\left(\sqrt{\frac{E}{2N_0}}\right)$$

For FSK, the signals are given by equal amplitude sinusoids with distinct center frequencies, that is, $s_i(t) = \sqrt{2E/T} \sin(2\pi f_i t)$ with $f_i T$ being two distinct integers. In this case, it is easily verified that the signal

FIGURE 12.4 P_e vs. the signal to noise ratio in decibels [$\text{dB} = 10 \log(E/N_0)$] for amplitude-shift keying, frequency-shift keying, and phase-shift keying; note that there is a 3-dB difference in performance from ASK to FSK to PSK.

space is a two-dimensional vector space with $\phi_i(t) = \sqrt{2/T} \sin(2\pi f_i t)$ resulting in $\|s_0 - s_1\| = \sqrt{2E}$. The corresponding error rate is given to be

$$P_e(\text{FSK}) = Q\left(\sqrt{\frac{E}{N_0}}\right)$$

Finally, with regard to PSK signalling, the most frequently utilized binary PSK signal set is an example of an antipodal signal set. Specifically, the antipodal signal set results in the greatest separation between the signals in the signal space subject to an energy constraint on both signals. This, in turn, translates into the energy constrained signal set with the minimum P_e . In this case, the $s_i(t)$ are typically given by $\sqrt{2E/T} \sin[2\pi f_c t + \theta(i)]$, where $\theta(0) = 0$ and $\theta(1) = \pi$. As in the ASK case, this results in a one-dimensional signal space, however, in this case $\|s_0 - s_1\| = 2\sqrt{E}$, resulting in probability of error given by

$$P_e(\text{PSK}) = Q\left(\sqrt{\frac{2E}{N_0}}\right)$$

In all three of the described cases, one can readily observe that the resulting performance is a function of only the signal-to-noise ratio E/N_0 . In the more general case, the performance will be a function of the intersignal energy to noise ratio. To gauge the relative difference in performance of the three signalling schemes, in Fig. 12.4, we have plotted the P_e as a function of the SNR. Please note the large variation in performance between the three schemes for even moderate values of SNR.

12.8 M -ary Optimal Receivers

In binary signalling schemes, one seeks to transmit a single bit over the bit interval $[0, T]$. This is to be contrasted with M -ary signalling schemes where one transmits multiple bits simultaneously over the so-called symbol interval $[0, T]$. For example, using a signal set with 16 separate waveforms will allow one to transmit a length four-bit sequence per symbol (waveform). Examples of M -ary waveforms are quadrature phase-shift keying (QPSK) and quadrature amplitude modulation (QAM).

The derivation of the optimum receiver structure for M -ary signalling requires the straightforward application of fundamental results in detection theory. As with binary signalling, the Karhunen–Loève expansion is the mechanism utilized to convert a hypotheses testing problem based on continuous waveforms into a vector classification problem. Depending on the complexity of the M waveforms, the signal space can be as large as an M -dimensional vector space.

By extending results from the binary signalling case, it is easily shown that the optimum M -ary receiver computes

$$\xi_i[R(t)] = \int_0^T s_i(t)R(t) dt - \frac{E_i}{2} + \frac{N_0}{2} \ln \pi_i \quad i = 1, \dots, M$$

where, as before, the $s_i(t)$ constitute the signal set with the π_i being the corresponding *a priori* probabilities. After computing M separate values of ξ_i , the minimum probability of error receiver simply chooses the largest amongst this set. Thus, the M -ary receiver is implemented with a bank of correlation or matched filters followed by choose-largest decision logic.

In many cases of practical importance, the signal sets are selected so that the resulting signal space is a two-dimensional vector space irrespective of the number of signals. This simplifies the receiver structure in that the sufficient statistics are obtained by implementing only two matched filters. Both QPSK and QAM signal sets fit into this category. As an example, in Fig. 12.5, we have depicted the signal locations for standard 16-QAM signalling with the associated decision boundaries. In this case, we have assumed an equally likely signal set. As can be seen, the optimal decision rule selects the signal representation that is closest to the received signal representation in this two-dimensional signal space.

FIGURE 12.5 Signal space representation of 16-QAM signal set. Optimal decision regions for equally likely signals are also noted.

FIGURE 12.6 Optimum receiver structure for noncoherent (random or unknown phase) ASK demodulation.

12.9 More Realistic Channels

As is unfortunately often the case, many channels of practical interest are not accurately modeled as simply an AWGN channel. It is often that these channels impose nonlinear effects on the transmitted signals. The best example of this is channels that impose a random phase and random amplitude onto the signal. This typically occurs in applications such as in mobile communications, where one often experiences rapidly changing path lengths from source to receiver.

Fortunately, by the judicious choice of signal waveforms, it can be shown that the selection of the ϕ_i in the Karhunen–Loève transformation is often independent of these unwanted parameters. In these situations, the random amplitude serves only to scale the signals in signal space, whereas the random phase simply imposes a rotation on the signals in signal space.

Since the Karhunen–Loève basis functions typically do not depend on the unknown parameters, we may again convert the continuous time classification problem to a vector channel problem where the received vector \mathbf{R} is computed as in Eq. (12.3). Since this vector is a function of both the unknown parameters (i.e., in this case amplitude A and phase ν), to obtain a likelihood ratio test independent of A and ν , we simply apply Bayes theorem to obtain the following form for the LRT:

$$L(\mathbf{R}) = \frac{E[p_{\mathbf{R}|H_1, A, \nu}(\mathbf{R}|H_1, A, \nu)] > \pi_0}{E[p_{\mathbf{R}|H_0, A, \nu}(\mathbf{R}|H_0, A, \nu)] < \pi_1} \quad \begin{matrix} H_1 \\ H_0 \end{matrix}$$

where the expectations are taken with respect to A and ν and where $p_{\mathbf{R}|H_i, A, \nu}$ are the conditional probability density functions of the signal representations. Assuming that the background noise is AWGN, it can be shown that the LRT simplifies to choosing the largest amongst

$$\xi_i[R(t)] = \pi_i \int_{A, \nu} \exp \left\{ \frac{2}{N_0} \int_0^T R(t) s_i(t|A, \nu) dt - \frac{E_i(A, \nu)}{N_0} \right\} p_{A, \nu}(A, \nu) dA d\nu \quad (12.11)$$

$$i = 1, \dots, M$$

It should be noted that in Eq. (12.11) we have explicitly shown the dependence of the transmitted signals s_i on the parameters A and ν . The final receiver structures, together with their corresponding performance are, thus, a function of both the choice of signal sets and the probability density functions of the random amplitude and random phase.

Random Phase Channels

If we consider first the special case where the channel simply imposes a uniform random phase on the signal, then it can be easily shown that the so-called in-phase and quadrature statistics obtained from the received signal $R(t)$ (denoted by R_I and R_Q , respectively) are sufficient statistics for the signal classification problem. These quantities are computed as

$$R_I(i) = \int_0^T R(t) \cos[2\pi f_c(i)t] dt$$

and

$$R_Q(i) = \int_0^T R(t) \sin[2\pi f_c(i)t] dt$$

where, in this case, the index i corresponds to the center frequencies of hypotheses H_i , (e.g., FSK signalling). The optimum binary receiver selects the largest from amongst

$$\xi_i[R(t)] = \pi_i \exp\left(-\frac{E_i}{N_0}\right) I_0\left[\frac{2}{N_0} \sqrt{R_I^2(i) + R_Q^2(i)}\right] \quad i = 1, \dots, M$$

where I_0 is a zeroth-order, modified Bessel function of the first kind. If the signals have equal energy and are equally likely (e.g., FSK signalling), then the optimum receiver is given by

$$\begin{array}{c} H_1 \\ R_I^2(1) + R_Q^2(1) > R_I^2(0) + R_Q^2(0) \\ < \\ H_0 \end{array}$$

One may readily observe that the optimum receiver bases its decision on the values of the two envelopes of the received signal $\sqrt{R_I^2(i) + R_Q^2(i)}$ and, as a consequence, is often referred to as an envelope or square-law detector. Moreover, it should be observed that the computation of the envelope is independent of the underlying phase of the signal and is, as such, known as a noncoherent receiver.

The computation of the error rate for this detector is a relatively straightforward exercise resulting in

$$P_e(\text{noncoherent}) = \frac{1}{2} \exp\left(-\frac{E}{2N_0}\right)$$

As before, note that the error rate for the noncoherent receiver is simply a function of the SNR.

Rayleigh Channel

As an important generalization of the described random phase channel, many communication systems are designed under the assumption that the channel introduces both a random amplitude and a random phase on the signal. Specifically, if the original signal sets are of the form $s_i(t) = m_i(t) \cos(2\pi f_c t)$ where $m_i(t)$ is the baseband version of the message (i.e., what distinguishes one signal from another), then the so-called **Rayleigh channel** introduces random distortion in the received signal of the following form:

$$s_i(t) = A m_i(t) \cos(2\pi f_c t + \nu)$$

where the amplitude A is a Rayleigh random variable* and where the random phase ν is a uniformly distributed between zero and 2π .

*The density of a Rayleigh random variable is given by $p_A(a) = a/\sigma^2 \exp(-a^2/2\sigma^2)$ for $a \geq 0$.

To determine the optimal receiver under this distortion, we must first construct an alternate statistical model for $s_i(t)$. To begin, it can be shown from the theory of random variables [4] that if X_I and X_Q are statistically independent, zero mean, Gaussian random variables with variance given by σ^2 , then

$$A m_i(t) \cos(2\pi f_c t + \nu) = m_i(t) X_I \cos(2\pi f_c t) + m_i(t) X_Q \sin(2\pi f_c t)$$

Equality here is to be interpreted as implying that both A and ν will be the appropriate random variables. From this, we deduce that the combined uncertainty in the amplitude and phase of the signal is incorporated into the Gaussian random variables X_I and X_Q . The in-phase and quadrature components of the signal $s_i(t)$ are given by $s_{I_i}(t) = m_i(t) \cos(2\pi f_c t)$ and $s_{Q_i}(t) = m_i(t) \sin(2\pi f_c t)$ respectively. By appealing to Eq. (12.11), it can be shown that the optimum receiver selects the largest from

$$\xi_i[R(t)] = \frac{\pi_i}{1 + \frac{2E_i}{N_0}\sigma^2} \exp \left[\frac{\sigma^2}{\frac{1}{2} + \frac{E_i}{N_0}\sigma^2} (\langle R(t), s_{I_i}(t) \rangle^2 + \langle R(t), s_{Q_i}(t) \rangle^2) \right]$$

where the inner product

$$\langle R(t), S_i(t) \rangle = \int_0^T R(t) s_i(t) dt$$

Further, if we impose the conditions that the signals be equally likely with equal energy over the symbol interval, then the optimum receiver selects the largest amongst

$$\xi_i[R(t)] = \sqrt{\langle R(t), s_{I_i}(t) \rangle^2 + \langle R(t), s_{Q_i}(t) \rangle^2}$$

Thus, much like for the random phase channel, the optimum receiver for the Rayleigh channel computes the projection of the received waveform onto the in-phase and quadrature components of the hypothetical signals. From a signal space perspective, this is akin to computing the length of the received vector in the subspace spanned by the hypothetical signal. The optimum receiver then chooses the largest amongst these lengths.

As with the random phase channel, computing the performance is a straightforward task resulting in (for the equally likely equal energy case)

$$P_e(\text{Rayleigh}) = \frac{\frac{1}{2}}{\left(1 + \frac{E\sigma^2}{N_0}\right)}$$

Interestingly, in this case, the performance depends not only on the SNR, but also on the variance (spread) of the Rayleigh amplitude A . Thus, if the amplitude spread is large, we expect to often experience what is known as deep fades in the amplitude of the received waveform and, as such, expect a commensurate loss in performance.

12.10 Dispersive Channels

The **dispersive channel** model assumes that the channel not only introduces AWGN but also distorts the signal through a filtering process. This model incorporates physical realities such as multipath effects and frequency selective fading. In particular, the standard model adopted is depicted in the block diagram given in Fig. 12.7. As can be seen, the receiver observes a filtered version of the signal plus AWGN. If the impulse response of the channel is known, then we arrive at the optimum receiver design by applying the previously presented theory. Unfortunately, the duration of the filtered signal can be a complicating factor.

FIGURE 12.7 Standard model for dispersive channel. The time varying impulse response of the channel is denoted by $h_c(t, \tau)$.

More often than not, the channel will increase the duration of the transmitted signals, hence, leading to the description, dispersive channel.

However, if the designers take this into account by shortening the duration of $s_i(t)$ so that the duration of $s_i^*(t)$ is less than T , then the optimum receiver chooses the largest amongst

$$\xi_i(R(t)) = \frac{N_0}{2} \ln \pi_i + \langle R(t), s_i^*(t) \rangle - \frac{1}{2} E_i^*$$

If we limit our consideration to equally likely binary signal sets, then the minimum P_e matches the received waveform to the filtered versions of the signal waveforms. The resulting error rate is given by

$$P_e(\text{dispersive}) = Q\left(\frac{\|s_0^* - s_1^*\|}{\sqrt{2N_0}}\right)$$

Thus, in this case, the minimum P_e is a function of the separation of the filtered version of the signals in the signal space.

The problem becomes substantially more complex if we cannot insure that the filtered signal durations are less than the symbol lengths. In this case, we experience what is known as **intersymbol interference (ISI)**. That is, observations over one symbol interval contain not only the symbol information of interest but also information from previous symbols. In this case, we must appeal to optimum sequence estimation [5] to take full advantage of the information in the waveform. The basis for this procedure is the maximization of the joint likelihood function conditioned on the sequence of symbols. This procedure not only defines the structure of the optimum receiver under ISI but also is critical in the decoding of convolutional codes and coded modulation. Alternate adaptive techniques to solve this problem involve the use of channel equalization.

Defining Terms

Additive white Gaussian noise (AWGN) channel: The channel whose model is that of corrupting a transmitted waveform by the addition of white (i.e., spectrally flat) Gaussian noise.

Bit (symbol) interval: The period of time over which a single symbol is transmitted.

Communication channel: The medium over which communication signals are transmitted. Examples are fiber optic cables, free space, or telephone lines.

Correlation or matched filter receiver: The optimal receiver structure for digital communications in AWGN.

Decision boundary: The boundary in signal space between the various regions where the receiver declares H_i . Typically a hyperplane when dealing with AWGN channels.

Dispersive channel: A channel that elongates and distorts the transmitted signal. Normally modeled as a time-varying linear system.

Intersymbol interference: The ill-effect of one symbol smearing into adjacent symbols thus interfering with the detection process. This is a consequence of the channel filtering the transmitted signals and therefore elongating their duration. See **dispersive channel**.

Karhunen–Loève expansion: A representation for second-order random processes. Allows one to express a random process in terms of a superposition of deterministic waveforms. The scale values are uncorrelated random variables obtained from the waveform.

Mean-square equivalence: Two random vectors or time-limited waveforms are mean-square equivalent if and only if the expected value of their mean-square error is zero.

Orthonormal: The property of two or more vectors or time-limited waveforms being mutually orthogonal and individually having unit length. Orthogonality and length are typically measured by the standard Euclidean inner product.

Rayleigh channel: A channel that randomly scales the transmitted waveform by a Rayleigh random variable while adding an independent uniform phase to the carrier.

Signal space: An abstraction for representing a time limited waveform in a low-dimensional vector space. Usually arrived at through the application of the Karhunen–Loève transformation.

Total probability of error: The probability of classifying the received waveform into any of the symbols that were not transmitted over a particular bit interval.

13.1 Introduction

In 1948, Claude Shannon issued a challenge to communications engineers by proving that communication systems could be made arbitrarily reliable as long as a fixed percentage of the transmitted signal was redundant [Shannon, 1948]. He showed that limits exist only on the rate of communication and not its accuracy, and he went on to prove that errorless transmission could be achieved in an additive white Gaussian noise (AWGN) environment with infinite bandwidth if the ratio of energy per data bit to noise power spectral density exceeds the **Shannon limit** of -1.6 dB. He did not, however, indicate how this could be achieved. Subsequent research has led to a number of techniques that introduce redundancy to allow for correction of errors without retransmission. These techniques, collectively known as forward error correction (FEC) coding techniques, are used in systems where a reverse channel is not available for requesting retransmission, the delay with retransmission would be excessive, the expected number of errors would require a large number of retransmissions, or retransmission would be awkward to implement [Sklar, 1988].

A simplified model of a digital communication system that incorporates FEC coding is shown in Fig. 13.1. The FEC code acts on a **discrete data channel** comprised of all system elements between the encoder output and decoder input. The encoder maps the source data to q -ary code symbols that are modulated and transmitted. During transmission, this signal can be corrupted, causing errors to arise in the demodulated symbol sequence. The FEC decoder attempts to correct these errors and restore the original source data.

A demodulator that outputs only a value for the q -ary symbol received during each symbol interval is said to make **hard decisions**. In the **binary symmetric channel** (BSC), hard decisions are made on binary symbols and the probability of error is independent of the value of the symbol. One example of

FIGURE 13.1 Block diagram of a digital communication system with forward error correction.

FIGURE 13.2 Hard and soft decision demodulation of a coherently-demodulated BPSK signal corrupted by AWGN. $f(z|1)$ and $f(z|0)$ are the Gaussianly distributed conditional probability density functions at the threshold device.

a BSC is the coherently demodulated BPSK signal corrupted by AWGN. The conditional probability density functions that result with this system are depicted in Fig. 13.2. The probability of error is given by the area under the density functions that lies across the decision threshold and is a function of the symbol energy E_s and the one-sided noise power spectral density N_0 .

Alternatively, the demodulator can make **soft decisions**, or output an estimate of the symbol value along with an indication of its confidence in this estimate. For example, if the BPSK demodulator uses three-bit quantization, the two least significant bits can be taken as a confidence measure. Possible soft-decision thresholds for the BPSK signal are depicted in Fig. 13.2. In practice, there is little to be gained by using many soft-decision quantization levels.

Block and convolutional codes introduce redundancy by adding parity symbols to the message data. They map k source symbols to n code symbols and are said to have **code rate** $R = k/n$. With fixed information rates, this redundancy results in increased bandwidth and lower energy per transmitted symbol. At low signal to noise ratios, these codes cannot compensate for these impairments, and performance is degraded. However, at higher ratios of information symbol energy E_b to noise spectral density N_0 , there is **coding gain** since the performance improvement offered by coding more than compensates for these impairments. Coding gain is usually defined as the reduction in required E_b/N_0 to achieve a specific error rate in an error-control coded system over one without coding. In contrast to block and convolutional codes, trellis-coded modulation introduces redundancy by expanding the size of the signal set rather than increasing the number of symbols transmitted and so offers the advantages of coding to bandlimited systems.

Each of these coding techniques is considered in turn. Following a discussion of interleaving and concatenated coding, an overview is given of the most recent significant advance in FEC coding, the development of turbo codes. A brief overview of FEC applications concludes this chapter.

13.2 Fundamentals of Block Coding

In block codes there is a one-to-one mapping between k -symbol source words and n -symbol codewords. With q -ary signaling, q^k out of the q^n possible n -tuples are valid code vectors. The set of all n -tuples forms a **vector space** in which the q^k code vectors are distributed. The **Hamming distance** between any two code vectors is the number of symbols in which they differ; the **minimum distance** d_{\min} of the code is the smallest Hamming distance between any two codewords.

Contradictory objectives of block codes are:

- to distribute the code vectors in the vector space such that the distance between them is maximized. Then, if the decoder receives a corrupted vector, by evaluating the nearest valid code vector it will decode the correct word with high probability.
- to pack the vector space with as many code vectors as possible to reduce the redundancy in transmission.

When code vectors differ in at least d_{\min} positions, a decoder that evaluates the nearest code vector to each received word is guaranteed to correct up to t random symbol errors per word if

$$d_{\min} \geq 2t + 1 \quad (13.1)$$

Alternatively, all $q^n - q^k$ illegal words can be detected, including all error patterns with $d_{\min} - 1$ or fewer errors. In general, a block code can correct all patterns of t or fewer errors and detect all patterns of u or fewer errors provided that $u \geq t$ and

$$d_{\min} \geq t + u + 1 \quad (13.2)$$

If $q = 2$, knowledge of the positions of the errors is sufficient for their correction; if $q > 2$, the decoder must determine both the positions and values of the errors. If the demodulator indicates positions in which the symbol values are unreliable, the decoder can assume their value unknown and has only to solve for the value of these symbols. These positions are called **erasures**. A block code can correct up to t errors and v erasures in each word if

$$d_{\min} \geq 2t + v + 1 \quad (13.3)$$

13.3 Structure and Decoding of Block Codes

Shannon showed that the performance limit of codes with fixed code rate improves as the block length increases. However, as n and k increase, practical implementation requires that the mapping from message to code vector not be arbitrary but that an underlying structure to the code exist. The structures developed to date limit the error correcting capability of these codes to below what Shannon proved possible, on average, for a code with random codeword assignments. Although turbo codes have made significant strides toward approaching the Shannon limit, the search for good constructive codes continues.

A property which simplifies implementation of the coding operations is that of code linearity. A code is **linear** if the addition of any two code vectors forms another code vector, which implies that the code vectors form a subspace of the vector space of n -tuples. This subspace, which contains the all-zero vector, is spanned by any set of k linearly independent code vectors. Encoding can be described as the multiplication of the information k -tuple by a **generator matrix** \mathbf{G} , of dimension $k \times n$, which contains these basis vectors as rows. That is, a message vector \mathbf{m}_i is mapped to a code vector \mathbf{c}_i according to

$$\mathbf{c}_i = \mathbf{m}_i \mathbf{G}, \quad i = 0, 1, \dots, q^k - 1 \quad (13.4)$$

where element-wise arithmetic is defined in the **finite field** $\text{GF}(q)$. In general, this encoding procedure results in code vectors with non-systematic form in that the values of the message symbols cannot be determined by inspection of the code vector. However, if \mathbf{G} has the form $[\mathbf{I}_k \ \mathbf{P}]$ where \mathbf{I}_k is the $k \times k$ identity matrix and \mathbf{P} is a $k \times (n - k)$ matrix of parity checks, then the k most significant symbols of each code vector are identical to the message vector and the code has **systematic** form. This notation assumes

that vectors are written with their most significant or first symbols in time on the left, a convention used throughout this article.

For each generator matrix there is an $(n - k) \times k$ **parity check matrix** \mathbf{H} whose rows are orthogonal to the rows in \mathbf{G} , i.e., $\mathbf{GH}^T = \mathbf{0}$. If the code is systematic, $\mathbf{H} = [\mathbf{P}^T, \mathbf{I}_{n-k}]$. Since all codewords are linear sums of the rows in \mathbf{G} , it follows that $\mathbf{c}\mathbf{H}^T = \mathbf{0}$ for all i , $i = 0, 1, \dots, q^k - 1$, and that the validity of the demodulated vectors can be checked by performing this multiplication. If a codeword \mathbf{c} is corrupted during transmission so that the hard-decision demodulator outputs the vector $\hat{\mathbf{c}} = \mathbf{c} + \mathbf{e}$, where \mathbf{e} is a non-zero error pattern, the result of this multiplication is an $(n - k)$ -tuple that is indicative of the validity of the sequence. This result, called the **syndrome** \mathbf{s} , is dependent only on the error pattern since

$$\mathbf{s} = \hat{\mathbf{c}}\mathbf{H}^T = (\mathbf{c} + \mathbf{e})\mathbf{H}^T = \mathbf{c}\mathbf{H}^T + \mathbf{e}\mathbf{H}^T = \mathbf{e}\mathbf{H}^T \quad (13.5)$$

If the error pattern is a code vector, the errors go undetected. However, for all other error patterns, the syndrome is non-zero. Since there are $q^{n-k} - 1$ non-zero syndromes, $q^{n-k} - 1$ error patterns can be corrected. When these patterns include all those with t or fewer errors and no others, the code is said to be a **perfect code**. Few codes are perfect; most codes are capable of correcting some patterns with more than t errors. **Standard array decoders** use look-up tables to associate each syndrome with an error pattern but become impractical as the block length and number of parity symbols increases. Algebraic decoding algorithms have been developed for codes with stronger structure. These algorithms are simplified with imperfect codes if the patterns corrected are limited to those with t or fewer errors, a simplification called **bounded distance decoding**.

Cyclic codes are a subclass of linear block codes with an algebraic structure that enables encoding to be implemented with a linear feedback shift register and decoding to be implemented without a look-up table. As a result, most block codes in use today are cyclic or are closely related to cyclic codes. These codes are best described if vectors are interpreted as polynomials and arithmetic follows the rules for polynomials where the element-wise operations are defined in $\text{GF}(q)$. In a cyclic code, all codeword polynomials are multiples of a **generator polynomial** $g(x)$ of degree $n - k$. This polynomial is chosen to be a divisor of $x^n - 1$ so that a cyclic shift of a code vector yields another code vector, giving this class of codes its name. A message polynomial $m_i(x)$ can be mapped to a codeword polynomial $c_i(x)$ in non-systematic form as

$$c_i(x) = m_i(x)g(x), \quad i = 0, 1, \dots, q^k - 1 \quad (13.6)$$

In systematic form, codeword polynomials have the form

$$c_i(x) = m_i(x)x^{n-k} - r_i(x), \quad i = 0, 1, \dots, q^k - 1 \quad (13.7)$$

where $r_i(x)$ is the remainder of $m_i(x)x^{n-k}$ divided by $g(x)$. Polynomial multiplication and division can be easily implemented with shift registers [Blahut, 1983].

The first step in decoding the demodulated word is to determine if the word is a multiple of $g(x)$. This is done by dividing it by $g(x)$ and examining the remainder. Since polynomial division is a linear operation, the resulting syndrome $s(x)$ depends only on the error pattern. If $s(x)$ is the all-zero polynomial, transmission is errorless or an undetectable error pattern has occurred. If $s(x)$ is non-zero, at least one error has occurred. This is the principle of the **cyclic redundancy check** (CRC). It remains to determine the most likely error pattern that could have generated this syndrome.

Single error correcting binary codes can use the syndrome to immediately locate the bit in error. More powerful codes use this information to determine the locations and values of multiple errors. The most prominent approach of doing so is with the iterative technique developed by Berlekamp. This technique, which involves computing an error-locator polynomial and solving for its roots, was subsequently interpreted by Massey in terms of the design of a minimum-length shift register. Once the location and values

of the errors are known, Chien's search algorithm efficiently corrects them. The implementation complexity of these decoders increases only as the square of the number of errors to be corrected [Bhargava, 1983] but does not generalize easily to accommodate soft-decision information. Other decoding techniques, including Chase's algorithm and threshold decoding, are easier to implement with soft-decision input [Clark and Cain, 1981]. Berlekamp's algorithm can be used in conjunction with transform-domain decoding which involves transforming the received block with a finite field Fourier-like transform and solving for errors in the transform domain. Since the implementation complexity of these decoders depends on the block length rather than the number of symbols corrected, this approach results in simpler circuitry for codes with high redundancy [Wu et al., 1987].

Other block codes have also been constructed, including product codes that extend the above ideas to two or more dimensions, codes that are based on transform-domain spectral properties, codes designed specifically for correction of burst errors, and codes that are decodable with straightforward threshold or majority logic decoders [Blahut, 1983; Clark and Cain, 1981; Lin and Costello, 1983].

13.4 Important Classes of Block Codes

When errors occur independently, Bose–Chaudhuri–Hocquenghem (BCH) codes provide among the best performance of known codes for a given block length and code rate. They are cyclic codes with $n = q^m - 1$ where m is any integer greater than two. They are designed to correct up to t errors per word and so have **designed distance** $d = 2t + 1$; the minimum distance may be greater. Generator polynomials for these codes are listed in many texts, including [Clark and Cain, 1981]. These polynomials have degree less than or equal to mt , and so $k \geq n - mt$. BCH codes can be shortened to accommodate system requirements by deleting positions for information symbols.

Some subclasses of these codes are of special interest. Hamming codes are perfect single error correcting binary BCH codes. Full length Hamming codes have $n = 2^m - 1$ and $k = n - m$ for any m greater than two. The duals of these codes are maximal-length codes, with $n = 2^m - 1$, $k = m$, and $d_{\min} = 2^{m-1}$. All $2^m - 1$ non-zero code vectors in these codes are cyclic shifts of a single non-zero code vector. Reed–Solomon (RS) codes are non-binary BCH codes defined over $GF(q)$, where q is often taken as a power of two so that symbols can be represented by a sequence of bits. In these cases, correction of even a single symbol allows for correction of a burst of bit errors. The block length is $n = q - 1$, and the minimum distance $d_{\min} = 2t + 1$ is achieved using only $2t$ parity symbols. Since RS codes meet the Singleton bound of $d_{\min} \leq n - k + 1$, they have the largest possible minimum distance for these values of n and k and are called **maximum distance separable** codes.

The Golay codes are the only non-trivial perfect codes that can correct more than one error. The (11, 6) ternary Golay code has minimum distance five. The (23, 12) binary code is a triple error correcting BCH code with $d_{\min} = 7$. To simplify implementation, it is often extended to a (24, 12) code through addition of an extra parity bit. The extended code has $d_{\min} = 8$.

The (23, 12) Golay code is also a binary quadratic residue code. These cyclic codes have prime length of the form $n = 8m \pm 1$, with $k = (n + 1)/2$ and $d_{\min} \geq \sqrt{n}$. Some of these codes are as good as the best codes known with these values of n and k , but it is unknown if there are good quadratic residue codes with large n [Blahut, 1983].

Reed–Muller codes are equivalent to binary cyclic codes with an additional overall parity bit. For any m , the r th-order Reed–Muller code has $n = 2^m$, $k = \sum_{i=0}^r \binom{m}{i}$, and $d_{\min} = 2^{m-r}$. The r th-order and $(m - r - 1)$ th-order codes are duals, and the first order codes are similar to maximal-length codes. These codes, and the closely related Euclidean geometry and projective geometry codes, can be decoded with threshold decoding.

The performance of several of these block codes is shown in Fig. 13.3 in terms of decoded bit error probability vs. E_b/N_0 for systems using coherent, hard-decision demodulated BPSK signaling. Many other block codes have also been developed, including Goppa codes, quasi-cyclic codes, burst error correcting Fire codes, and other lesser-known codes.

FIGURE 13.3 Block code performance. (From Sklar, B., 1988, *Digital Communications: Fundamentals and Applications*, Prentice-Hall, Englewood Cliffs, NJ. With permission.)

13.5 Principles of Convolutional Coding

Convolutional codes map successive information k -tuples to a series of n -tuples such that the sequence of n -tuples has distance properties that allow for detection and correction of errors. Although these codes can be defined over any alphabet, their implementation has largely been restricted to binary signals, and only binary convolutional codes are considered here.

In addition to the code rate $R = k/n$, the **constraint length** K is an important parameter for these codes. Definitions vary; we will use the definition that K equals the number of k -tuples that affect formation of each n -tuple during encoding. That is, the value of an n -tuple depends on the k -tuple which arrives at the encoder during that encoding interval as well as the $K - 1$ previous information k -tuples.

Binary convolutional encoders can be implemented with $k(K - 1)$ -stage shift registers and n modulo-2 adders, an example of which is given in Fig. 13.4(a) for a rate 1/2, constraint length 3 code. The structure depicted in this figure is the encoder for a non-recursive, non-systematic convolutional code because the encoder does not involve feedback and the data sequence is not directly visible in the encoded sequence; recursive and systematic structures are described below. Regardless of their recursive or systematic nature, each convolutional encoder shifts in a new k -tuple during each encoding interval and samples the outputs of the adders sequentially to form the coded output.

Although connection diagrams similar to that of Fig. 13.4(a) completely describe the code, a more concise description can be given by stating the values of n , k , and K and giving the adder connections in the form of vectors or polynomials. For instance, the rate 1/2 code has the generator vectors $\mathbf{g}_1 = 111$ and $\mathbf{g}_2 = 101$, or equivalently, the generator polynomials $g_1(x) = x^2 + x + 1$ and $g_2(x) = x^2 + 1$. Since feedforward shift registers of this form implement polynomial multiplication [Blahut, 1983], the sequence of bits from each tap can be interpreted as the product of the source sequence and the corresponding

(d) Trellis diagram

FIGURE 13.4 A rate 1/2, constraint length 3, non-recursive, non-systematic convolutional code.

generator polynomial. Alternatively, a convolutional code can be characterized by its impulse response, the coded sequence generated due to input of a single logic-1. It is straightforward to verify that the impulse response of the circuit in Fig. 13.4(a) is 111011 followed by zeros. Since modulo-2 addition is a linear operation, convolutional codes are linear and the coded output can be viewed as the convolution of the input sequence with the impulse response, hence the name of this coding technique. Shifted versions of the impulse response or generator vectors can be combined to form an infinite-order generator matrix that also describes the code.

Shift register circuits can be modeled as finite state machines. A Mealy machine description of a convolutional encoder requires $2^{k(K-1)}$ states, each describing a different value of the $K - 1$ k -tuples in the shift register. Each state has 2^k exit paths that correspond to the value of the incoming k -tuple. A state machine description for the rate 1/2 encoder depicted in Fig. 13.4(a) is given in Fig. 13.4(b). States are labeled with the contents of the shift register; edges are labeled with information bit values followed by their corresponding coded output.

The dimension of time is added to the description of the encoder with tree and trellis diagrams. The tree diagram for the rate 1/2 convolutional code is given in Fig. 13.4(c), assuming the shift register is initially clear. Each node represents an encoding interval, from which the upper branch is taken if the input bit is a 0 and the lower branch is taken if the input bit is a 1. Each branch is labeled with the corresponding output bit sequence. A drawback of the tree representation is that it grows without bound as the length of the input sequence increases. This is overcome with the trellis diagram depicted in Fig. 13.4(d). Again, encoding results in left-to-right movement, where the upper of the two branches is taken whenever the input is a 0, the lower branch is taken when the input is a 1, and the output is the bit sequence that weights the branch taken. Each level of nodes corresponds to a state of the encoder, as shown on the left-hand side of the diagram.

Figure 13.5(a) depicts a recursive systematic convolutional encoder that generates a code that is equivalent to the code depicted in Fig. 13.4. This encoder is systematic because the source bit stream is copied directly into the encoded sequence; it is recursive because it involves feedback. Since a feedback shift register implements polynomial division, the sequence of non-systematic bits can be interpreted as the source sequence divided by the feedback polynomial $g_1(x) = x^2 + x + 1$ and multiplied by the feedforward polynomial $g_2(x) = x^2 + 1$. The codes in Figs. 13.4 and 13.5 are equivalent because their state diagrams, code trees, and trellises are identical with the exception of the mapping from source sequence to encoded sequence. For example, the state diagram in Fig. 13.5(b) for the recursive systematic code exhibits the same structure as the diagram in Fig. 13.4(b); only the input data bits weighting some of the branches differ. Recursive non-systematic codes and non-recursive systematic codes also exist.

If the received sequence contains errors, it may no longer depict a valid path through the tree or trellis. It is the job of the decoder to determine the original path. In doing so, the decoder does not so much correct errors as find the closest valid path to the received sequence. As a result, the error correcting

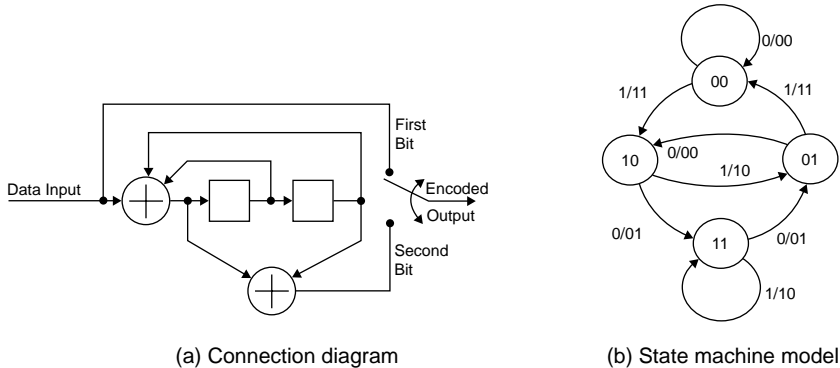

FIGURE 13.5 A rate 1/2, constraint length 3, recursive systematic convolutional code.

capability of a convolutional code is more difficult to quantify than that of a block code; it depends on how valid paths differ. One measure of this difference is the **column distance** $d_c(i)$, the minimum Hamming distance between all coded sequences generated over i encoding intervals that differ in the first interval. The non-decreasing sequence of column distance values is the **distance profile** of the code. The column distance after K intervals is the minimum distance of the code, and is important for evaluating the performance of a code that uses threshold decoding. As i increases, $d_c(i)$ approaches the **free distance** of the code d_{free} which is the minimum Hamming distance in the set of arbitrarily long paths that diverge and then remerge in the trellis.

With maximum likelihood decoding, convolutional codes can generally correct up to t errors within three to five constraint lengths, depending on how the errors are distributed, where

$$d_{\text{free}} \geq 2t + 1 \quad (13.8)$$

The free distance can be calculated by exhaustively searching for the minimum weight path that returns to the all-zero state or by evaluating the term of lowest degree in the generating function of the code.

The objective of a convolutional code is to maximize these distance properties. They generally improve as the constraint length of the code increases, and non-recursive, non-systematic codes generally have better properties than non-recursive systematic ones. As indicated above, non-recursive, non-systematic codes always have an equivalent recursive systematic form that has identical distance properties. Good codes have been found by computer search and are tabulated in many texts, including [Clark and Cain, 1981].

Convolutional codes with high code rate can be constructed by **puncturing** or periodically deleting coded symbols from a low rate code. A list of low rate codes and perforation matrices that result in good high rate codes can be found in many sources, including [Wu et al., 1987]. The performance of good punctured codes approaches that of the best convolutional codes known with similar rate, and decoder implementation is significantly less complex.

Convolutional codes can be **catastrophic**, having the potential to generate an unlimited number of decoded bit errors in response to a finite number of errors in the demodulated bit sequence. Catastrophic error propagation is avoided if the code has generator polynomials with a greatest common divisor of the form x^a for any a , or equivalently, if there are no closed loop paths in the state diagram with all-zero output other than the one taken with all-zero input. Systematic codes are not catastrophic.

13.6 Decoding of Convolutional Codes

Maximum Likelihood Decoding

Maximum likelihood (ML) decoding selects the source sequence \mathbf{m}_i that maximizes the probability $P(\mathbf{x}|\mathbf{m}_i)$, $i \in 0, 1, \dots, 2^L - 1$, where \mathbf{x} is the received sequence and L is the number of symbols in the source sequence. Maximizing this probability is equivalent to selecting the path through the tree or trellis that differs from the received sequence by the smallest amount. In 1967, Viterbi developed a maximum likelihood decoding algorithm that takes advantage of the trellis structure to reduce the complexity of this evaluation. This algorithm has become known as the **Viterbi algorithm**. With each received n -tuple, the decoder computes a **metric** or measure of likelihood for all paths that could have been taken during that interval and discards all but the most likely to terminate on each node. An arbitrary decision is made if path metrics are equal. The metrics can be formed using either hard- or soft-decision information with little difference in implementation complexity.

If the message has finite length and the encoder is subsequently flushed with zeros, a single decoded path remains. With a BSC, this path corresponds to the valid code sequence with minimum Hamming distance from the demodulated sequence. Full-length decoding becomes impractical as the length of the message sequence increases. However, the most likely paths tend to have a common stem, and selecting

the trace value four or five times the constraint length prior to the present decoding depth results in near-optimum performance. Since the number of paths examined during each interval increases exponentially with the constraint length, the Viterbi algorithm becomes impractical for codes with large constraint length.

Maximum A Posteriori (MAP) Decoding

In contrast to ML decoding, **maximum a posteriori (MAP) decoding** selects the source sequence \mathbf{m}_i that maximizes the *a posteriori* probability $P(\mathbf{m}_i|\mathbf{x})$, $i \in \{0, 1, \dots, 2^L - 1\}$, where \mathbf{x} and L are as defined above. Using Bayes rule, this probability can be written

$$P(\mathbf{m}_i|\mathbf{x}) = \frac{P(\mathbf{x}|\mathbf{m}_i)P(\mathbf{m}_i)}{P(\mathbf{x})}, \quad i \in \{0, 1, \dots, 2^L - 1\} \tag{13.9}$$

Since the denominator is constant for all \mathbf{m}_i it does not affect selection of the source sequence. The difference between MAP and ML decoding lies in the fact that through the $P(\mathbf{m}_i)$ term in the numerator, MAP decoding takes into account the different probabilities of occurrence of different source sequences. When all source sequences are equally likely, ML and MAP decoding techniques are equivalent.

Several MAP decoding algorithms have been developed. One of the most efficient for non-recursive convolutional codes is the BCJR algorithm [Bahl et al., 1974]. This algorithm has been modified to accommodate recursive codes. The BCJR algorithm requires both a forward and reverse recursion through the trellis, evaluating and using metrics in a fashion similar to the Viterbi algorithm. This algorithm is practical only for codes with relatively small constraint lengths, and because of the dual pass nature of this algorithm, its complexity exceeds twice that of the Viterbi algorithm. Further, under most practical conditions, the performance of the Viterbi algorithm is almost identical to the performance of the BCJR algorithm. However, a strength of the BCJR algorithm is its ability to easily provide soft, rather than hard, decision information for each source symbol. This characteristic is necessary for decoding of turbo codes.

Sub-Optimal Decoding Techniques

The inherent complexity of the Viterbi and BCJR algorithms make them unsuitable for decoding convolutional codes with constraint lengths larger than about 12. Other decoding techniques, such as sequential and threshold decoding, can be used with larger constraint lengths. Sequential decoding was proposed by Wozencraft, and the most widely used algorithm was developed by Fano. Rather than tracking multiple paths through the trellis, the sequential decoder operates on a single path while searching the code tree for a path with high probability. It makes tentative decisions regarding the transmitted sequence, computes a metric between its proposed path and the demodulated sequence, and moves forward through the tree as long as the metric indicates that the path is likely. If the likelihood of the path becomes low, the decoder moves backward, searching other paths until it finds one with high probability. The number of computations involved in this procedure is almost independent of the constraint length and is typically quite small, but can be highly variable, depending on the channel. Buffers must be provided to store incoming sequences as the decoder searches the tree. Their overflow is a significant limiting factor in the performance of these decoders.

Figure 13.6 compares the performance of the Viterbi and sequential decoding algorithms for several convolutional codes operating on coherently-demodulated BPSK signals corrupted by AWGN. Other decoding algorithms have also been developed, including syndrome decoding methods such as table look-up feedback decoding and threshold decoding [Clark and Cain, 1981]. These algorithms are easily implemented but suffer from a reduction in performance.

13.7 Trellis-Coded Modulation

Trellis-coded modulation (TCM) has received considerable attention since its development by Ungerboeck in the late 1970s [Ungerboeck, 1987]. Unlike block and convolutional codes, TCM schemes achieve coding gain by increasing the size of the signal alphabet and using multi-level/phase signaling. Like convolutional codes, sequences of coded symbols are restricted to certain valid patterns. In TCM, these patterns are chosen to have large Euclidean distance from one another so that a large number of corrupted sequences can be corrected. The Viterbi algorithm is often used to decode these sequences. Since the symbol transmission rate does not increase, coded and uncoded signals require the same transmission bandwidth. If transmission power is held constant, the signal constellation of the coded signal is denser. However, the loss in symbol separation is more than overcome by the error correction capability of the code.

Ungerboeck investigated the increase in channel capacity which can be obtained by increasing the size of the signal set and restricting the pattern of transmitted symbols, and he concluded that almost all of the additional capacity can be gained by doubling the number of points in the signal constellation. This is accomplished by encoding the binary data with a rate $R = k/(k + 1)$ code and mapping sequences of $k + 1$ coded bits to points in a constellation of 2^{k+1} symbols. For example, the rate 2/3 encoder of Fig. 13.7(a) encodes pairs of source bits to three coded bits. Figure 13.7(b) depicts one stage in the trellis of the coded output where, as with the convolutional code, the state of the encoder is defined by the contents of the shift register. Note that unlike the trellis for the convolutional code, this trellis contains parallel paths between nodes.

The key to improving performance with TCM is to map the coded bits to points in the signal space such that the Euclidean distance between transmitted sequences is maximized. A method that ensures

FIGURE 13.7 A rate 2/3 TCM code.

improved Euclidean distance is the method of **set partitioning**. This involves separating all parallel paths on the trellis with maximum distance and assigning the next greatest distance to paths that diverge from or merge onto the same node. Figure 13.7(c) and (d) gives examples of mappings for the rate 2/3 code with 8-PSK and 8-PAM signal constellations, respectively.

As with convolution codes, the free distance of a TCM code is defined as the minimum distance between paths through the trellis, where the distance of concern is now Euclidean distance rather than Hamming distance. The free distance of an uncoded signal is defined as the distance between the closest signal points. When coded and uncoded signals have the same average power, the coding gain of the TCM system is defined as

$$\text{coding gain} = 20 \log_{10} \left(\frac{d_{\text{free, coded}}}{d_{\text{free, uncoded}}} \right). \quad (13.10)$$

It can be shown that the simple rate 2/3 8-PSK and 8-PAM TCM systems provide gains of 3 dB and 3.3 dB, respectively [Clark and Cain, 1981]. More complex TCM systems yield gains up to 6 dB. Tables of good codes are given in [Ungerboeck, 1987].

13.8 Additional Measures

When the demodulated sequence contains bursts of errors, the performance of codes designed to correct independent errors improves if coded sequences are **interleaved** prior to transmission and deinterleaved prior to decoding. Deinterleaving separates the burst errors, making them appear more random and increasing the likelihood of accurate decoding. It is generally sufficient to interleave several block lengths of a block coded signal or several constraint lengths of a convolutionally encoded signal. Block interleaving is the most straightforward approach, but delay and memory requirements are halved with convolutional and helical interleaving techniques. Periodicity in the way sequences are combined is avoided with pseudo-random interleaving.

Serially **concatenated codes**, first investigated by Forney, use two levels of coding to achieve a level of performance with less complexity than a single coding stage would require. The inner code interfaces with the modulator and demodulator and corrects the majority of the errors; the outer code corrects errors which appear at the output of the inner-code decoder. A convolutional code with Viterbi decoding is usually chosen as the inner code, and an RS code is often chosen as the outer code due to its ability to correct the bursts of bit errors that can result with incorrect decoding of trellis-coded sequences. Interleaving and deinterleaving outer-code symbols between coding stages offers further protection against the burst error output of the inner code.

Product codes effectively place the data in a two (or more)-dimensional array and use FEC techniques over the rows and columns of this array. Not only do these codes result in error protection in multiple dimensions, but the manner in which the array is constructed can offer advantages similar to those achieved through interleaving.

13.9 Turbo Codes

The most recent significant advancement in FEC coding is the development of **turbo codes** [Berrou, Glavieux, and Thitimajshima, 1993]. The principle of this coding technique is to encode the data with two or more simple **constituent codes** concatenated through an interleaver. The received sequence is decoded in an iterative, serial approach using soft-input, soft-output decoders. The iterative decoder involves feedback of information in a manner similar to processes within the turbo engine, giving this coding technique its name.

Turbo codes effectively result in the construction of relatively long codewords with few codewords being close in terms of Hamming distance, while at the same time constraining the implementation complexity of the decoder to practical limits. The first turbo codes that were developed used recursive systematic convolutional codes as the constituent codes and concatenated them in parallel through a pseudo-random interleaver, as depicted in Fig. 13.8(a). The use of other types of constituent codes, and the serial concatenation of constituent codes, has since been considered.

As in other multi-stage coding techniques, the complexity of the turbo decoder is limited through use of separate decoding stages for each constituent code. The input to the first stage is the soft output of the demodulator for a finite-length received symbol sequence. As shown in Fig. 13.8(b), subsequent stages use both the demodulator output and the **extrinsic information** from the previous decoding stage. Extrinsic information is the new, soft information evaluated in each stage of decoding that can be used as *a priori* information for each source symbol during the next stage of decoding.

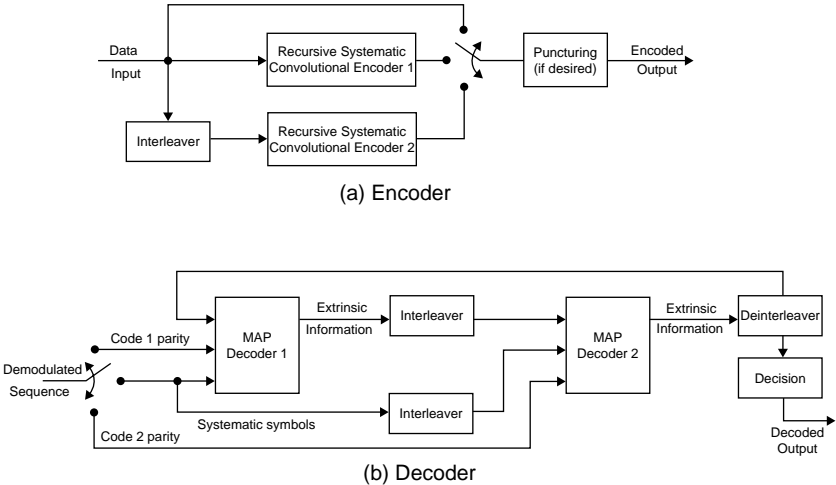

FIGURE 13.8 Turbo code with parallel concatenated constituent codes.

FIGURE 13.9 Performance in AWGN of a turbo code with parallel concatenated constituent codes of rate 1/2 and constraint length 4. Pseudo-random interleaver of size 65536.

Decoding proceeds by iterating through constituent decoders, each forwarding updated extrinsic information to the next decoder until a predefined number of iterations has been completed or the extrinsic information indicates that high reliability has been achieved. Typical simulation results are shown in Fig. 13.9. As indicated in this figure, performance tends to improve with the number of iterations, where the largest performance gains are made during the initial iterations. Excellent performance can be obtained at signal-to-noise ratios appreciably less than 1 dB, however at higher values of E_b/N_0 , the performance curves tend to exhibit flattening similar to error floors. Flattening of the BER curves is a result of the relatively small overall Hamming distance typical of most turbo codes.

Since the discovery of turbo codes, a significant amount of effort has been directed towards explaining and analyzing their performance. Recent work demonstrating the relationship between turbo codes and belief propagation in Bayesian networks shows promise in furthering these goals. There has also been significant effort in determining optimal code parameters. With convolutional constituent codes, it has been found that coding gain through turbo decoding is only possible with recursive codes and that there is little advantage to using codes with constraint lengths larger than about five. These short constraint lengths allow the soft-in, soft-out BCJR algorithm to be used. It has also been recognized that decoding performance increases with decreased correlation between the extrinsic information and the demodulated data at the input of the constituent decoders, implying that highly random interleavers should be used. It has also been established that it is important for interleavers to ensure that sequences highly susceptible to error not occur simultaneously in both constituent codes.

Even though great strides have been made over the last few years in understanding the structure of these codes and relating them to serially concatenated and product codes, work regarding their analysis, optimization, and efficient implementation will interest coding theorists and practitioners for many years to come.

13.10 Applications

FEC coding remained of theoretical interest until advances in digital technology and improvements in decoding algorithms made their implementation possible. It has since become an attractive alternative to improving other system components or boosting transmission power. FEC codes are commonly used in digital storage systems, deep-space and satellite communication systems, terrestrial wireless and band-limited wireline systems, and have also been proposed for fiber optic transmission. Accordingly, the theory and practice of error correcting codes now occupies a prominent position in the field of communications engineering.

Deep-space systems began using forward error correction in the early 1970s to reduce transmission power requirements, and used multiple error correcting RS codes for the first time in 1977 to protect against corruption of compressed image data in the Voyager missions [Wicker and Bhargava, 1994]. The Consultative

Committee for Space Data Systems (CCSDS) has recommended use of a concatenated coding system which uses a rate $1/2$, constraint length 7 convolutional inner code and a (255, 223) RS outer code.

Coding is now commonly used in satellite systems to reduce power requirements and overall hardware costs and allow closer orbital spacing of geosynchronous satellites [Berlekamp, 1987]. FEC codes play integral roles in the VSAT, MSAT, INTELSAT, and INMARSAT systems [Wu et al., 1987]. Further, a (31, 15) RS code is used in the joint tactical information distribution system (JTIDS), a (7, 2) RS code is used in the air force satellite communication system (AFSATCOM), and a (204, 192) RS code has been designed specifically for satellite TDMA systems. Another code designed for military applications involves concatenation of a Golay and RS code with interleaving to ensure an imbalance of 1s and 0s in the transmitted symbol sequence and enhance signal recovery under severe noise and interference [Berlekamp, 1987].

TCM has become commonplace in transmission of data over voiceband telephone channels. Modems developed since 1984 use trellis coded QAM modulation to provide robust communication at rates above 9.6 kb/s.

Various coding techniques are used in the new digital cellular and personal communication standards [Rappaport, 1996]. Convolutional codes are employed in the second generation GSM, TDM, and CDMA systems. More recent standards use turbo coding to provide error protection for data signals.

FEC codes have also been widely used in digital recording systems, most prominently in the compact disc digital audio system. This system uses two levels of coding and interleaving in the cross-interleaved RS coding (CIRC) system to correct errors which result from disc imperfections and dirt and scratches which accumulate during use. Steps are also taken to mute uncorrectable sequences [Wicker and Bhargava, 1994].

Defining Terms

Binary symmetric channel: A memoryless discrete data channel with binary signaling, hard-decision demodulation, and channel impairments that do not depend on the value of the symbol transmitted.

Bounded distance decoding: Limiting the error patterns which are corrected in an imperfect code to those with t or fewer errors.

Catastrophic code: A convolutional code in which a finite number of code symbol errors can cause an unlimited number of decoded bit errors.

Code rate: The ratio of source word length to codeword length, indicative of the amount of information transmitted per encoded symbol.

Coding gain: The reduction in signal-to-noise ratio required for specified error performance in a block or convolutional coded system over an uncoded system with the same information rate, channel impairments, and modulation and demodulation techniques. In TCM, the ratio of the squared free distance in the coded system to that of the uncoded system.

Column distance: The minimum Hamming distance between convolutionally encoded sequences of a specified length with different leading n -tuples.

Constituent codes: Two or more FEC codes that are combined in concatenated coding techniques.

Cyclic code: A block code in which cyclic shifts of code vectors are also code vectors.

Cyclic redundancy check: When the syndrome of a cyclic block code is used to detect errors.

Designed distance: The guaranteed minimum distance of a BCH code designed to correct up to t errors.

Discrete data channel: The concatenation of all system elements between FEC encoder output and decoder input.

Distance profile: The minimum Hamming distance after each encoding interval of convolutionally encoded sequences which differ in the first interval.

Erasures: A position in the demodulated sequence where the symbol value is unknown.

Extrinsic information: The output of a constituent soft decision decoder that is forwarded as *a priori* information for the source symbols to the next decoding stage in iterative decoding of turbo codes.

Finite field: A finite set of elements and operations of addition and multiplication which satisfy specific properties. Often called Galois fields and denoted $GF(q)$, where q is the number of elements in the field. Finite fields exist for all q which are prime or the power of a prime.

Free distance: The minimum Hamming weight of convolutionally encoded sequences which diverge and remerge in the trellis. Equals the maximum column distance and the limiting value of the distance profile.

Generator matrix: A matrix used to describe a linear code. Code vectors equal the information vectors multiplied by this matrix.

Generator polynomial: The polynomial which is a divisor of all codeword polynomials in a cyclic block code; a polynomial which describes circuit connections in a convolutional encoder.

Hamming distance: The number of symbols in which codewords differ.

Hard decision: Demodulation which outputs only a symbol value for each received symbol.

Interleaving: Shuffling the coded bit sequence prior to modulation and reversing this operation following demodulation. Used to separate and redistribute burst errors over several codewords (block codes) or constraint lengths (trellis codes) for higher probability of correct decoding by codes designed to correct random errors.

Linear code: A code whose code vectors form a vector space. Equivalently, a code where the addition of any two code vectors forms another code vector.

Maximum a posteriori decoding: A decoding algorithm that selects the source sequence that maximizes the probability of the source sequence being transmitted, given reception of the received sequence.

Maximum distance separable: A code with the largest possible minimum distance given the block length and code rate. These codes meet the Singleton bound of $d_{\min} \leq n - k + 1$.

Maximum likelihood decoding: A decoding algorithm that selects the source sequence that maximizes the probability of the received sequence occurring given transmission of this source sequence.

Metric: A measure of goodness against which items are judged. In the Viterbi algorithm, an indication of the probability of a path being taken given the demodulated symbol sequence.

Minimum distance: In a block code, the smallest Hamming distance between any two codewords. In a convolutional code, the column distance after K intervals.

Parity check matrix: A matrix whose rows are orthogonal to the rows in the generator matrix of a linear code. Errors can be detected by multiplying the received vector by this matrix.

Perfect code: A t error correcting (n, k) block code in which $q^{n-k} - 1 = \sum_{i=1}^t \binom{n}{i} (q-1)^i$.

Puncturing: Periodic deletion of code symbols from the sequence generated by a convolutional encoder for purposes of constructing a higher rate code. Also, deletion of parity bits in a block code.

Set partitioning: Rules for mapping coded sequences to points in the signal constellation which always result in a larger Euclidean distance for a TCM system than an uncoded system, given appropriate construction of the trellis.

Shannon limit: The ratio of energy per data bit E_b to noise power spectral density N_0 in an AWGN channel above which errorless transmission is possible when no bandwidth limitations are placed on the signal and transmission is at channel capacity. This limit has the value $\ln 2 = 0.693 = -1.6$ dB.

Soft decision: Demodulation which outputs an estimate of the received symbol value along with an indication of the reliability of this value. Usually implemented by quantizing the received signal to more levels than there are symbol values.

Standard array decoding: Association of an error pattern with each syndrome by way of a look-up table.

Syndromes: An indication of whether or not errors are present in the demodulated symbol sequence.

Systematic code: A code in which the values of the message symbols can be identified by inspection of the code vector.

Vector space: An algebraic structure comprised of a set of elements in which operations of vector addition and scalar multiplication are defined. For our purposes, a set of n -tuples consisting of symbols from $\text{GF}(q)$ with addition and multiplication defined in terms of element-wise operations from this finite field.

Viterbi algorithm: A maximum-likelihood decoding algorithm for trellis codes which discards low probability paths at each stage of the trellis, thereby reducing the total number of paths which must be considered.

For Further Information

There is now a large amount of literature on the subject of FEC coding. An introduction to the philosophy and limitations of these codes can be found in the second chapter of Lucky's book *Silicon Dreams: Information, Man, and Machine*, St. Martin's Press, New York, 1989. More practical introductions can be found in overview chapters of many communications texts. The number of texts devoted entirely to this subject also continues to grow. Although these texts summarize the algebra underlying block codes, more in-depth treatments can be found in mathematical texts. Survey papers appear occasionally in the literature, but the interested reader is directed to the seminal papers by Shannon, Hamming, Reed and Solomon, Bose and Chaudhuri, Hocquenghem, Wozencraft, Fano, Forney, Berlekamp, Massey, Viterbi, Ungerboeck, and Berrou and Glavieux, among others. The most recent advances in the theory and implementation of error control codes are published in *IEEE Transactions on Information Theory*, *IEEE Transactions on Communications*, and special issues of *IEEE Journal on Selected Areas in Communications*.

14.1 Introduction

In most digital communication systems, whenever error events occur in the transmitted messages, some action must be taken to correct these events. This action may take the form of an **error correction** procedure. In some applications where a two-way communication link exists between the sender and the receiver, the receiver may inform the sender that a message has been received in error and, hence, request a repeat of that message. In principle, the procedure may be repeated as many times as necessary until that message is received error free. An error control system in which the erroneously received messages are simply retransmitted is called *automatic-repeat-request* (ARQ).

In ARQ systems, the receiver must perform only an **error detection** procedure on the received messages without attempting to correct the errors. Hence, an error detecting code, in the form of specific redundant or parity-check symbols, must be added to the information-bearing sequence. In general, as the error detecting capability of the code increases, the number of added redundant symbols must also be increased. Clearly, with such a system, an erroneously received message is delivered to the user only if the receiver fails to detect the presence of errors. Since error detection coding is simple, powerful, and quite robust, ARQ systems constitute a simple and efficient method for providing highly reliable transfer of messages from the source to the user over a variety of transmission channels. ARQ systems are therefore widely used in data communication systems that are highly sensitive to errors, such as in computer-to-computer communications.

This chapter presents and discusses principles, performances, limitations, and variants of basic ARQ strategies. The fundamentals of the basic ARQ schemes are presented in [Section 14.2](#), whereas the

performance analysis and the limitations are carried out in [Section 14.3](#). [Section 14.4](#) presents some of the most common variants of the basic ARQ schemes, and hybrid forward error control (FEC)/ARQ techniques are outlined in [Section 14.5](#). Finally, an application problem is provided in [Section 14.6](#).

14.2 Fundamentals and Basic Automatic Repeat Request Schemes

Messages transmitted on a communication channel are subjected to errors, which must be detected and/or corrected at the receiver. This section presents the basic principles underlying the concept of error control using retransmission schemes.

Basic Principles

In the seven-layer open system interconnection (OSI) model, error control refers to some basic functions that may be performed at several layers, especially at the *transport layer* (level 4) and at the *data link layer* (level 2). The transport layer is responsible for the end-to-end transport of information processed as *protocol data unit* (PDU) through a network infrastructure. An intermediate layer, called the *network layer* (level 3), ensures that messages, which are broken down into smaller blocks called *packets*, can successfully be switched from one node to another of the network.

The error control on each individual link of the network is performed by the data link layer, which transforms packets received from the network layer into *frames* by adding address, control, and error check fields prior to their transmission into the channel. [Figure 14.1](#) shows an example of the frame structure, whose length, which depends on the particular data link protocol used, usually varies approximately between 50 and 200 bytes. The length of each field also depends on the particular data link control protocol employed. The data link layer must ensure a correct and orderly delivery of packets between switching nodes in the network. The objective of the error control is to maintain the integrity of the data in the frames as they transit through the links, overcoming the loss, duplication, desequencing, and damage of data and control information bits at these various levels. Most ARQ error control techniques integrate error detection using standard *cyclic redundancy check* (CRC), as well as requests for retransmission using PDU.

Error control coding consists essentially of adding to the *information* bits to be transmitted some extra or redundant bits, called *parity-check* bits, in a regular and controlled manner. These parity-check bits, which are removed at the receiver, do not convey information but allow the receiver to detect and possibly correct errors in the received frames.

The single parity-check bit used in ASCII is an example of a redundant bit for error detection purposes. It is an eighth bit added to the seven information bits in the frame representing the alphanumeric character to be transmitted. This bit takes the value 1 if the number of 1s in the first seven bits is odd (odd parity), and 0 otherwise. At the receiver, the parity-check bit of the received frame is computed again in order to verify whether it agrees with the received parity check bit. A mismatch of these parity-check bits indicates that an odd number of errors has occurred during transmission, leading the receiver to request a retransmission of the erroneous frame.

FIGURE 14.1 Structure of a frame.

ARQ refers to retransmission techniques, which basically operate as follows. Erroneously received frames are retransmitted until they are received or detected as being error-free; errors are detected using a simple detection code. Positive (ACK) or negative (NAK) acknowledgments are sent back by the receiver to the sender over a reliable **feedback channel** in order to report whether a previously transmitted frame has been received error-free or with errors. In principle, a positive acknowledgment signals the transmitter to send the next data frame, whereas a negative acknowledgment is a request for frame retransmission. *Stop-and-wait*, *go-back-N*, and *selective-repeat* are the three basic versions of ARQ, the last two schemes being usually referred to as *sliding window protocols*.

Stop-and-Wait Automatic Repeat Request

Stop-and-wait ARQ is a very simple acknowledgment scheme, which works as follows. Sender and receiver communicate through a **half-duplex** point-to-point **link**. Following transmission of a single frame to the receiver, the sender waits for an acknowledgment from the receiver before sending the next data frame or repeating the same frame. Upon receiving a frame, the receiver sends back to the sender a positive acknowledgment (ACK) if the frame is correct; otherwise it transmits a negative acknowledgment (NAK).

Figure 14.2 illustrates the frame flow for stop-and-wait ARQ. Frames F_1, F_2, F_3, \dots are in queue for transmission. At time t_0 , the sender transmits frame F_1 to the receiver and stays idle until either an ACK or NAK is received for that frame. At time t_1 , F_1 is correctly received, hence an ACK is sent back. At time t_2 , the sender receives this ACK and transmits the next frame F_2 , which is received at time t_3 and detected in error. Frame F_2 is then discarded at the receiver and a NAK is therefore returned to the sender. At time t_4 , the sender receiving a NAK for F_2 retransmits a copy of that frame and waits again, until it receives at time t_6 either an ACK or NAK for F_2 . Assuming it is an ACK, as illustrated in Fig. 14.2, the sender then proceeds to transmit the next frame F_3 , and so on. Clearly, such a technique requires the sender to store in a buffer a copy of a transmitted frame until a positive acknowledgment has been received for that frame.

Obviously, this technique does not take into account all contingencies. Indeed, it is possible that some transmitted frames damaged by transmission impairments do not even reach the receiver, in which case the receiver cannot even acknowledge them. To overcome this situation, a timer is integrated in the sender for implementing a *time-out* mechanism. A time-out is some pre-established time interval beyond which a transmitted frame is considered lost if its acknowledgment is not received; a timed-out frame is usually simply retransmitted.

Another undesirable situation can be described as follows. The sender transmits a copy of some frame F_i which is received correctly by the receiver. A positive acknowledgment (ACK) is then returned to the sender. Unfortunately, this ACK may be corrupted during its transmission in the feedback channel so that it becomes unrecognizable by the sender which therefore transmits another copy of the same frame. As a result, there is a possibility of frame duplication at the receiver leading to an ambiguity between a

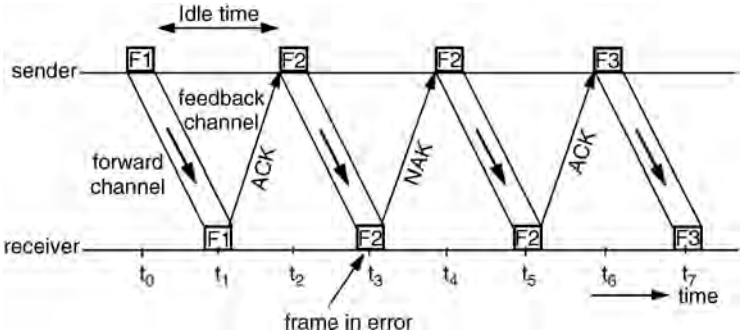

FIGURE 14.2 Stop-and-wait ARQ.

frame and its immediate predecessor or successor. This ambiguity can be easily resolved by attaching a sequence number in each transmitted frame. In practice, a single-bit (0 or 1) inserted in the header of each frame is sufficient to distinguish a frame from its duplicate at the receiver.

Stop-and-wait ARQ schemes offer the advantage of great simplicity. However, they are not very suitable for high-speed modern communication systems since data is transmitted in one direction only. Protocols in which the ACK for a frame must be received by the sender prior to the transmission of the next frame are referred to as *positive acknowledgment with retransmission* (PAR) protocols. The principal weakness of PAR schemes is an inefficient link utilization related to the time lost waiting for acknowledgments before sending another frame, especially if the propagation delay is significantly longer than the packet transmission time, such as in satellite links. To overcome this shortcoming, PAR schemes have been adapted to more practical situations, which require transmitting frames in both directions, using **full-duplex links** between sender and receiver. Clearly then, each direction of transmission acts as the **forward channel** for the frames and as the return channel for the acknowledgments. Now in order to improve further the efficiency of each channel, ACK/NAK control packets and information frames need not be sent separately. Instead, the acknowledgment about each previously received frame is simply appended to the next transmitted frame. In this technique, called *piggybacking*, transmission of the acknowledgment of a received frame is clearly delayed by the transmission of the next data frame. A fixed maximum waiting time for the arrival of a new frame is thus set. If no new frame has arrived by the end of that waiting time, then the acknowledgment frame is sent separately. Even with piggybacking, PAR schemes still require the sender to wait for an acknowledgment before transmitting another frame. An obvious improvement of the efficiency may be achieved by relaxing this condition and allowing the sender to transmit up to W , $W > 1$ frames without waiting for an acknowledgment. A further improvement still is to allow a continuous transmission of the frames without any waiting for acknowledgments. These protocols are called *Continuous ARQ* and are associated with the concept of sliding window protocols.

Sliding Window Protocols

To overcome the inefficiency of PAR schemes, an obvious solution is not to stay idle between frame transmissions. One approach is to use a sliding window protocol where a window refers to a subset of consecutive frames.

Consider a window that contains N frames numbered ω , $\omega + 1, \dots, \omega + N - 1$, as shown in Fig. 14.3. Every frame using a number smaller than ω has been sent and acknowledged, as identified in Fig. 14.3 as *frames before the window*, whereas no frame with a number larger than or equal to $\omega + N$, identified as *frames beyond the window*, has yet been sent. Frames in the window that have been sent but that have not yet been acknowledged are said to be *outstanding frames*. As outstanding frames are being acknowledged, the window shifts to the right to exclude acknowledged frames and, subsequently, to include the

FIGURE 14.3 Frame sequencing in a sliding window protocol (sender side).

new frames that have to be sent. Since the window must always contain frames that are numbered consecutively, the frames are excluded from the window in the same order in which they were included.

To limit the number of outstanding frames, a limit on the window size may be determined. When this limit is reached, the sender accepts no more frames. A window size $N = 1$ corresponds to the stop-and-wait protocol, whereas a window size greater than the total number of frames that can be represented in the header field of the frame refers to an *unrestricted protocol*. Clearly, the window size has some influence on the network traffic and on buffering requirements. Go-back- N and selective-repeat may be considered as two common implementations of a sliding window protocol, as will be described next.

Go-Back-N Automatic Repeat Request

Go-back- N ARQ schemes use continuous transmission without waiting for ACK between frames. Clearly, a full-duplex link between the sender and the receiver is required, allowing a number of consecutive frames to be sent without receiving an acknowledgment. In fact, ACKs may not even be transmitted. Upon detecting a frame in error, the receiver sends a NAK for that frame and discards that frame and all succeeding frames until that erroneous frame has been correctly received. Following reception of a NAK, the sender completes the transmission of the current frame and retransmits the erroneous frame and all subsequent ones.

In accordance with the sliding window protocol, each frame is numbered by an integer $\ell = 0, 1, 2, \dots, 2^k - 1$, where k denotes the number of bits in the number field of the frame. In general, in order to facilitate their interpretation, frames are all numbered consecutively modulo- 2^k . For example, for $k = 3$, frames are numbered 0–7 repeatedly.

It is important to fix the maximum window size, that is, the maximum number of outstanding frames waiting to be transmitted at any one time. To avoid two different outstanding frames having the same number, as well as to prevent pathological protocol failures, the maximum window size is $N = 2^k - 1$. It follows that the number of discarded frames is at most equal to N ; however, the actual exact number of discarded frames depends also on the propagation delay. For most usual applications, a window of size $N = 7$ (i.e., $k = 3$) is adequate, whereas for some satellite links the window size N is usually equal to 127.

Figure 14.4 illustrates the frame flow for a go-back- N ARQ scheme, with $k = 3$ and, hence, $N = 7$. Thus, the sender can transmit sequences of frames numbered $F_0, F_1, F_2, \dots, F_7$. As shown in Fig. 14.4, since the receiver detects an error on frame F_3 , it returns NAK3 to the sender and discards both F_3 and the succeeding frames F_4, F_5 , and F_6 , which because of propagation delays have already been transmitted by the sender before it received the negative acknowledgment NAK3. Then, the sender retransmits F_3 and the sequence of frames F_4, F_5 , and F_6 , and proceeds to transmit F_7 (using the current sequencing)

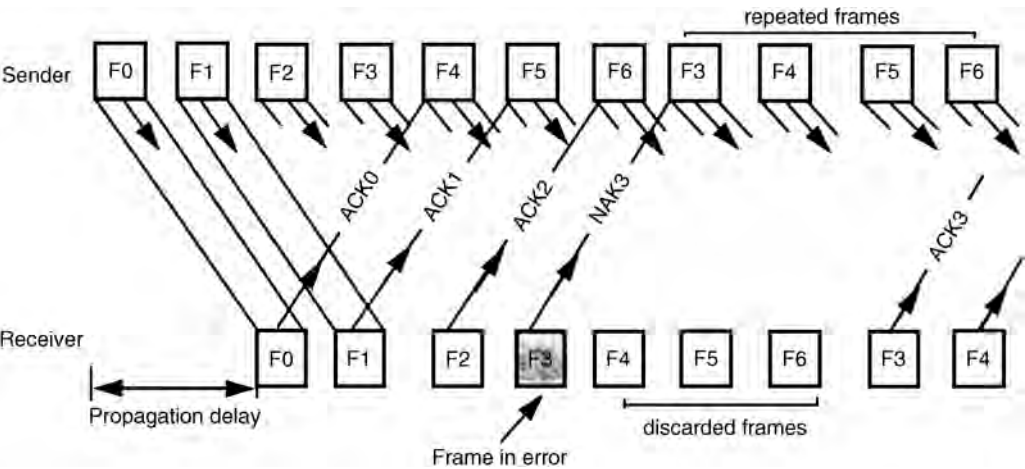

FIGURE 14.4 Go-back- N ARQ.

as well as frames F_0, F_1, \dots , using the next sequencing. Obviously, should any of the preceding frames be received in error, then the same repeat procedure is implemented, starting from that frame in error.

Go-back- N procedures have been implemented in various data link protocols such as high-level data link control (HDLC), which refers to layer 2 of the seven-layer OSI model, and transmission control protocol/internet protocol (TCP/IP), which supports the Internet, the world's largest interconnection of computer networks. Indeed, to ensure reliable end-to-end connections and improve the performance, TCP uses a sliding window protocol with timers. In accordance with this protocol, the sender can transmit several TCP messages or frames before an acknowledgment is received for any of the frames. The number of frames allowed in transit is negotiated dynamically using the window field in the TCP header.

As an implementation of the sliding window protocol, the go-back- N scheme is more efficient and more general than the stop-and-wait scheme, which is clearly equivalent to go-back- N , with $N = 1$. However, go-back- N presents the disadvantage of requiring a prerequisite numbering of frames as well as the buffering in the window of N frames awaiting positive acknowledgments. Furthermore, in the absence of a controlled source, all incoming frames not yet accepted by the window must be buffered while they wait to be inserted in the window. Inefficiency is also due to the discarding of all frames that follow the frame received in error, even though these frames may be error free. On the other hand, such a procedure presents the advantage of maintaining the proper sequencing of the frames accepted at the receiver.

Selective-Repeat Automatic Repeat Request

To overcome the inefficiency resulting from unnecessarily retransmitting the error-free frames, retransmission can be restricted to only those frames that have been detected in error. Repeated frames correspond to erroneous or damaged frames that are negatively acknowledged as well as frames for which the time-out has expired. Such a procedure is referred to as selective-repeat ARQ, which obviously should improve the performance over both stop-and-wait and go-back- N schemes. Naturally, a full-duplex link is again assumed.

Figure 14.5 illustrates the frame flow for selective-repeat ARQ. The frames appear to be disjointed but there is no idle time between consecutive frames. The sender transmits a sequence of frames F_1, F_2, F_3, \dots . As illustrated in Fig. 14.5, the receiver detects an error on the third frame F_3 and thus returns a negative acknowledgment denoted NAK3 to the sender. However, due to the continuous nature of the protocol, the succeeding frames F_4, F_5 , and F_6 have already been sent and are in the pipeline by the time the sender receives NAK3. Upon receiving NAK3, the sender completes the transmission of the current frame (F_6) and then retransmits F_3 before sending the next frame F_7 in the sequence. The correctly

FIGURE 14.5 Selective-repeat ARQ.

received but incomplete sequence $F4, F5, F6$ must be buffered at the receiver, until $F3$ has been correctly received and inserted in its proper place to complete the sequence $F3, F4, F5, F6, \dots$, which is then delivered.

If $F3$ is correctly received at the first retransmission, the buffered sequence is $F4, F5$, and $F6$. However, if $F3$ is received in error during its retransmission and hence must be retransmitted again, then clearly the buffered sequence is $F4, F5, F6, F7, F8, F9$. Therefore, multiple retransmissions of a given frame lead to an ever larger buffering, which may be theoretically unbounded. To circumvent such a possibility and the ensuing buffer overflow, a time-out mechanism is usually incorporated in all practical selective-repeat ARQ systems.

In practice, each correctly received frame prior to the appearance of an erroneous frame denoted F is delivered to the user (i.e., the physical layer). Thereafter, all error-free successive frames are buffered at the receiver, until frame F is correctly received. It is then inserted at the beginning of the buffered sequence, which can thus be safely delivered to the user up to the next frame received in error. However, the reordering becomes somewhat more complex if other frames are received in error before frame F is finally received error free. As a consequence, proper buffering must be provided by the sender, which must also integrate the appropriate logic in order to send frames that are out of sequence. The receiver must also be provided with adequate buffering to store the out-of-order frames within the window until the frame in error is correctly received, in addition to being provided with the appropriate logic for inserting the accepted frames in their proper place in the sequence. The required buffers may be rather large for satellite transmission with long propagation delays and long pipelines corresponding to the many frames in transit between sender and receiver. As a result, the selective-repeat ARQ procedure tends to be less commonly used than the go-back- N ARQ scheme, even though it may be more efficient from a throughput point of view.

14.3 Performance Analysis and Limitations

In ARQ systems, the performance is usually measured using two parameters: throughput efficiency and undetected error probability on the data bits. The throughput efficiency is defined as the ratio of the average number of information bits per second delivered to the user to the average number of bits per second that have been transmitted in the system. This throughput efficiency is obviously smaller than 100%. For example, using an error-detecting scheme with a coding rate $R = 0.98$, an error-free transmission would then correspond to a throughput efficiency of 98%, and clearly, any frame retransmission yields a further decrease of the throughput efficiency.

The reliability of an ARQ system is measured by its frame error probability, which may take one of the following forms:

- P = Probability of error detection. It is the probability of an erroneously received frame detected in error by the error detecting code.
- P_u = Probability of undetected error. It is the probability of an erroneously received frame *not* detected in error by the error-detecting code.

Let P_c denote the probability of receiving an error-free frame. We then have $P_c = 1 - P - P_u$. All of these probabilities depend on both the channel error statistics and the error detection code implemented by the CRC. By a proper selection of the CRC, these error probabilities can be made very small. Assuming white noise on a channel having a bit error probability p , the probabilities of correctly receiving a frame of length L is $P_c = (1 - p)^L$. As for the undetectable error probability P_u , it is usually vanishingly small, typically $P_u < 1 \times 10^{-10}$.

Stop-and-Wait Automatic Repeat Request

For error-free operation using the stop-and-wait ARQ technique, the *utilization rate* U_R of a link is defined as

$$U_R = \frac{T_S}{T_T} \quad (14.1)$$

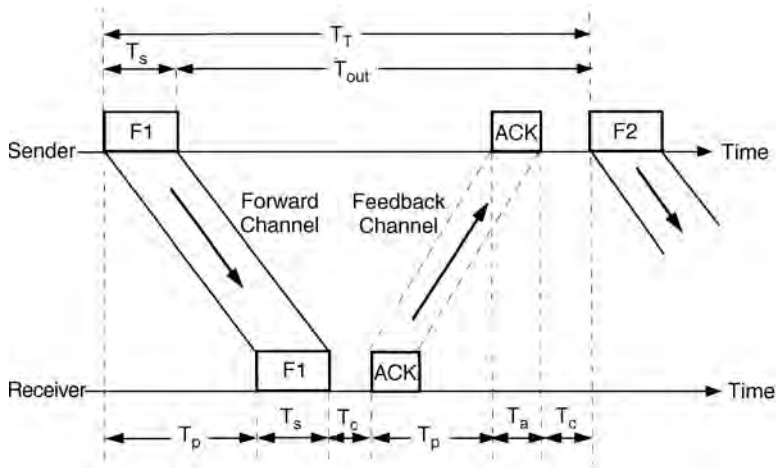

FIGURE 14.6 Timing of successive frames in stop-and-wait ARQ scheme.

where T_s denotes the time required to transmit a single frame, and T_T is the overall time between transmission of two consecutive frames, including processing and ACK/NAK transmissions. As shown in Fig. 14.6, the total time T_T can be expressed as

$$T_T = T_p + T_s + T_c + T_p + T_a + T_c \quad (14.2)$$

In this expression, T_p denotes the propagation delay, that is, the time needed for a transmitted bit to reach the receiver; T_c is the processing delay, that is, the time required for either the sender or the receiver to perform the necessary processing and error checking, whereas T_s and T_a denote the transmission duration of a data frame and of an ACK/NAK frame, respectively.

Assuming the processing time T_c is negligible with respect to T_p and that the sizes of the ACK/NAK frames are very small, leading to negligible value for T_a , then Eq. (14.2) becomes

$$T_T \approx T_s + 2T_p \quad (14.3)$$

Defining the propagation delay ratio $\alpha = T_p/T_s$, then Eq. (14.1) can be written as

$$U_R = \frac{1}{1 + 2\alpha} \quad (14.4)$$

Clearly Eq. (14.4) may be seen as a lower bound on the utilization rate or throughput efficiency that the communication link can achieve over all of the frames.

The utilization rate expressed by Eq. (14.4) may be used to evaluate the throughput efficiency on a per frame basis. In the remainder of the chapter, unless specified otherwise, the throughput efficiency is considered on a per frame basis. Because of repetitions caused by transmission errors, using Eq. (14.1), the *average utilization rate*, or *throughput efficiency*, is defined as

$$\eta = \frac{U_R}{N_t} = \frac{T_s}{N_t T_T} \quad (14.5)$$

where N_t is the expected number of transmissions per frame.

In this definition of the throughput efficiency, the coding rate of the error detecting code, as well as the other overhead bits, are not taken into account. That is, definition (14.5) represents the throughput efficiency on a per frame performance basis. Some other definitions of the throughput efficiency may be related to the number of information bits actually delivered to the destination. In such a case, the new

throughput efficiency η^* is simply equal to

$$\eta^* = \eta(1 - \rho)$$

where ρ represents the fraction of all redundant and overhead bits in the frame.

Assuming error-free transmissions of ACK and NAK frames, and assuming independence for each frame transmission, the probability of requiring exactly k attempts to successfully receive a given frame is $P_k = P^{k-1}(1 - P)$, $k = 1, 2, 3, \dots$, where P is the frame error probability. The average number of transmissions N_t that are required before a frame is accepted by the receiver is then

$$N_t = \sum_{k=1}^{\infty} kP_k = \sum_{k=1}^{\infty} kP^{k-1}(1 - P) = \frac{1}{1 - P} \quad (14.6)$$

Using Eqs. (14.4–14.6) the throughput efficiency can thus be written as

$$\eta = \frac{1 - P}{1 + 2\alpha} \quad (14.7)$$

The average overall transmission time T_v , for an accepted frame, is then given by

$$T_v = \sum_{k=1}^{\infty} kP_k T_T = \frac{T_T}{1 - P} \quad (14.8)$$

As expected, Eq. (14.8) indicates that if the channel is error-free and thus $P = 0$, then $T_v = T_T$, whereas if the channel is very noisy with $P \rightarrow 1$, then the average transmission time T_v may become theoretically unbounded.

Continuous Automatic Repeat Request: Sliding Window Protocols

For continuous ARQ schemes, the basic expression of the throughput efficiency, Eq. (14.5), must be used with the following assumptions: the transmission duration of a data frame is normalized to $T_s = 1$; the transmission time of an ACK/NAK frame, T_a , as well as the processing delay of any frame, T_c , are negligible. Since $\alpha = T_p/T_s$ and $T_s = 1$, then the propagation delay T_p is equal to α .

Let the sender start transmitting the first frame $F1$ at time t_0 . Since $T_p = \alpha$, the beginning of that frame will reach the receiver at time $t_0 + \alpha$. Therefore, given that $T_s = 1$, frame $F1$ will be entirely received at time $(t_0 + \alpha + 1)$. The processing delay being negligible, the receiver can immediately acknowledge frame $F1$ by returning ACK1. As a result, since the transmission duration T_a of an ACK/NAK frame is negligible, ACK1 will be delivered to the sender at time $(t_0 + 2\alpha + 1)$. Let N be the window size, then two cases may be considered: $N \geq 2\alpha + 1$ and $N < 2\alpha + 1$.

If $N \geq 2\alpha + 1$, the acknowledgment ACK1 for frame $F1$ will reach the sender before it has exhausted (e.g., emptied) its own window, and hence the sender can transmit continuously without stopping. In this case, the utilization rate of the transmission link is 100%, that is, $U_R = 1$.

If $N < 2\alpha + 1$, the sender will have exhausted its window at time $t_0 + N$, and thus cannot transmit additional frames until time $(t_0 + 2\alpha + 1)$. In this case, the utilization rate is obviously smaller than 100% and can be expressed as $U_R = N/(2\alpha + 1)$. Furthermore, the protocol is no longer a continuous protocol since there is a break in the sender transmission.

Assuming there are no transmission errors, it follows that the utilization rate of the transmission link for a continuous ARQ using a sliding window protocol of size N is given by

$$U_R = \begin{cases} 1, & N \geq 2\alpha + 1 \\ \frac{N}{1 + 2\alpha}, & N < 2\alpha + 1 \end{cases} \quad (14.9)$$

Selective-Repeat Automatic Repeat Request

For selective-repeat ARQ scheme, the expression for the throughput efficiency can be obtained by dividing Eq. (14.9) by $N_t = 1/(1 - P)$ yielding

$$\eta_{\text{SR}} = \begin{cases} 1 - P, & N \geq 2\alpha + 1 \\ \frac{N(1 - P)}{1 + 2\alpha}, & N < 2\alpha + 1 \end{cases} \quad (14.10)$$

Go-Back-N Automatic Repeat Request

For the go-back- N ARQ scheme, each frame in error necessitates the retransmission of M frames ($M \leq N$) rather than just one frame, where M depends on the roundtrip propagation delay and the frame size. Let $g(k)$ denote the total number of transmitted frames corresponding to a particular frame being transmitted k times. Since each repetition involves M frames, we can write [Stallings, 1994]

$$g(k) = 1 + (k - 1)M = (1 - M) + kM$$

Using the same approach as in Eq. (14.6), the average number of transmitted frames N_t to successfully transmit one frame can be expressed as

$$N_t = \sum_{k=1}^{\infty} g(k)P^{k-1}(1 - P) = \frac{1 - P + PM}{1 - P} \quad (14.11)$$

If $N \geq 2\alpha + 1$, the sender transmits continuously and, consequently, M is approximately equal to $2\alpha + 1$. In this case, in accordance with Eq. (14.11), $N_t = (1 + 2\alpha P)/(1 - P)$. Dividing Eq. (14.9) by N_t , the throughput efficiency becomes $\eta = (1 - P)/(1 + 2\alpha P)$.

If $N < 2\alpha + 1$, then $M = N$, and hence $N_t = (1 - P + PN)/(1 - P)$. Dividing Eq. (14.9) again by N_t , we obtain $\eta = N(1 - P)/(1 + 2\alpha)(1 - P + PN)$.

Summarizing, the throughput efficiency of go-back- N ARQ is given by

$$\eta_{\text{GB}} = \begin{cases} \frac{1 - P}{1 + 2\alpha P}, & N \geq 2\alpha + 1 \\ \frac{N(1 - P)}{(1 + 2\alpha)(1 - P + PN)}, & N < 2\alpha + 1 \end{cases} \quad (14.12)$$

Assuming negligible processing times, the average transmission time of a frame as seen by the sender is given by

$$T_v = T_s + N_t T_T = T_s + \sum_{k=1}^{\infty} k P^k (1 - P) T_T \quad (14.13)$$

where T_s is the actual transmission duration of a frame and where again $T_T = T_s + 2T_p$. Since $\alpha = T_p/T_s$, then the total time T_T can be written as: $T_T = T_s + 2\alpha T_s = T_s(1 + 2\alpha)$. As a result, using Eq. (14.13) the average transmission time of a frame becomes

$$T_v = T_s + \frac{P T_T}{1 - P} = T_s \left(\frac{1 + 2\alpha P}{1 - P} \right) \quad (14.14)$$

FIGURE 14.7 Throughput efficiency for various ARQ protocols ($P = 0.1$).

FIGURE 14.8 Throughput efficiency for various ARQ protocols ($P = 0.01$).

Figures 14.7–14.10 show the throughput efficiency η of the three basic ARQ schemes as a function of the propagation delay ratio α , for frame error probabilities $P = 1 \times 10^{-1}$, 1×10^{-2} , 1×10^{-3} , and 1×10^{-4} , respectively.

Basic ARQ schemes present some limitations. The stop-and-wait scheme suffers from inefficiency due to the fact that the channel is idle between the transmission of the frame and the reception of the acknowledgment from the receiver. As shown in Figs. 14.7–14.10, this inefficiency is especially severe for

FIGURE 14.9 Throughput efficiency for various ARQ protocols ($P = 0.001$).

FIGURE 14.10 Throughput efficiency for various ARQ protocols ($P = 0.0001$).

large values of α , that is, when the roundtrip delay between the sender and the receiver is long compared to the transmission duration of a frame. In systems where the channel roundtrip delay is large and/or when the frame error probability P is relatively high, such as in satellite broadcast channels, the throughput efficiency of a stop-and-wait ARQ scheme becomes too poor to be acceptable. On the other hand, the selective-repeat ARQ scheme offers the best performance in terms of throughput efficiency, and, as shown in Figs. 14.7–14.10, it is insensitive to the propagation delay ratio. To overcome some of these limitations, hybrid FEC/ARQ schemes have been proposed.

14.4 Variants of the Basic Automatic Repeat Request Schemes

Several variants of the basic ARQ schemes with the objective of increasing the throughput efficiency and decreasing both buffer size and average transmission time have been proposed in the literature [Sastry, 1995; Despins and Haccoun, 1993]. Some variants have been proposed with the objective of alleviating particular drawbacks of specific ARQ schemes or satisfying special constraints for specific applications. However, these objectives may not be all satisfied, they may even be conflicting.

The main idea of these variants is to send multiple copies of a retransmitted frame rather than just sending a single copy. Variants of both stop-and-wait and continuous ARQ schemes have been proposed by Sastry [1995] for improving the throughput for channels having high error rates and long transmission delays such as satellite links. The modification consists of sending consecutively n copies, $n > 1$, of an erroneous frame before waiting for an ACK. This procedure substantially improves the probability of correctly receiving at least one error-free copy of that frame, which, hence, decreases multiple requests for retransmission of a given frame. For channels with long transmission delays, the increased transmission time for the n copies is more than compensated for by the fewer retransmission requests, leading to improved throughput efficiency over the usual stop-and-wait scheme. For continuous ARQ, whenever a NAK for a frame is received by the sender, that same frame is repeatedly transmitted until reception by the sender of its corresponding ACK. Here again the throughput may be substantially improved, especially for high error rate channels having a transmission delay much larger than the transmission duration of a frame.

A variation of the usual selective-repeat ARQ protocol has been recently proposed and analyzed by Despins and Haccoun [1993] for full-duplex channels suffering from a high error rate in both the forward and reverse directions. It consists essentially of sending a frame composed entirely of NAKs instead of piggybacking a single NAK on a data frame over the feedback channel. The idea is to provide a virtual error-free feedback channel for the NAKs, thus eliminating the need for implementing a time-out and buffer control procedure. For very severely degraded channels, the procedure is further refined by sending a number m ($m > 1$) of NAK frames for each incorrectly received data frame. The number of NAK frames m is calculated to ensure a practically error-free feedback channel. It is shown that the elimination of needless retransmissions outweighs the additional overhead of the NAK frames, leading to higher throughput efficiency and smaller buffer requirements over conventional selective-repeat ARQ, especially over fading channels.

For point-to-multipoint communication, Wang and Silvester [1993] have proposed adaptive multireceiver ARQ schemes. These variants can be applied to all three basic ARQ schemes. They differ from the classic schemes in the way the sender utilizes the outcome of a previous transmission to alter its next transmission. Basically, upon receiving a NAK for an erroneous frame from some given receivers, instead of repeating the transmission of that frame to all of the receivers in the system, the sender transmits a number of copies of that frame to only those receivers that previously received that frame in error. It has been shown that the optimal number of copies that the sender should transmit depends on the transmission error probability, the roundtrip propagation delay, and the number of receivers that have incorrectly received the data frame.

14.5 Hybrid Forward Error Control/Automatic Repeat Request Schemes

In systems where the channel roundtrip delay is large and/or where there is a large number of receivers, such as in satellite broadcast channels, the throughput efficiencies of the basic ARQ schemes, especially stop-and-wait, become unacceptable. Thus, hybrid ARQ schemes, consisting of an FEC subsystem integrated into an ARQ system, can overcome the drawbacks of ARQ and FEC schemes considered separately. Such combined schemes are commonly named *hybrid FEC/ARQ schemes*.

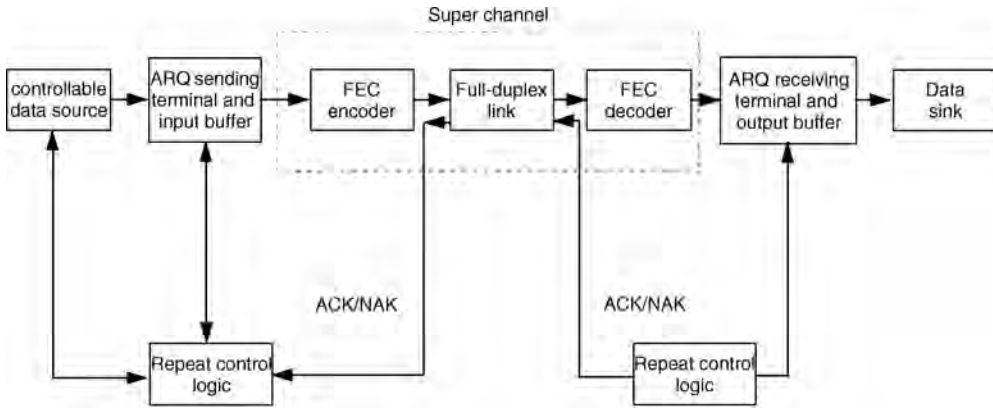

FIGURE 14.11 Principle of hybrid FEC/ARQ schemes.

The principle of hybrid FEC/ARQ schemes is to reduce the number of retransmissions by improving the channel using an FEC procedure. As shown in Fig. 14.11, a hybrid FEC/ARQ system is a concatenated system consisting of an inner FEC system and an outer ARQ system. The function of the inner FEC system is to improve the quality of the channel as seen by the ARQ system by correcting as many frames in error as possible, within its error correcting capability. Since only those erroneous frames that have not been corrected by the FEC will be retransmitted, clearly, under a poor channel condition where frame error rates are high and retransmission requests numerous, hybrid FEC/ARQ schemes can be especially useful for improving the efficiency of conventional ARQ schemes.

Hybrid FEC/ARQ schemes in data point-to-point communications over noisy channels are retransmission techniques that employ both error correction and error detection coding in order to achieve high throughput and low undetected error probabilities. There are two basic types of hybrid FEC/ARQ schemes: *type I hybrid ARQ* scheme, which includes parity bits for both error detection and error correction in each transmitted frame, and *type II hybrid ARQ* scheme, where parity bits for error correction only are sent on the first transmission.

In a type I hybrid FEC/ARQ scheme, when a frame is detected in error, the receiver first attempts to correct these errors. If the error-correcting capability allows the receiver to correct all of the errors detected in the frame, those errors are then corrected and the decoded frame is considered ready to be delivered to the user. In the case where a frame detected in error is revealed uncorrectable, the receiver rejects that frame and requests its retransmission, until that frame is successfully received or decoded. Clearly, a code designed to perform simultaneous error detection and correction is required. As a result, type I hybrid FEC/ARQ schemes require more parity-check bits than a code used only for error detection in a basic ARQ scheme. These extra redundant bits obviously increase the overhead of each transmission.

For low channel error probabilities, type I hybrid FEC/ARQ schemes provide lower throughput efficiencies than any basic ARQ scheme. However, for high channel error probabilities, since the number of retransmissions is reduced by the error-correcting capability of the system, type I hybrid FEC/ARQ schemes provide higher throughput efficiencies than any basic ARQ scheme. These schemes require that a fixed number of parity-check bits are sent with every frame for error correction purposes. Consequently, they are not adaptive to changing channel conditions and are best suited for channels with fairly constant noise or interference levels. For varying channel conditions, other adaptive error control techniques called type II hybrid FEC/ARQ schemes have been proposed [Rice and Wicker, 1994].

Type II hybrid FEC/ARQ schemes basically operate as follows. A frame F to be sent is coded, for its first transmission, with parity-check bits which only allow error detection. If that frame is detected in error in the form F^* , the receiver stores F^* in its buffer and then requests a retransmission. Instead of

retransmitting F in its original form, the sender retransmits a parity-check frame F_1 consisting of the original frame F and an error-correcting code. The receiver, which receives this parity-check frame F_1 , uses it to correct the erroneous frame F^* currently stored in its buffer. In the case of error correction failure, a second retransmission of the original frame F is requested by the receiver. Depending on the retransmission strategy and the type of error-correcting codes that are used, the second retransmission may be either a repetition of the original frame F or the transmission of another parity-check frame denoted F_2 [Lin, Costello, and Miller, 1984].

Both type I and type II hybrid FEC/ARQ schemes may use block or convolutional error-correcting codes. It is shown, by means of analysis as well as computer simulations, that both hybrid schemes are capable of providing high throughput efficiencies over a wide range of signal-to-noise ratios. More precisely, performance analysis of type II hybrid FEC/ARQ scheme shows that it is fairly robust against nonstationary channel noise due to the use of parity retransmission. In summary, hybrid FEC/ARQ schemes are suitable for large file transfers in applications where high throughput and high reliability are required over noisy channels, such as in satellite communications.

14.6 Application Problem

In this section, some numerical calculations on performance are presented for illustration purposes.

A satellite channel with a data rate of 2 Mb/s transmits 1000-bit frames. The roundtrip propagation time is 250 ms and the frame error probability is $P = 1 \times 10^{-3}$. Assuming that ACK and NAK frames are error-free, and assuming negligible processing and acknowledgment times:

1. Calculate the throughput efficiency for stop-and-wait ARQ.
2. Determine the average time for correct reception of a frame.
3. Find the average transmission time and the throughput efficiency for error-free operation using go-back- N ARQ, with a window size $N = 127$.
4. Compare the throughput efficiency for go-back- N ARQ and for selective-repeat ARQ, with the same window size $N = 127$.
5. Repeat step 4 using a window size $N = 2047$. Discuss.

Solution

The propagation delay $T_p = 1/2 \times 250 = 125$ ms. For a channel transmitting 1000-bit frames, at 2 Mb/s, the transmission duration of a single frame is

$$T_s = 1000/(2 \times 10^6) = 500 \times 10^{-6} \text{ s} = 0.5 \text{ ms}$$

The propagation delay ratio is then

$$\alpha = T_p/T_s = 125/(0.5) = 250$$

and, hence,

$$(2\alpha + 1) = 501$$

1. Given that ACK and NAK frames are error-free, and assuming the processing and acknowledgment times are negligible, the throughput efficiency for stop-and-wait ARQ can be calculated using Eq. (14.7)

$$\eta_{\text{sw}} = (1 - P)/(1 + 2\alpha) = 0.999/(501) = 2 \times 10^{-3}$$

The throughput efficiency of stop-and-wait ARQ schemes over such a channel is vanishingly low as also observed in Fig. 14.9. Clearly, stop-and-wait ARQ on satellite channels is not suitable.

- Using Eq. (14.8), the average time for correct reception of a frame is $T_v = T_T/(1 - P)$, where T_T can be computed using Eq. (14.3)

$$T_T = T_s + 2T_p = 0.5 + 2 \times 125 = 250.5 \text{ ms}$$

It follows that

$$T_v = 250.5/0.999 = 250.75 \text{ ms}$$

Hence, due to the low value of P , the average time for the correct retransmission of a frame is nearly equal to the roundtrip propagation time.

- The average transmission time for go-back- N ARQ is given by Eq. (14.14)

$$T_v = 0.5[(1 + 500 \times 10^{-3})/0.999] = 751 \text{ ms}$$

The throughput efficiency for go-back- N ARQ can be computed using Eq. (14.12). Since the window size is $N = 127$ and $(2\alpha + 1) = 501$, it follows that

$$\eta_{GB} = 127(0.999)/[(501)(0.999 + 0.127)] = 0.225$$

This value for the throughput efficiency may also be read directly from Fig. 14.9. The improvement in throughput efficiency of the go-back- N ARQ over the stop-and-wait scheme is then substantial.

- The throughput efficiency for selective-repeat ARQ is given by Eq. (14.10). With a window size $N = 127$ and $(2\alpha + 1) = 501$, then

$$\eta_{SR} = 127(0.999)/501 = 0.253$$

Again, this value can be read directly from Fig. 14.9, which shows that for these values of N and α , the throughput efficiencies of go-back- N and selective-repeat ARQ are approximately equal.

- Since $N = 2047$ and $(2\alpha + 1) = 501$, using Eqs. (14.12) and (14.10), respectively, it follows that for go-back- N the throughput efficiency is

$$\eta_{GB} = (0.999)/[1 + (2 \times 250 \times 0.001)] = 0.667$$

For selective-repeat ARQ we obtain

$$\eta_{SR} = (1 - 0.001) = 0.999$$

Therefore, the selective-repeat ARQ scheme provides nearly the maximum possible throughput efficiency and is substantially more efficient than go-back- N .

14.7 Conclusion

Fundamentals, performances, limitations, and variants of the basic ARQ schemes have been presented. These schemes offer reliability and robustness at buffering cost and reduced throughput. In systems such as packet radio and satellite networks, which are characterized by relatively large frame lengths and high noise or interference levels, the use of error correction coding may not provide the desired reliability. A combination of error correction coding and error detection coding may be therefore especially

attractive to overcome this shortcoming. Furthermore, over real channel systems characterized by great variations in the quality of the channel, ARQ systems tend to provide the robustness of the required error performance. New trends in digital communications systems using ARQ tend toward increasing the throughput efficiency without increasing buffering. These tendencies are being integrated into many applications involving point-to-multipoint communications over broadcast links used for file distribution, videotex systems, and teleconferencing. Such applications are becoming more and more popular, especially with the deployment of *Integrated Services Digital Networks* (ISDN) linked worldwide by satellite communication systems. Similarly, for wireless communication channels, which are corrupted by noise, fading, interference and shadowing, ARQ schemes can be used in order to provide adequate robustness and performance.

Defining Terms

Error correction: Procedure by which additional redundant symbols are added to the messages in order to allow the correction of errors in those messages.

Error detection: Procedure by which additional redundant symbols are added to the messages in order to allow the detection of errors in those messages.

Feedback channel: Return channel used by the receiver in order to inform the sender that erroneous frames have been received.

Forward channel: One-way channel used by the sender to transmit data frames to the receiver.

Full-duplex (or duplex) link: Link used for exchanging data or ACK/NAK frames between two connected devices in both directions simultaneously.

Half-duplex link: Link used for exchanging data or ACK/NAK frames between two connected devices in both directions but alternatively. Thus, the two devices must be able to switch between send and receive modes after each transmission.

15.1 A Brief History

Spread spectrum (SS) has its origin in the military arena where the friendly communicator is (1) susceptible to detection/interception by the enemy and (2) vulnerable to intentionally introduced unfriendly interference (jamming). Communication systems that employ spread spectrum to reduce the communicator's detectability and combat the enemy-introduced interference are respectively referred to as **low probability of intercept (LPI)** and **antijam (AJ) communication systems**. With the change in the current world political situation wherein the U.S. Department of Defense (DOD) has reduced its emphasis on the development and acquisition of new communication systems for the original purposes, a host of new commercial applications for SS has evolved, particularly in the area of cellular mobile communications. This shift from military to commercial applications of SS has demonstrated that the basic concepts that make SS techniques so useful in the military can also be put to practical peacetime use. In the next section, we give a simple description of these basic concepts using the original military application as the basis of explanation. The extension of these concepts to the mentioned commercial applications will be treated later on in the chapter.

15.2 Why Spread Spectrum?

Spread spectrum is a communication technique wherein the transmitted modulation is *spread* (increased) in bandwidth prior to transmission over the channel and then *despread* (decreased) in bandwidth by the same amount at the receiver. If it were not for the fact that the communication channel introduces some form of narrowband (relative to the spread bandwidth) interference, the receiver performance would be transparent to the spreading and despreading operations (assuming that they are identical inverses of each other). That is, after **despreading** the received signal would be identical to the transmitted signal prior to **spreading**. In the presence of narrowband interference, however, there is a significant advantage to employing the spreading/despreading procedure described. The reason for this is as follows.

Since the interference is introduced after the transmitted signal is spread, then, whereas the despreading operation at the receiver shrinks the desired signal back to its original bandwidth, at the same time it spreads the undesired signal (interference) in bandwidth by the same amount, thus reducing its power spectral density. This, in turn, serves to diminish the effect of the interference on the receiver performance, which depends on the amount of interference power in the despread bandwidth. It is indeed this very simple explanation which is at the heart of all spread spectrum techniques.

15.3 Basic Concepts and Terminology

To describe this process analytically and at the same time introduce some terminology that is common in spread spectrum parlance, we proceed as follows. Consider a communicator that desires to send a message using a transmitted power S Watts (W) at an information rate R_b bits/s (bps). By introducing an SS modulation, the bandwidth of the transmitted signal is increased from R_b Hz to W_{SS} Hz, where $W_{SS} \gg R_b$ denotes the **spread spectrum bandwidth**. Assume that the channel introduces, in addition to the usual thermal noise (assumed to have a single-sided power spectral density (PSD) equal to N_0 W/Hz), an additive interference (jamming) having power J distributed over some bandwidth W_j . After despreading, the desired signal bandwidth is once again now equal to R_b Hz and the interference PSD is now $N_j = J/W_{SS}$. Note that since the thermal noise is assumed to be white, i.e., it is uniformly distributed over all frequencies, its PSD is unchanged by the despreading operation and, thus, remains equal to N_0 . Regardless of the signal and interferer waveforms, the equivalent bit energy-to-total noise spectral density ratio is, in terms of the given parameters,

$$\frac{E_b}{N_t} = \frac{E_b}{N_0 + N_j} = \frac{S/R_b}{N_0 + J/W_{SS}} \quad (15.1)$$

For most practical scenarios, the jammer limits performance, and, thus, the effects of receiver noise in the channel can be ignored. Thus, assuming $N_j \gg N_0$, we can rewrite Eq. (15.1) as

$$\frac{E_b}{N_t} \cong \frac{E_b}{N_j} = \frac{S/R_b}{J/W_{SS}} = \frac{S W_{SS}}{J R_b} \quad (15.2)$$

where the ratio J/S is the *jammer-to-signal power ratio* and the ratio W_{SS}/R_b is the **spreading ratio** and is defined as the **processing gain** of the system. Since the ultimate error probability performance of the communication receiver depends on the ratio E_b/N_t , we see that from the communicator's viewpoint his goal should be to minimize J/S (by choice of S) and maximize the processing gain (by choice of W_{SS} for a given desired information rate). The possible strategies for the jammer will be discussed in the section on military applications dealing with AJ communications.

15.4 Spread Spectrum Techniques

By far the two most popular spreading techniques are **direct sequence (DS) modulation** and **frequency hopping (FH) modulation**. In the following subsections, we present a brief description of each.

Direct Sequence Modulation

A direct sequence modulation $c(t)$ is formed by linearly modulating the output sequence $\{c_n\}$ of a pseudorandom number generator onto a train of pulses, each having a duration T_c called the **chip time**. In mathematical form,

$$c(t) = \sum_{n=-\infty}^{\infty} c_n p(t - nT_c) \quad (15.3)$$

FIGURE 15.1 A DS-BPSK system (complex form).

where $p(t)$ is the basic pulse shape and is assumed to be of rectangular form. This type of modulation is usually used with binary phase-shift-keyed (BPSK) information signals, which have the complex form $d(t)\exp\{j(2\pi f_c t + \theta_c)\}$, where $d(t)$ is a binary-valued data waveform of rate $1/T_b$ bits/s and f_c and θ_c are the frequency and phase of the data-modulated carrier, respectively. As such, a DS/BPSK signal is formed by multiplying the BPSK signal by $c(t)$ (see Fig. 15.1), resulting in the real transmitted signal

$$x(t) = \text{Re}\{c(t)d(t)\exp[j(2\pi f_c t + \theta_c)]\} \quad (15.4)$$

Since T_c is chosen so that $T_b \gg T_c$, then relative to the bandwidth of the BPSK information signal, the bandwidth of the DS/BPSK signal¹ is effectively increased by the ratio $T_b/T_c = W_{SS}/2R_b$, which is one-half the spreading factor or processing gain of the system. At the receiver, the sum of the transmitted DS/BPSK signal and the channel interference $I(t)$ (as discussed before, we ignore the presence of the additive thermal noise) are ideally multiplied by the identical DS modulation (this operation is known as despreading), which returns the DS/BPSK signal to its original BPSK form whereas the real interference signal is now the real wideband signal $\text{Re}\{I(t)c(t)\}$. In the previous sentence, we used the word ideally, which implies that the PN waveform used for despreading at the receiver is identical to that used for spreading at the transmitter. This simple implication covers up a multitude of tasks that a practical DS receiver must perform. In particular, the receiver must first acquire the PN waveform. That is, the local PN random generator that generates the PN waveform at the receiver used for despreading must be aligned (synchronized) to within one chip of the PN waveform of the received DS/BPSK signal. This is accomplished by employing some sort of **search algorithm** which typically steps the local PN waveform sequentially in time by a fraction of a chip (e.g., half a chip) and at each position searches for a high degree of correlation between the received and local PN reference waveforms. The search terminates when the correlation exceeds a given threshold, which is an indication that the alignment has been achieved. After bringing the two PN waveforms into **coarse alignment**, a **tracking algorithm** is employed to maintain **fine alignment**. The most popular forms of tracking loops are the continuous time **delay-locked loop** and its time-multiplexed version the **tau-dither loop**. It is the difficulty in synchronizing the receiver PN generator to subnanosecond accuracy that limits PN chip rates to values on the order of hundreds of Mchips/s, which implies the same limitation on the DS spread spectrum bandwidth W_{SS} .

Frequency Hopping Modulation

A **frequency hopping (FH) modulation** $c(t)$ is formed by nonlinearly modulating a train of pulses with a sequence of pseudorandomly generated frequency shifts $\{f_n\}$. In mathematical terms, $c(t)$ has the complex form

$$c(t) = \sum_{n=-\infty}^{\infty} \exp\{j(2\pi f_n + \phi_n)\}p(t - nT_h) \quad (15.5)$$

¹For the usual case of a rectangular spreading pulse $p(t)$, the PSD of the DS/BPSK modulation will have $(\sin x/x)^2$ form with first zero crossing at $1/T_c$, which is nominally taken as one-half the spread spectrum bandwidth W_{SS} .

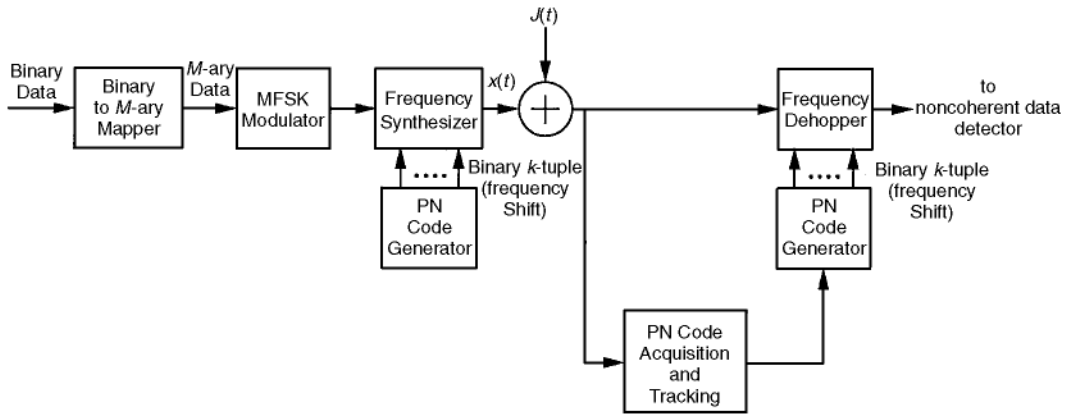

FIGURE 15.2 An FH-MFSK system.

where $p(t)$ is again the basic pulse shape having a duration T_h , called the **hop time**, and $\{\phi_n\}$ is a sequence of random phases associated with the generation of the hops. FH modulation is traditionally used with multiple-frequency-shift-keyed (MFSK) information signals, which have the complex form $\exp\{j[2\pi(f_c + d(t))t]\}$, where $d(t)$ is an M -level digital waveform (M denotes the symbol alphabet size) representing the information frequency modulation at a rate $1/T_s$ symbols/s (sps). As such, an FH/MFSK signal is formed by complex multiplying the MFSK signal by $c(t)$ resulting in the real transmitted signal

$$x(t) = \text{Re}\{c(t) \exp\{j[2\pi(f_c + d(t))t]\}\} \quad (15.6)$$

In reality, $c(t)$ is never generated in the transmitter. Rather, $x(t)$ is obtained by applying the sequence of pseudorandom frequency shifts $\{f_n\}$ directly to the frequency synthesizer that generates the carrier frequency f_c (see Fig. 15.2). In terms of the actual implementation, successive (not necessarily disjoint) k -chip segments of a PN sequence drive a frequency synthesizer, which hops the carrier over 2^k frequencies. In view of the large bandwidths over which the frequency synthesizer must operate, it is difficult to maintain phase coherence from hop to hop, which explains the inclusion of the sequence $\{\phi_n\}$ in the Eq. (15.5) model for $c(t)$. On a short term basis, e.g., within a given hop, the signal bandwidth is identical to that of the MFSK information modulation, which is typically much smaller than W_{SS} . On the other hand, when averaged over many hops, the signal bandwidth is equal to W_{SS} , which can be on the order of several GHz, i.e., an order of magnitude larger than that of implementable DS bandwidths. The exact relation between W_{SS} , T_h , T_s and the number of frequency shifts in the set $\{f_n\}$ will be discussed shortly.

At the receiver, the sum of the transmitted FH/MFSK signal and the channel interference $I(t)$ is ideally complex multiplied by the identical FH modulation (this operation is known as **dehopping**), which returns the FH/MFSK signal to its original MFSK form, whereas the real interference signal is now the wideband (in the average sense) signal $\text{Re}\{I(t)c(t)\}$. Analogous to the DS case, the receiver must acquire and track the FH signal so that the dehopping waveform is as close to the hopping waveform $c(t)$ as possible.

FH systems are traditionally classified in accordance with the relationship between T_h and T_s . **Fast frequency-hopped (FFH)** systems are ones in which there exist one or more hops per data symbol, that is, $T_s = NT_h$ (N an integer), whereas **slow frequency-hopped (SFH)** systems are ones in which there exist more than one symbol per hop, that is, $T_h = NT_s$. It is customary in SS parlance to refer to the FH/MFSK tone of shortest duration as a “chip,” despite the same usage for the PN chips associated with the code generator that drives the frequency synthesizer. Keeping this distinction in mind, in an FFH system where, as already stated, there are multiple hops per data symbol, a chip is equal to a hop. For SFH, where there are multiple data symbols per hop, a chip is equal to an MFSK symbol. Combining these two statements,

the chip rate R_c in an FH system is given by the larger of $R_h = 1/T_h$ and $R_s = 1/T_s$ and, as such, is the highest system clock rate.

The frequency spacing between the FH/MFSK tones is governed by the chip rate R_c and is, thus, dependent on whether the FH modulation is FFH or SFH. In particular, for SFH where $R_c = R_s$, the spacing between FH/MFSK tones is equal to the spacing between the MFSK tones themselves. For noncoherent detection (the most commonly encountered in FH/MFSK systems), the separation of the MFSK symbols necessary to provide orthogonality² is an integer multiple of R_s . Assuming the minimum spacing, i.e., R_s , the entire spread spectrum band is then partitioned into a total of $N_t = W_{ss}/R_s = W_{ss}/R_c$ equally spaced FH tones. One arrangement, which is by far the most common, is to group these N_t tones into $N_b = N_t/M$ contiguous, nonoverlapping bands, each with bandwidth $MR_s = MR_c$; see Fig. 15.3a. Assuming symmetric MFSK modulation around the carrier frequency, then the center frequencies of the $N_b = 2^k$ bands represent the set of hop carriers, each of which is assigned to a given k -tuple of the PN code generator. In this fixed arrangement, each of the N_t FH/MFSK tones corresponds to the combination of a unique hop carrier (PN code k -tuple) and a unique MFSK symbol. Another arrangement, which provides more protection against the sophisticated interferer (jammer), is to overlap adjacent M -ary bands by an amount equal to R_c ; see Fig. 15.3b. Assuming again that the center frequency of each band corresponds to a possible hop carrier, then since all but $M - 1$ of the N_t tones are available as center frequencies, the number of hop carriers has been increased from N_t/M to $N_t - (M - 1)$, which for $N_t \gg M$ is approximately an increase in randomness by a factor of M .

For FFH, where $R_c = R_h$, the spacing between FH/MFSK tones is equal to the hop rate. Thus, the entire spread spectrum band is partitioned into a total of $N_t = W_{ss}/R_h = W_{ss}/R_c$ equally spaced FH tones, each of which is assigned to a unique k -tuple of the PN code generator that drives the frequency synthesizer. Since for FFH there are R_h/R_s hops per symbol, then the metric used to make a noncoherent decision on a particular symbol is obtained by summing up R_h/R_s detected chip (hop) energies, resulting in a so-called *noncoherent combining loss*.

Time Hopping Modulation

Time hopping (TH) is to spread spectrum modulation what pulse position modulation (PPM) is to information modulation. In particular, consider segmenting time into intervals of T_f seconds and further segment each T_f interval into M_T increments of width T_f/M_T . Assuming a pulse of maximum duration equal to T_f/M_T , then a **time hopping spread spectrum** modulation would take the form

$$c(t) = \sum_{n=0}^{M_T-1} p \left[t - \left(n + \frac{a_n}{M_T} \right) T_f \right] \quad (15.7)$$

where a_n denotes the pseudorandom position (one of M_T uniformly spaced locations) of the pulse within the T_f -second interval.

For DS and FH, we saw that *multiplicative* modulation, that is, the transmitted signal is the product of the SS and information signals, was the natural choice. For TH, *delay* modulation is the natural choice. In particular, a TH-SS modulation takes the form

$$x(t) = \text{Re}\{c(t-d(t)) \exp[j(2\pi f_c + \phi)]\} \quad (15.8)$$

²An optimum noncoherent MFSK detector consists of a bank of energy detectors each matched to one of the M frequencies in the MFSK set. In terms of this structure, the notion of *orthogonality* implies that for a given transmitted frequency there will be no crosstalk (energy spillover) in any of the other $M - 1$ energy detectors.

FIGURE 15.3(a) Frequency distribution for FH-4FSK—nonoverlapping bands. Dashed lines indicate location of hop frequencies.

where $d(t)$ is a digital information modulation at a rate $1/T_s$ sps. Finally, the dehopping procedure at the receiver consists of removing the sequence of delays introduced by $c(t)$, which restores the information signal back to its original form and spreads the interferer.

Hybrid Modulations

By blending together several of the previous types of SS modulation, one can form **hybrid** modulations that, depending on the system design objectives, can achieve a better performance against the interferer than can any of the SS modulations acting alone. One possibility is to multiply several of the $c(t)$ wideband

FIGURE 15.3(b) Frequency distribution for FH-4FSK—overlapping bands.

waveforms [now denoted by $c^{(i)}(t)$ to distinguish them from one another] resulting in a SS modulation of the form

$$c(t) = \prod_i c^{(i)}(t) \tag{15.9}$$

Such a modulation may embrace the advantages of the various $c^{(i)}(t)$, while at the same time mitigating their individual disadvantages.

15.5 Applications of Spread Spectrum

Military

Antijam (AJ) Communications

As already noted, one of the key applications of spread spectrum is for antijam communications in a hostile environment. The basic mechanism by which a **direct sequence spread spectrum** receiver attenuates a noise jammer was illustrated in Section 15.3. Therefore, in this section, we will concentrate on tone jamming.

Assume the received signal, denoted $r(t)$, is given by

$$r(t) = Ax(t) + I(t) + n_w(t) \tag{15.10}$$

where $x(t)$ is given in Eq. (15.4), A is a constant amplitude,

$$I(t) = \alpha \cos(2\pi f_c t + \theta) \tag{15.11}$$

and $n_w(t)$ is additive white Gaussian noise (AWGN) having two-sided spectral density $N_0/2$. In Eq. (15.11), α is the amplitude of the tone jammer and θ is a random phase uniformly distributed in $[0, 2\pi]$.

If we employ the standard correlation receiver of Fig. 15.4, it is straightforward to show that the final test statistic out of the receiver is given by

$$g(T_b) = AT_b + \alpha \cos \theta \int_0^{T_b} c(t) dt + N(T_b) \tag{15.12}$$

where $N(T_b)$ is the contribution to the test statistic due to the AWGN. Noting that, for rectangular chips, we can express

$$\int_0^{T_b} c(t) dt = T_c \sum_{i=1}^M c_i \tag{15.13}$$

where

$$M \triangleq \frac{T_b}{T_c} \tag{15.14}$$

is one-half of the processing gain, it is straightforward to show that, for a given value of θ , the signal-to-noise-plus-interference ratio, denoted by S/N_{total} , is given by

$$\frac{S}{N_{total}} = \frac{1}{\frac{N_0}{2E_b} + \left(\frac{J}{MS}\right) \cos^2 \theta} \tag{15.15}$$

In Eq.(15.15), the jammer power is

$$J \triangleq \frac{\alpha^2}{2} \tag{15.16}$$

FIGURE 15.4 Standard correlation receiver.

and the signal power is

$$S \triangleq \frac{A^2}{2} \quad (15.17)$$

If we look at the second term in the denominator of Eq. (15.15), we see that the ratio J/S is divided by M . Realizing that J/S is the ratio of the jammer power to the signal power before despreading, and J/MS is the ratio of the same quantity after despreading, we see that, as was the case for noise jamming, the benefit of employing direct sequence spread spectrum signalling in the presence of tone jamming is to reduce the effect of the jammer by an amount on the order of the processing gain.

Finally, one can show that an estimate of the average probability of error of a system of this type is given by

$$P_e = \frac{1}{2\pi} \int_0^{2\pi} \phi\left(-\sqrt{\frac{S}{N_{\text{total}}}}\right) d\theta \quad (15.18)$$

where

$$\phi(x) \triangleq \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-y^2/2} dy \quad (15.19)$$

If Eq. (15.18) is evaluated numerically and plotted, the results are as shown in Fig. 15.5. It is clear from this figure that a large initial power advantage of the jammer can be overcome by a sufficiently large value of the processing gain.

Low-Probability of Intercept (LPI)

The opposite side of the AJ problem is that of LPI, that is, the desire to hide your signal from detection by an intelligent adversary so that your transmissions will remain unnoticed and, thus, neither jammed nor exploited in any manner. This idea of designing an LPI system is achieved in a variety of ways, including transmitting at the smallest possible power level, and limiting the transmission time to as short an interval in time as is possible. The choice of signal design is also important, however, and it is here that spread spectrum techniques become relevant.

The basic mechanism is reasonably straightforward; if we start with a conventional narrowband signal, say a BPSK waveform having a spectrum as shown in Fig. 15.6a, and then spread it so that its new spectrum is as shown in Fig. 15.6b, the peak amplitude of the spectrum after spreading has been reduced by an amount on the order of the processing gain relative to what it was before spreading. Indeed, a sufficiently large processing gain will result in the spectrum of the signal after spreading falling below the ambient thermal noise level. Thus, there is no easy way for an unintended listener to determine that a transmission is taking place.

That is not to say the spread signal cannot be detected, however, merely that it is more difficult for an adversary to learn of the transmission. Indeed, there are many forms of so-called intercept receivers that are specifically designed to accomplish this very task. By way of example, probably the best known and simplest to implement is a **radiometer**, which is just a device that measures the total power present in the received signal. In the case of our intercept problem, even though we have lowered the power spectral density of the transmitted signal so that it falls below the noise floor, we have not lowered its power (i.e., we have merely spread its power over a wider frequency range). Thus, if the radiometer integrates over a sufficiently long period of time, it will eventually determine the presence of the transmitted signal buried in the noise. The key point, of course, is that the use of the spreading makes the interceptor's task much more difficult, since he has no knowledge of the spreading code and, thus, cannot despread the signal.

FIGURE 15.5 Plotted results of Eq. (11.18).

FIGURE 15.6a

Commercial

Multiple Access Communications

From the perspective of commercial applications, probably the most important use of spread spectrum communications is as a multiple accessing technique. When used in this manner, it becomes an alternative to either frequency division multiple access (FDMA) or time division multiple access (TDMA) and is typically referred to as either code division multiple access (CDMA) or spread spectrum multiple access (SSMA). When using CDMA, each signal in the set is given its own spreading sequence. As opposed to either FDMA, wherein all users occupy disjoint frequency bands but are transmitted simultaneously in time, or TDMA, whereby all users occupy the same bandwidth but transmit in disjoint intervals of time, in CDMA, all signals occupy the same bandwidth and are transmitted simultaneously in time; the different waveforms in CDMA are distinguished from one another at the receiver by the specific spreading codes they employ.

Since most CDMA detectors are correlation receivers, it is important when deploying such a system to have a set of spreading sequences that have relatively low-pairwise cross-correlation between any two sequences in the set. Further, there are two fundamental types of operation in CDMA, synchronous and asynchronous. In the former case, the symbol transition times of all of the users are aligned; this allows for orthogonal sequences to be used as the spreading sequences and, thus, eliminates interference from one user to another. Alternately, if no effort is made to align the sequences, the system operates asynchronously; in this latter mode, multiple access interference limits the ultimate channel capacity, but the system design exhibits much more flexibility.

CDMA has been of particular interest recently for applications in wireless communications. These applications include cellular communications, personal communications services (PCS), and wireless local area networks. The reason for this popularity is primarily due to the performance that spread spectrum waveforms display when transmitted over a multipath fading channel.

To illustrate this idea, consider DS signalling. As long as the duration of a single chip of the spreading sequence is less than the multipath delay spread, the use of DS waveforms provides the system designer with one of two options. First, the multipath can be treated as a form of interference, which means the receiver should attempt to attenuate it as much as possible. Indeed, under this condition, all of the multipath returns that arrive at the receiver with a time delay greater than a chip duration from the multipath return to which the receiver is synchronized (usually the first return) will be attenuated because of the processing gain of the system.

Alternately, the multipath returns that are separated by more than a chip duration from the main path represent independent “looks” at the received signal and can be used constructively to enhance the overall performance of the receiver. That is, because all of the multipath returns contain information regarding the data that is being sent, that information can be extracted by an appropriately designed receiver. Such a receiver, typically referred to as a RAKE receiver, attempts to resolve as many individual multipath returns as possible and then to sum them coherently. This results in an *implicit* diversity gain, comparable to the use of *explicit* diversity, such as receiving the signal with multiple antennas.

The condition under which the two options are available can be stated in an alternate manner. If one envisions what is taking place in the frequency domain, it is straightforward to show that the condition of the chip duration being smaller than the multipath delay spread is equivalent to requiring that the spread bandwidth of the transmitted waveform exceed what is called the coherence bandwidth of the channel. This latter quantity is simply the inverse of the multipath delay spread and is a measure of the range of frequencies that fade in a highly correlated manner. Indeed, anytime the coherence bandwidth of the channel is less than the spread bandwidth of the signal, the channel is said to be *frequency selective* with respect to the signal. Thus, we see that to take advantage of DS signalling when used over a multipath fading channel, that signal should be designed such that it makes the channel appear frequency selective.

In addition to the desirable properties that spread spectrum signals display over multipath channels, there are two other reasons why such signals are of interest in cellular-type applications. The first has to do with a concept known as the reuse factor. In conventional cellular systems, either analog or digital, in order to avoid excessive interference from one cell to its neighbor cells, the frequencies used by a given

cell are not used by its immediate neighbors (i.e., the system is designed so that there is a certain spatial separation between cells that use the same carrier frequencies). For CDMA, however, such spatial isolation is typically not needed, so that so-called *universal reuse* is possible.

Further, because CDMA systems tend to be interference limited, for those applications involving voice transmission, an additional gain in the capacity of the system can be achieved by the use of *voice activity detection*. That is, in any given two-way telephone conversation, each user is typically talking only about 50% of the time. During the time when a user is quiet, he is not contributing to the instantaneous interference. Thus, if a sufficiently large number of users can be supported by the system, statistically only about one-half of them will be active simultaneously, and the effective capacity can be doubled.

Interference Rejection

In addition to providing multiple accessing capability, spread spectrum techniques are of interest in the commercial sector for basically the same reasons they are used in the military community, namely their AJ and LPI characteristics. However, the motivations for such interest differ. For example, whereas the military is interested in ensuring that the systems they deploy are robust to interference generated by an intelligent adversary (i.e., exhibit jamming resistance), the interference of concern in commercial applications is unintentional. It is sometimes referred to as cochannel interference (CCI) and arises naturally as the result of many services using the same frequency band at the same time. And while such scenarios almost always allow for some type of spatial isolation between the interfering waveforms, such as the use of narrow-beam antenna patterns, at times the use of the inherent interference suppression property of a spread spectrum signal is also desired. Similarly, whereas the military is very much interested in the LPI property of a spread spectrum waveform, as indicated in [Section 15.3](#), there are applications in the commercial segment where the same characteristic can be used to advantage.

To illustrate these two ideas, consider a scenario whereby a given band of frequencies is somewhat sparsely occupied by a set of conventional (i.e., nonspread) signals. To increase the overall spectral efficiency of the band, a set of spread spectrum waveforms can be overlaid on the same frequency band, thus forcing the two sets of users to share a common spectrum. Clearly, this scheme is feasible only if the mutual interference that one set of users imposes on the other is within tolerable limits. Because of the interference suppression properties of spread spectrum waveforms, the despreading process at each spread spectrum receiver will attenuate the components of the final test statistic due to the overlaid narrowband signals. Similarly, because of the LPI characteristics of spread spectrum waveforms, the increase in the overall noise level as seen by any of the conventional signals, due to the overlay, can be kept relatively small.

Defining Terms

Antijam communication system: A communication system designed to resist intentional jamming by the enemy.

Chip time (interval): The duration of a single pulse in a direct sequence modulation; typically much smaller than the information symbol interval.

Coarse alignment: The process whereby the received signal and the despreading signal are aligned to within a single chip interval.

Dehopping: Despreading using a frequency-hopping modulation.

Delay-locked loop: A particular implementation of a closed-loop technique for maintaining fine alignment.

Despreading: The notion of decreasing the bandwidth of the received (spread) signal back to its information bandwidth.

Direct sequence modulation: A signal formed by linearly modulating the output sequence of a pseudorandom number generator onto a train of pulses.

Direct sequence spread spectrum: A spreading technique achieved by multiplying the information signal by a direct sequence modulation.

Fast frequency-hopping: A spread spectrum technique wherein the hop time is less than or equal to the information symbol interval, i.e., there exist one or more hops per data symbol.

Fine alignment: The state of the system wherein the received signal and the despreading signal are aligned to within a small fraction of a single chip interval.

Frequency-hopping modulation: A signal formed by nonlinearly modulating a train of pulses with a sequence of pseudorandomly generated frequency shifts.

Hop time (interval): The duration of a single pulse in a frequency-hopping modulation.

Hybrid spread spectrum: A spreading technique formed by blending together several spread spectrum techniques, e.g., direct sequence, frequency-hopping, etc.

Low-probability-of-intercept communication system: A communication system designed to operate in a hostile environment wherein the enemy tries to detect the presence and perhaps characteristics of the friendly communicator's transmission.

Processing gain (spreading ratio): The ratio of the spread spectrum bandwidth to the information data rate.

Radiometer: A device used to measure the total energy in the received signal.

Search algorithm: A means for coarse aligning (synchronizing) the despreading signal with the received spread spectrum signal.

Slow frequency-hopping: A spread spectrum technique wherein the hop time is greater than the information symbol interval, i.e., there exists more than one data symbol per hop.

Spread spectrum bandwidth: The bandwidth of the transmitted signal after spreading.

Spreading: The notion of increasing the bandwidth of the transmitted signal by a factor far in excess of its information bandwidth.

Tau-dither loop: A particular implementation of a closed-loop technique for maintaining fine alignment.

Time-hopping spread spectrum: A spreading technique that is analogous to pulse position modulation.

Tracking algorithm: An algorithm (typically closed loop) for maintaining fine alignment.

16.1 Introduction

Diversity is a commonly used technique in mobile radio systems to combat signal **fading**. The basic principle of diversity is as follows. If several replicas of the same information-carrying signal are received over multiple channels with comparable strengths, which exhibit independent fading, then there is a good likelihood that at least one or more of these received signals will not be in a fade at any given instant in time, thus making it possible to deliver an adequate signal level to the receiver. Without diversity techniques, in noise limited conditions, the transmitter would have to deliver a much higher power level to protect the link during the short intervals when the channel is severely faded. In mobile radio, the power available on the reverse link is severely limited by the battery capacity of hand-held subscriber units. Diversity methods play a crucial role in reducing transmit power needs. Also, cellular communication networks are mostly interference limited and, once again, mitigation of channel fading through use of diversity can translate into reduced variability of carrier-to-interference ratio (C/I), which in turn means lower C/I margin and hence better reuse factors and higher system capacity.

The basic principles of diversity have been known since 1927, when the first experiments in space diversity were reported. There are many techniques for obtaining independently fading branches, and these can be subdivided into two main classes. The first are explicit techniques where explicit redundant signal transmission is used to exploit diversity channels. Use of dual polarized signal transmission and reception in many point-to-point radios is an example of explicit diversity. Clearly, such redundant signal transmission involves a penalty in frequency spectrum or additional power. In the second class are implicit diversity techniques: the signal is transmitted only once, but the decorrelating effects in the propagation medium such as multipaths are exploited to receive signals over multiple diversity channels. A good example of implicit diversity is the **RAKE receiver** in code division multiple access (CDMA) systems, which uses independent fading of resolvable multipaths to achieve diversity gain. [Figure 16.1](#) illustrates the principle of diversity where two independently fading signals are shown along with the selection diversity output signal which selects the stronger signal. The fades in the resulting signal have been substantially smoothed out while also yielding higher average power.

FIGURE 16.1 Example of diversity combining. Two independently fading signals 1 and 2. The signal 3 is the result of selecting the strongest signal.

If antennas are used in transmit, they can be exploited for diversity. If the transmit channel is known, the antennas can be driven with complex conjugate channel weighting to co-phase the signals at the receive antenna. If the forward channel is not known, we have several methods to convert space selective fading at the transmit antennas to other forms of diversity exploitable in the receiver.

Exploiting diversity needs careful design of the communication link. In explicit diversity, multiple copies of the same signal are transmitted in channels using either a frequency, time, or polarization dimension. At the receiver end we need arrangements to receive the different diversity branches (this is true for both explicit and implicit diversity). The different diversity branches are then combined to reduce signal **outage probability** or bit error rate.

In practice, the signals in the diversity branches may not show completely independent fading. The envelope cross correlation ρ between these signals is a measure of their independence.

$$r = \frac{E[(r_1 - \bar{r}_1][r_2 - \bar{r}_2])}{\sqrt{E|r_1 - \bar{r}_1|^2 E|r_2 - \bar{r}_2|^2}}$$

where r_1 and r_2 represent the instantaneous envelope levels of the normalized signals at the two receivers and \bar{r}_1 and \bar{r}_2 are their respective means. It has been shown that a cross correlation of 0.7 [3] between signal envelopes is sufficient to provide a reasonable degree of diversity gain. Depending on the type of diversity employed, these diversity channels must be sufficiently *separated* along the appropriate diversity dimension. For spatial diversity, the antennas should be separated by more than the *coherence distance* to ensure a cross correlation of less than 0.7. Likewise in frequency diversity, the frequency separation must be larger than the *coherence bandwidth*, and in time diversity the separation between channel reuse in time should be longer than the *coherence time*. These coherence factors in turn depend on the channel characteristics. The coherence distance, coherence bandwidth, and coherence time vary inversely as the angle spread, delay spread, and Doppler spread, respectively.

If the receiver has a number of diversity branches, it has to combine these branches to maximize the signal level. Several techniques have been studied for diversity combining. We will describe three main techniques: selection combining, equal gain combining, and maximal ratio combining.

Finally, we should note that diversity is primarily used to combat fading, and if the signal does not show significant fading in the first place, for example, when there is a direct path component, diversity combining may not provide significant diversity gain. In the case of antenna diversity, array gain proportional to the number of antennas will still be available.

16.2 Diversity Schemes

There are several techniques for obtaining diversity branches, sometimes also known as diversity dimensions. The most important of these are discussed in the following sections.

Space Diversity

This has historically been the most common form of diversity in mobile radio base stations. It is easy to implement and does not require additional frequency spectrum resources. Space diversity is exploited on the reverse link at the base station receiver by spacing antennas apart so as to obtain sufficient decorrelation. The key for obtaining minimum uncorrelated fading of antenna outputs is adequate spacing of the antennas. The required spacing depends on the degree of multipath angle spread. For example, if the multipath signals arrive from all directions in the azimuth, as is usually the case at the mobile, antenna spacing (coherence distance) of the order of 0.5λ to 0.8λ is quite adequate [5]. On the other hand, if the multipath angle spread is small, as in the case of base stations, the coherence distance is much larger. Also, empirical measurements show a strong coupling between antenna height and spatial correlation. Larger antenna heights imply larger coherence distances. Typically, 10λ to 20λ separation is adequate to achieve $\rho = 0.7$ at base stations in suburban settings when the signals arrive from the broadside direction. The coherence distance can be 3 to 4 times larger for endfire arrivals. The endfire problem is averted in base stations with trisectored antennas as each sector needs to handle only signals arriving $\pm 60^\circ$ off the broadside. The coherence distance depends strongly on the terrain. Large multipath angle spread means smaller coherence distance. Base stations normally use space diversity in the horizontal plane only. Separation in the vertical plane can also be used, and the necessary spacing depends upon vertical multipath angle spread. This can be small for distant mobiles making vertical plane diversity less attractive in most applications.

Space diversity is also exploitable at the transmitter. If the forward channel is known, it works much like receive space diversity. If it is not known, then space diversity can be transformed to another form of diversity exploitable at the receiver. (See the section on Transformed Diversity).

If antennas are used at transmit and receive, the M transmit and N receive antennas both contribute to diversity. It can be shown that if simple weighting is used without additional bandwidth or time/memory processing, then maximum diversity gain is obtained if the transmitter and receiver use the left and right singular vectors of the $M \times N$ channel matrix, respectively. However, to approach the maximum $M \times N$ order diversity will require the use of additional bandwidth or time/memory-based methods.

Polarization Diversity

In mobile radio environments, signals transmitted on orthogonal polarizations exhibit low fade correlation and, therefore, offer potential for diversity combining. Polarization diversity can be obtained either by explicit or implicit techniques. Note that with polarization, only two diversity branches are available as compared to space diversity, where several branches can be obtained using multiple antennas. In explicit polarization diversity, the signal is transmitted and received in two orthogonal polarizations. For a fixed total transmit power, the power in each branch will be 3 dB lower than if single polarization is used. In the implicit polarization technique, the signal is launched in a single polarization but is received with cross-polarized antennas. The propagation medium couples some energy into the cross-polarization plane. The observed cross-polarization coupling factor lies between 8 to 12 dB in mobile radio [8,1].

The cross-polarization envelope decorrelation has been found to be adequate. However, the large branch imbalance reduces the available diversity gain.

With hand-held phones, the handset can be held at random orientations during a call. This results in energy being launched with varying polarization angles ranging from vertical to horizontal. This further increases the advantage of cross-polarized antennas at the base station since the two antennas can be combined to match the received signal polarization. This makes polarization diversity even more attractive. Recent work [4] has shown that with variable launch polarization, a cross-polarized antenna can give comparable overall (matching plus diversity) performance to a vertically polarized space diversity antenna.

Finally, we should note that cross-polarized antennas can be deployed in a compact antenna assembly and do not need large physical separation as needed in space diversity antennas. This is an important advantage in the PCS base stations where low profile antennas are needed.

Angle Diversity

In situations where the angle spread is very high, such as indoors or at the mobile unit in urban locations, signals collected from multiple nonoverlapping beams offer low fade correlation with balanced power in the diversity branches. Clearly, since directional beams imply use of antenna aperture, angle diversity is closely related to space diversity. Angle diversity has been utilized in indoor wireless LANs, where its use allows substantial increase in LAN throughputs [2].

Frequency Diversity

Another technique to obtain decorrelated diversity branches is to transmit the same signal over different frequencies. The frequency separation between carriers should be larger than the coherence bandwidth. The coherence bandwidth, of course, depends on the multipath delay spread of the channel. The larger the delay spread, the smaller the coherence bandwidth and the more closely we can space the frequency diversity channels. Clearly, frequency diversity is an explicit diversity technique and needs additional frequency spectrum.

A common form of frequency diversity is multicarrier (also known as multitone) modulation. This technique involves sending redundant data over a number of closely spaced carriers to benefit from frequency diversity, which is then exploited by applying **interleaving** and **channel coding/forward error correction** across the carriers. Another technique is to use **frequency hopping** wherein the interleaved and channel coded data stream is transmitted with widely separated frequencies from burst to burst. The wide frequency separation is chosen to guarantee independent fading from burst to burst.

Path Diversity

This implicit diversity is available if the signal bandwidth is much larger than the channel coherence bandwidth. The basis for this method is that when the multipath arrivals can be resolved in the receiver and since the paths fade independently, diversity gain can be obtained. In CDMA systems, the multipath arrivals must be separated by more than one *chip* period and the RAKE receiver provides the diversity [9]. In TDMA systems, the multipath arrivals must be separated by more than one *symbol* period and the MLSE receiver provides the diversity.

Time Diversity

In mobile communications channels, the mobile motion together with scattering in the vicinity of the mobile causes time selective fading of the signal with Rayleigh fading statistics for the signal envelope. Signal fade levels separated by the *coherence time* show low correlation and can be used as diversity branches if the same signal can be transmitted at multiple instants separated by the coherence time. The coherence time depends on the Doppler spread of the signal, which in turn is a function of the mobile speed and the carrier frequency.

Time diversity is usually exploited via interleaving, forward-error correction (FEC) coding, and **automatic request for repeat** (ARQ). These are sophisticated techniques to exploit channel coding and time

diversity. One fundamental drawback with time diversity approaches is the delay needed to collect the repeated or interleaved transmissions. If the coherence time is large, as, for example, when the vehicle is slow moving, the required delay becomes too large to be acceptable for interactive voice conversation.

The statistical properties of fading signals depend on the field component used by the antenna, the vehicular speed, and the carrier frequency. For an idealized case of a mobile surrounded by scatterers in all directions, the autocorrelation function of the received signal $x(t)$ (note this is not the envelope $r(t)$) can be shown to be

$$E[x(t)x(t+t)] = J_0(2\pi\tau v/\lambda)$$

where J_0 is a Bessel function of the 0th order and v is the mobile velocity.

Transformed Diversity

In transformed diversity, the space diversity branches at the transmitter are transformed into other forms of diversity branches exploitable at the receiver. This is used when the forward channel is not known and shifts the responsibility of diversity combining to the receiver which has the necessary channel knowledge.

Space to Frequency

- *Antenna-delay.* Here the signal is transmitted from two or more antennas with delays of the order of a chip or symbol period in CDMA or TDMA, respectively. The different transmissions simulate resolved path arrivals that can be used as diversity branches by the RAKE or MLSE equalizer.
- *Multicarrier modulation.* The data stream after interleaving and coding is modulated as a multi-carrier output using an inverse DFT. The carriers are then mapped to the different antennas. The space selective fading at the antennas is now transformed to frequency selective fading and diversity is obtained during decoding.

Space to Time

- *Antenna hopping/phase rolling.* In this method the data stream after coding and interleaving is switched randomly from antenna to antenna. The space selective fading at the transmitter is converted into a time selective fading at the receiver. This is a form of “active” fading.
- *Space-time coding.* The approach in space-time coding is to split the encoded data into multiple data streams, each of which is modulated and simultaneously transmitted from different antennas. The received signal is a superposition of the multiple transmitted signals. Channel decoding can be used to recover the data sequence. Since the encoded data arrive over uncorrelated fade branches, diversity gain can be realized.

16.3 Diversity Combining Techniques

Several diversity combining methods are known. We describe three main techniques: selection, maximal ratio, and equal gain. They can be used with each of the diversity schemes discussed above.

Selection Combining

This is the simplest and perhaps the most frequently used form of diversity combining. In this technique, one of the two diversity branches with the highest carrier-to-noise ratio (C/N) is connected to the output. See Fig. 16.2(a).

The performance improvement due to selection diversity can be seen as follows. Let the signal in each branch exhibit Rayleigh fading with mean power σ^2 . The density function of the envelope is given by

$$p(r_i) = \frac{r_i}{\sigma^2} e^{-\frac{r_i^2}{2\sigma^2}} \quad (16.1)$$

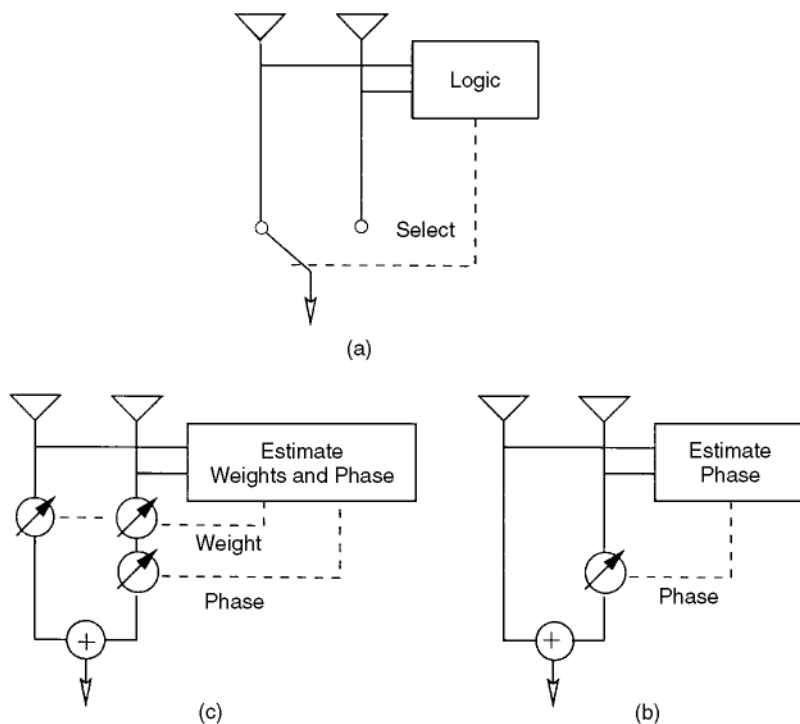

FIGURE 16.2 Diversity combining methods for two diversity branches.

where r_i is the signal envelope in each branch. If we define two new variables

$$g_i = \frac{\text{Instantaneous signal power in each branch}}{\text{Mean noise power}}$$

$$G = \frac{\text{Mean signal power in each branch}}{\text{Mean noise power}}$$

then the probability that the C/N is less than or equal to some specified value γ_s is

$$\text{Prob}[\gamma_i \leq \gamma_s] = 1 - e^{-\gamma_s/\Gamma} \quad (16.2)$$

The probability that γ_i in all branches with independent fading will be simultaneously less than or equal to γ_s is then

$$\text{Prob}[\gamma_1, \gamma_2, \dots, \gamma_M \leq \gamma_s] = (1 - e^{-\gamma_s/\Gamma})^M \quad (16.3)$$

This is the distribution of the best signal envelope from the two diversity branches. Figure 16.3 shows the distribution of the combiner output C/N for $M = 1, 2, 3$, and 4 branches. The improvement in signal quality is significant. For example, at 99% reliability level, the improvement in C/N is 10 dB for two branches and 16 dB for four branches.

Selection combining also increases the mean C/N of the combiner output and can be shown to be [3]

$$\text{Mean}(\gamma_s) = \Gamma \sum_{k=1}^M \frac{1}{k} \quad (16.4)$$

FIGURE 16.3 Probability distribution of signal envelope for selection combining.

This indicates that with 4 branches, for example, the mean C/N of the selected branch is 2.08 better than the mean C/N in any one branch.

Maximal Ratio Combining

In this technique the M diversity branches are first co-phased and then weighted proportionally to their signal level before summing. See Fig. 16.2(b). The distribution of the maximal ratio combiner has been shown to be [5]

$$\text{Prob}[\gamma \leq \gamma_m] = 1 - e^{(-\gamma_m/\Gamma)} \sum_{k=1}^M \frac{(\gamma_m/\Gamma)^{k-1}}{(k-1)!} \quad (16.5)$$

The distribution of output of a maximal ratio combiner is shown in Fig. 16.4. Maximal ratio combining is known to be optimal in the sense that it yields the best statistical reduction of fading of any linear diversity combiner. In comparison to the selection combiner, at 99% reliability level, the maximal ratio combiner provides a 11.5 dB gain for two branches and a 19 dB gain for four branches, an improvement of 1.5 and 3 dB, respectively, over the selection diversity combiner.

The mean C/N of the combined signal may be easily shown to be

$$\text{Mean}\{\gamma_m\} = M\Gamma \quad (16.6)$$

Therefore, combiner output mean varies linearly with M . This confirms the intuitive result that the output C/N averaged over fades should provide gain proportional to the number of diversity branches. This is a situation similar to conventional beamforming.

Equal Gain Combining

In some applications, it may be difficult to estimate the amplitude accurately, the combining gains may all be set to unity, and the diversity branches merely summed after co-phasing. [See Fig. 16.2(c)].

FIGURE 16.4 Probability distribution for signal envelope for maximal ratio combining.

The distribution of equal gain combiner does not have a neat expression and has been computed by numerical evaluation. Its performance has been shown to be very close to within a decibel to maximal ratio combining. The mean C/N can be shown to be [3]

$$\text{Mean}(\gamma_e) = \Gamma \left[1 + \frac{\pi}{4}(M-1) \right] \quad (16.7)$$

Like maximal ratio combining, the mean C/N for equal gain combining grows almost linearly with M and is approximately only one decibel poorer than maximal ratio combining even with an infinite number of branches.

Loss of Diversity Gain Due to Branch Correlation and Unequal Branch Powers

The above analysis assumed that the fading signals in the diversity branches were all uncorrelated and of equal power. In practice, this may be difficult to achieve and, as we saw earlier, the branch cross-correlation coefficient $\rho = 0.7$ is considered to be acceptable. Also, equal mean powers in diversity branches are rarely available. In such cases we can expect a certain loss of diversity gain. However, since most of the damage in fading is due to deep fades, and also since the chance of coincidental deep fades is small even for moderate branch correlation, one can expect a reasonable tolerance to branch correlation.

The distribution of the output signal envelope of maximal ratio combiner has been shown to be [6]:

$$\text{Prob}[\gamma_m] = \sum_{n=1}^M \frac{A_n}{2\lambda_n} e^{-\gamma_m/2\lambda_n} \quad (16.8)$$

where λ_n are the eigenvalues of the $M \times M$ branch envelope covariance matrix whose elements are defined by

$$\mathbf{R}_{ij} = E[r_i r_j^*] \quad (16.9)$$

and A_n is defined by

$$A_n = \prod_{k=1}^M \frac{1}{1 - \lambda_k / \lambda_n} \quad (16.10)$$

16.4 Effect of Diversity Combining on Bit Error Rate

So far we have studied the distribution of the instantaneous envelope or C/N after diversity combining. We will now briefly survey how diversity combining affects BER performance in digital radio links; we assume maximal ratio combining.

To begin let us first examine the effect of Rayleigh fading on the BER performance of digital transmission links. This has been studied by several authors and is summarized in [7]. Table 16.1 gives the BER expressions in the large E_b/N_0 case for coherent binary PSK and coherent binary orthogonal FSK for unfaded and Rayleigh faded AWGN (additive white Gaussian noise channels) channels. \bar{E}_b/N_0 represents the average E_b/N_0 for the fading channel.

Observe that error rates decrease only inversely with SNR as compared to exponential decreases for the unfaded channel. Also note that for fading channels, coherent binary PSK is 3 dB better than coherent binary FSK, exactly the same advantage as in the unfaded case. Even for the modest target BER of 10^{-2} that is usually needed in mobile communications, the loss due to fading can be very high—17.2 dB.

To obtain the BER with maximal ratio diversity combining, we have to average the BER expression for the unfaded BER with the distribution obtained for the maximal ratio combiner given in Eq. (16.5). Analytical expressions have been derived for these in [7]. For a branch SNR greater than 10 dB, the BER after maximal ratio diversity combining is given in Table 16.2.

We observe that the probability of error varies as $1/\bar{E}_b/N_0$ raised to the L th power. Thus, diversity reduces the error rate exponentially as the number of independent branches increases.

TABLE 16.1 Comparison of BER Performance for Unfaded and Rayleigh Faded Signals

Modulaton	Unfaded BER	Faded BER
Coh BPSK	$\frac{1}{2} \operatorname{erfc}(\sqrt{E_b/N_0})$	$\frac{1}{4(\bar{E}_b/N_0)}$
Coh FSK	$\frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{1}{2} E_b/N_0}\right)$	$\frac{1}{2(\bar{E}_b/N_0)}$

TABLE 16.2 BER Performance for Coherent BPSK and FSK with Diversity

Modulaton	Post Diversity BER
Coherent BPSK	$\left(\frac{1}{4\bar{E}_b/N_0}\right)^L \binom{2L-1}{L}$
Coherent FSK	$\left(\frac{1}{2\bar{E}_b/N_0}\right)^L \binom{2L-1}{L}$

16.5 Concluding Remarks

Diversity provides a powerful technique for combating fading in mobile communication systems. Diversity techniques seek to generate and exploit multiple branches over which the signal shows low fade correlation. To obtain the best diversity performance, the multiple access, modulation, coding, and antenna design of the wireless link must all be carefully chosen so as to provide a rich and reliable level of well-balanced, low-correlation diversity branches in the target propagation environment. Successful diversity exploitation can impact a mobile network in several ways. Reduced power requirements can result in increased coverage or improved battery life. Low signal outage improves voice quality and handoff performance. Finally, reduced fade margins directly translate to better reuse factors and, hence, increased system capacity.

Defining Terms

Automatic request for repeat: An error control mechanism in which received packets that cannot be corrected are retransmitted.

Channel coding/forward error correction: A technique that inserts redundant bits during transmission to help detect and correct bit errors during reception.

Fading: Fluctuation in the signal level due to shadowing and multipath effects.

Frequency hopping: A technique where the signal bursts are transmitted at different frequencies separated by random spacing that are multiples of signal bandwidth.

Interleaving: A form of data scrambling that spreads burst of bit errors evenly over the received data allowing efficient forward error correction.

Outage probability: The probability that the signal level falls below a specified minimum level.

PCS: Personal communications services.

RAKE receiver: A receiver used in direct sequence spread spectrum signals. The receiver extracts energy in each path and then adds them together with appropriate weighting and delay.

17.1 Introduction

The field of information theory has its origin in Claude Shannon's 1948 paper, "A mathematical theory of communication." Shannon's motivation was to study "[The problem] of reproducing at one point either exactly or approximately a message selected at another point." Whereas in this section we will be concerned only with Shannon's original problem, one should keep in mind that information theory is a growing field of research whose profound impact has reached various areas such as statistical physics, computer science, statistical inference, and probability theory. For an excellent treatment of information theory that extends beyond the area of communication we recommend Cover and Thomas [1991]. For the reader who is strictly interested in communication problems we also recommend Gallager [1968], Blahut [1987], and McEliece [1977].

17.2 The Communication Problem

A rather general diagram for a (point-to-point) communication system is shown in [Fig. 17.1](#).

The source might be digital (e.g., a data file) or analog (e.g., a video signal). Since an analog source can be sampled without loss of information (see chapter on sampling, this volume), without loss of generality we consider only discrete-time sources and model them as discrete-time stochastic processes.

The channel could be a pair of wires, an optical fiber, a radio link, etc. The channel model specifies the set of possible channel inputs and, for each input, specifies the output process. Most real-world channels are waveform channels, meaning that the input and output sets are sets of waveforms. It is often the case that the communication engineer is given a waveform channel with a modulator and a demodulator. In a satellite communication system, the modulator might be a phase-shift keying modulator whose input alphabet V is the set $\{0, 1\}$; the channel might be modeled by the additive white Gaussian noise channel, and the demodulator attempts to output a guess (perhaps incorrect) of the modulator input. In this case, the modulator output alphabet W equals V . In more sophisticated cases, where $|W| > |V|$ and $|\cdot|$ denotes the number of elements in the enclosed set, the digital data demodulator can also furnish information about the reliability of the decision. Either way, one would consider the modulator and the demodulator as part of the channel. If the statistics of the channel output at a given time depend

FIGURE 17.1 Block diagram of a communications system.

FIGURE 17.2 Block diagram of an encoder and a decoder, each split into two parts.

only on the value of the corresponding position of the input sequence, then the channel is a discrete memoryless channel. This is an important class of channel models that will receive particular attention in this chapter. Even if the modulator and the demodulator are not given, assuming that the bandwidth of the waveform channel is limited, one can always use the sampling theorem to convert a waveform channel into a channel with discrete-time input and output.

The destination is merely a place holder to remind us that the user has some expectation concerning the quality of the reproduced signal. If the source output symbols are elements of a finite set, then the destination may specify a maximum value for the probability of error. Otherwise, it may specify a maximum distortion computed according to some specified criterion (e.g., mean square error).

It is generally assumed that the source, the channel, and the destination are given and fixed. On the other hand, the communication engineer usually is completely free to design the encoder and the decoder to meet the desired performance specifications.

An important result of information theory is that, without loss of optimality, the encoder in Fig. 17.1 can be decomposed into two parts: a source encoder that produces a sequence of binary data and a channel encoder, as shown in Fig. 17.2. Similarly, the decoder may be split into a channel decoder and a source decoder.

The objective of the source encoder is to compress the source, that is, to minimize the average number of bits necessary to represent a source symbol. The most important questions concerning the source encoder are the following: What is the minimum number of bits required (on average) to represent a source output symbol? How do we design a source encoder that achieves this minimum? These questions will be considered here. It turns out that the output of an ideal source encoder is a sequence of independent and uniformly distributed binary symbols. The purpose of the channel encoder/decoder pair is to create a reliable bit pipe for the binary sequence produced by the source encoder. Here the most important question is whether or not it is possible to design such an encoder/decoder pair. This question will also be considered in some detail. The fact that we can split the encoder into two parts as described is important. First of all, it allows us to study the source and the channel separately and to assume that they are connected by a binary interface. Second, it tells us that for a given channel we may design the channel encoder and the channel decoder to maximize the rate of the resulting (virtually error-free) bit pipe without having to know the nature of the source that will use it.

17.3 Source Coding for Discrete-Alphabet Sources

We start by considering the simplest possible source, namely, a discrete-time discrete-alphabet memoryless information source modeled by a random variable X taking values on a finite alphabet X . A (binary source) **code C** for X is a mapping from X into the set of finite length binary sequences called codewords. Such a code can be represented by a binary tree, as shown in the following example.

Example 1

Let X take on values in $\{1, 2, 3, 4, 5, 6, 7\}$. A possible binary code for X is given by the (ordered) set of binary sequences $\{1, 010, 011, 0000, 0001, 0010, 0011\}$. The corresponding tree is shown in Fig. 17.3. Notice that the codeword corresponding to a given source output symbol is the label sequence from the root to the node corresponding to that symbol.

In Example 1, source output symbols correspond to leaves in the tree. Such a code is called *prefix free* since no codeword is the prefix of another codeword. Given a concatenation of codewords of a prefix-free code, we can parse it in a unique way into codewords. Codes with this property are called *uniquely decodable*. Although there are uniquely decodable codes which are *not* prefix free, we will restrict our attention to prefix-free codes, as it can be shown that the performance of general uniquely decodable codes is no better than that of prefix-free codes (see Cover and Thomas [1991]).

For each i in X , let $C(i)$ be the codeword associated to the symbol i , let l_i be its length, $L = \max_i l_i$, and let p_i be the probability that $X = i$. A complete binary tree of depth L has 2^L leaves. To each leaf at depth l , $l \leq L$, of the binary code tree (which is not necessarily complete) there correspond 2^{L-l} leaves at depth L of the corresponding complete tree (obtained by extending the binary code tree). Further, any two distinct leaves in the code tree have distinct associated leaves at depth L in the complete binary tree. Hence, summing up over all leaves of the code tree (all codewords) we get

$$2^L \geq \sum_i 2^{L-l_i} \sum_i 2^{-l_i} \leq 1$$

The right-hand side is called the *Kraft inequality* and is a necessary condition on the codeword lengths of any prefix-free code. Conversely, for any set of codeword lengths satisfying the displayed inequality, we can construct a prefix-free code having codeword lengths l_i (start with a complete binary tree of sufficient length; to each l_i associate a node in this tree at level l_i and make this node a leaf by deleting all of its descendants). The problem of finding the best source code then reduces to that of finding a set of lengths that satisfies the Kraft inequality and minimizes the average codeword lengths $L^* = \sum_i l_i p_i$. Such a code is called *optimal*.

To any source X with probabilities p_i , we associate the quantity $H(X)$, which we call **entropy** and which is defined as

$$H(X) = -\sum_i p_i \log p_i$$

FIGURE 17.3 Example of a code tree.

Usually we take the base of the logarithm to be 2, in which case the units of entropy are called *bits*.

It is straightforward to show by means of Lagrange multipliers that if we neglect the integer constraint on l_i , then the minimization of L^* subject to the Kraft inequality yields $l_i^* = -\log p_i$. This noninteger choice of codeword lengths yields

$$L^* = \sum_i p_i l_i^* = -\sum_i p_i \log p_i = H(X)$$

On the other hand, the (not necessarily optimal) integer choice $l_i = \lceil -\log p_i \rceil$ satisfies the Kraft inequality and yields an expected codeword length

$$L(C) = \sum_i p_i \lceil -\log p_i \rceil \leq -\sum_i p_i \log p_i + \sum_i p_i = H(X) + 1$$

Hence, we have the following theorem.

Theorem 1. The average length L^* of the optimal prefix-free code for the random variable X satisfies $H(X) \leq L^* \leq H(X) + 1$.

Example 2

Let X be a random variable that takes on the values 1 and 0 with probabilities θ ($0 \leq \theta \leq 1$) and $1 - \theta$, respectively. Then $H(X) = h(\theta)$, where $h(\theta) = -\theta \log \theta - (1 - \theta) \log(1 - \theta)$. The function $h(\theta)$ is called the *binary entropy function*. In particular, it can be shown that $h(\theta) \leq 1$ with equality if and only if $\theta = \frac{1}{2}$. More generally, if X takes on $|X|$ values, then $H(X) \leq \log |X|$ with equality if and only if X is uniformly distributed.

A simple algorithm that generates optimal prefix-free codes is the Huffman algorithm, which can be described as follows:

Step 1. Re-index to arrange the probabilities in decreasing order, $p_1 \geq p_2 \geq \dots \geq p_m$.

Step 2. Form a subtree by combining the last two probabilities p_{m-1} and p_m into a single node of weight $p'_m = p_{m-1} + p_m$.

Step 3. Recursively execute steps 1 and 2, decreasing the number of nodes each time, until a single node is obtained.

Step 4. Use the tree constructed above to assign codewords.

Example 3

As in Example 1, let X take on the values $\{1, 2, 3, 4, 5, 6, 7\}$. Assume their corresponding probabilities are $\{0.4, 0.1, 0.1, 0.1, 0.1, 0.1, 0.1\}$. Figure 17.4 shows the steps in the construction of the **Huffman code**. For simplicity, probabilities are not shown. The final tree is given in Example 1.

Given a block of n random variables X_1, \dots, X_n , with joint distribution $p(X_1, \dots, X_n)$, define their entropy as

$$H(X_1, \dots, X_n) = -\sum_{x_1} \sum_{x_2} \dots \sum_{x_n} p(x_1, \dots, x_n) \log p(x_1, \dots, x_n)$$

FIGURE 17.4 Construction of a Huffman code of X as given in Example 1.

Note that for the special case of n independent random variables, we have $H(X_1, \dots, X_n) = nH(X)$. This agrees with the intuitive notion that if it takes $H(X)$ bits to encode one source output symbol, then it should take $nH(X)$ bits to encode n independent output symbols. For a sequence of random variables X_1, X_2, \dots, X_n , we define $H_n = \frac{1}{n}H(X_1, \dots, X_n)$. If X_1, X_2, \dots, X_n is a stationary random process, as n goes to infinity H_n converges to a limit H_\bullet called the *entropy rate* of the process.

Applying Theorem 1 to blocks of random variables, we obtain

$$H_n \leq \frac{L}{n} < H_n + \frac{1}{n}$$

In the special case that the process X_1, X_2, \dots, X_n is stationary, the left and the right side will both tend to H_\bullet as $n \rightarrow \infty$. This shows that by encoding a sufficiently large number of source output symbols at a time, one can get arbitrarily close to the fundamental limit of H_∞ bits per symbol.

17.4 Universal Source Coding

The Huffman algorithm produces optimal codes, but it requires knowing the statistics of the source. It is a surprising fact that there are source coding algorithms that are asymptotically optimal without requiring prior knowledge of the source statistics. Such algorithms are called *universal* source coding algorithms. The best known universal source coding algorithm is the **Lempel–Ziv** algorithm, which has been implemented in various forms on computers (as PKZIP command for Windows and Linux-based systems). There are two versions of the Lempel–Ziv algorithm: the LZ77, see Ziv and Lempel [1977], and the LZ78, see Lempel and Ziv [1978]. We will describe the basic idea of the LZ77.

Consider the sequence X_1, X_2, \dots, X_k taking values in $\{a, b, c\}$, shown in Fig. 17.5, and assume that the first w letters ($w = 6$ in our example) are passed to the decoder with no attempt at compression. At this point the encoder identifies the longest string $X_{w+1}, X_{w+2}, \dots, X_{w+L}$ such that a copy, $X_{w-p+1}, \dots, X_{w-p+L}$ begins (but not necessarily ends) in the portion of data already available to the decoder. In our example this string is $aabaa$, $L = 5$, and $p = 3$; see Fig. 17.5. Next, the encoder transmits a binary representation of the pair (L, p) as this is sufficient for the decoder to reconstruct X_{w+1}, \dots, X_{w+L} . At this point, the procedure can be repeated with w replaced by $w + L$. There are two exceptions: the first occurs when X_{w+L} is a new letter that does not appear in X_1, \dots, X_w ; the second exception occurs when it is more efficient to encode X_{w+1}, \dots, X_{w+L} directly than to encode (L, p) . In order to handle such special cases, the algorithm has the option of encoding a substring directly, without attempt at compression. It is surprising that the Lempel–Ziv algorithm is asymptotically optimal for all finite alphabet stationary ergodic sources. This has been shown in Wyner and Ziv [1994].

FIGURE 17.5 Encoding procedure of the Lempel–Ziv algorithm.

17.5 Rate Distortion Theory

Thus far we have assumed that X is a discrete alphabet and that the decoder must be able to perfectly reconstruct the source output. Now we drop both assumptions.

Let X_1, X_2, \dots be a sequence of independent identically distributed random variables. Let \mathcal{X} denote the source alphabet and \mathcal{Y} be a suitably chosen representation alphabet (where \mathcal{Y} is not necessarily equal to \mathcal{X}). A *distortion measure* is a function $d: \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^+$. The most common distortion measures are the *Hamming distortion* d_H and the *squared error distortion* d_E defined as follows:

$$d_H(x, y) = \begin{cases} 0 & \text{if } x = y \\ 1 & \text{if } x \neq y \end{cases}$$

$$d_E(x, y) = (x - y)^2$$

Such a single-letter distortion measure can be extended to a distortion measure on n -tuples by defining

$$d(x^n, y^n) = \frac{1}{n} \sum_{i=1}^n d(x_i, y_i)$$

The *encoder* maps an n -length source output X^n to an index $U \in \{1, 2, \dots, 2^{\lfloor nR \rfloor}\}$, where R denotes the number of bits per source symbol that we are allowed or willing to use. The *decoder* maps U into an n -tuple Y^n , called the representation of X^n . We will call U together with the associated encoding and decoding function a *rate distortion code*. Let f be the function that maps X^n to its representation Y^n , that is, f is the mapping describing the concatenation of the encoding and the decoding function. The expected distortion D is then given by

$$D = \sum_{x^n} p(x^n) d(x^n, f(x^n))$$

The objective is to minimize the average number of bits per symbol, denoted by R , for a given average distortion D . What is the minimum R ?

Definition. The rate distortion pair (R, D) is said to be *achievable* if there exists a rate distortion code of rate R with expected distortion D . The **rate distortion function** $R(D)$ is the infimum of rates R such that (R, D) is achievable for a given D .

Entropy played a key role in describing the limits of lossless coding. When distortion is allowed, a similar role is played by a quantity called mutual information.

Definition. Given the random variables X and Y with their respective distributions $p(x)$, $p(y)$, and $p(x, y)$, the **mutual information** $I(X; Y)$ between X and Y is defined as

$$I(X; Y) = \sum_{x \in \mathcal{X}} \sum_{y \in \mathcal{Y}} p(x, y) \log \frac{p(x, y)}{p(x)p(y)}$$

FIGURE 17.6 Examples of rate distortion functions.

This definition can be extended to blocks of random variables X^n and Y^n by replacing $p(x)$, $p(y)$, and $p(x, y)$ with their higher-dimensional counterparts. We can now state the fundamental theorem of rate distortion theory. For its proof see Cover and Thomas [1991].

Theorem 2. The rate distortion function for an independent identically distributed source X with distribution $p(x)$ and distortion function $d(x, y)$ is

$$R(D) = \min_{p(y|x): \sum_{x,y} p(x)p(y|x)d(x,y) \leq D} I(X; Y)$$

The rate distortion functions for a *binary source* that outputs 1 with probability θ and Hamming distortion and for a *Gaussian source* of variance σ^2 and squared error distortion are as follows:

$$R_B(D) = \begin{cases} h(\theta) - h(D), & 0 \leq D \leq \min\{\theta, 1 - \theta\} \\ 0, & D > \min\{\theta, 1 - \theta\} \end{cases}$$

$$R_G(D) = \begin{cases} \frac{1}{2} \log \frac{\sigma^2}{D}, & 0 \leq D \leq \sigma^2 \\ 0, & D > \sigma^2 \end{cases}$$

These two functions are plotted in Fig. 17.6.

Some insight can be gained by considering the extreme values of both $R_B(D)$ and $R_G(D)$. Assume that X_1, X_2, \dots is a sequence of independent and identically distributed binary random variables and let θ be the probability that $X_i = 1$. Without loss of generality, we may assume that $\theta \geq 1 - \theta$. If we let $Y^n = (0, \dots, 0)$ regardless of X^n , then the expected Hamming distortion equals θ . Hence, it must be true that $R_B(D) = 0$ for $D \geq \theta$. On the other hand, $D = 0$ means that the reproduction Y_n must be a perfect copy of X^n . From Theorem 1 and Example 2 we know that this means $R_B(0) = H(X) = h(\theta)$. Similar considerations hold for $R_G(D)$. It is interesting to observe that $R_G(D)$ tells us that if we are allowed to use R bits per symbol to describe a sequence of independent Gaussian random variables with variance σ^2 , then we need to accept a mean squared error of $\sigma^2 2^{-2R}$.

17.6 Channel Coding

Now we consider the fundamental limit for the amount of information that can be transmitted through a noisy channel and discuss practical methods to approach it. For simplicity, we assume that the channel can be modeled as a discrete memoryless channel, defined as follows:

A **discrete memoryless channel (DMC)** is a system consisting of an input alphabet \mathcal{X} , an output alphabet \mathcal{Y} , and a collection of probability mass functions $p(y|x)$, one for each $x \in \mathcal{X}$. A specific DMC will be denoted by $(\mathcal{X}, p(y|x), \mathcal{Y})$.

An **(M, n) channel code** for the DMC $(\mathcal{X}, p(y|x), \mathcal{Y})$ consists of the following:

1. an index set $\{1, 2, \dots, M\}$
2. an encoding function $X^n: \{1, 2, \dots, M\} \rightarrow \mathcal{X}^n$, yielding codewords $X^n(1), X^n(2), \dots, X^n(M)$ (the set of codewords is called the *code book*)
3. a decoding function $g: \mathcal{Y}^n \rightarrow \{1, 2, \dots, M\}$, which is a deterministic rule that assigns a guess to each possible received vector

The most important figures of merit for a channel code for a DMC are the *maximal probability of error*, defined by

$$\lambda^{(n)} \equiv \max_{i \in \{1, 2, \dots, M\}} Pr\{g(Y^n) \neq i | X^n = X^n(i)\}$$

and the *transmission rate*,

$$R = \frac{\log M}{n} \quad \text{bits/channel use}$$

It makes sense to define the rate in this way since the M codewords can be labeled with $\log M$ bits. Hence, every time we transmit a codeword, we actually transmit $\log M$ bits of information. Since it takes n uses of the channel to transmit one codeword, the resulting information rate is $(\log M)/n$ bits per channel use.

For a given DMC, a rate R is said to be *achievable* if, for any desired probability of error P_e and sufficiently large block length n , there exists a $(\lceil 2^{nR} \rceil, n)$ code for that DMC with maximal probability of error $\lambda^{(n)} \leq P_e$.

The *operational capacity* of a discrete memoryless channel is the supremum of all achievable rates. One would expect that determining the operational capacity would be a formidable task. One of the most remarkable results of information theory is a relatively easy-to-compute way to determine the operational capacity.

We define the **information channel capacity** of a discrete memoryless channel $(\mathcal{X}, p(y|x), \mathcal{Y})$ as

$$C \equiv \max_{p(x)} I(X; Y)$$

where the maximum is taken over all possible input distributions $p(x)$. As we will show in the next example, it is straightforward to compute the information channel capacity for many discrete memoryless channels of interest. Shannon's channel coding theorem establishes that the information channel capacity equals the operational channel capacity.

Theorem (Shannon's channel coding theorem). For a DMC, the *information channel capacity* equals the *operational channel capacity*, that is, for every rate $R < C$, there exists a sequence of $(\lceil 2^{nR} \rceil, n)$ codes for the DMC with maximum probability of error $\lambda^{(n)} \rightarrow 0$. Conversely, for any sequence of $(\lceil 2^{nR} \rceil, n)$ for codes this DMC with the property that $\lambda^{(n)} \rightarrow 0$, the rate R must satisfy $R \leq C$.

This is perhaps the most important result of information theory. In order to shed some light on the interpretation of mutual information and to provide an efficient way to determine C , it is convenient to rewrite $I(X; Y)$ in terms of conditional entropy. Given two random variables X and Y with joint probability mass function $p(x, y)$, marginal probability mass function $p(x) = \sum_y p(x, y)$, and conditional probability mass function $p(x|y) = p(x, y)/p(y)$, we define the conditional entropy of X given that $Y = y$ as

$$H(X|Y = y) = -\sum_x p(x|y) \log p(x|y)$$

Its average is the conditional entropy of X given Y , denoted by $H(X|Y)$ and defined as

$$\begin{aligned} H(X|Y) &= \sum_y p(y)H(X|Y=y) \\ &= -\sum_{x,y} p(x,y)\log p(x|y) \\ &= E[-\log p(X|Y)] \end{aligned}$$

Recall that for the discrete variable X with probability mass function $p(x)$, $H(X)$ is the average number of binary symbols necessary to describe X . Now let X be the random variable at the input of a DMC and let Y be the output. The knowledge that $Y = y$ changes the probability mass function of the channel input from $p(x)$ to $p(x|y)$ and its entropy from $H(X)$ to $H(X|Y = y)$. According to our previous result, $H(X|Y = y)$ is the average number of bits necessary to describe X after the observation that $Y = y$. Since $H(X)$ is the average number of bits needed to describe X (without knowledge of Y), $H(X) - H(X|Y = y)$ is the average amount of information about X acquired by the observation that $Y = y$, and

$$H(X) - H(X|Y)$$

is the average amount of information about X acquired by the observation of Y . One can easily verify that the latter expression is another way to write $I(X; Y)$. Moreover,

$$\begin{aligned} I(X; Y) &= H(X) - H(X|Y) \\ &= H(Y) - H(Y|X) \\ &= I(Y; X) \end{aligned}$$

Hence, the amount of information that Y gives about X is the same as the amount of information that X gives about Y . For this reason, $I(X; Y)$ is called the mutual information between X and Y .

Example (Binary Symmetric Channel). Let $X = \{0, 1\}$, $Y = \{0, 1\}$, and $p(y|x) = p$ when $x \neq y$ and $1 - p$ otherwise. This DMC can be conveniently depicted as in Fig. 17.7. For obvious reasons it is called the *binary symmetric channel* (BSC).

For the BSC, we bound the mutual information by

$$\begin{aligned} I(X; Y) &= H(Y) - H(Y|X) \\ &= H(Y) - \sum_x p(x)H(Y|X=x) \\ &= H(Y) - h(p) \\ &\leq 1 - h(p) \end{aligned}$$

FIGURE 17.7 Discrete memoryless channel with crossover probability p .

FIGURE 17.8 Capacity of the BSC as a function of p .

where the last inequality follows because Y is a binary random variable (see Example 2). Equality is achieved when the input distribution is uniform since in this case the output distribution is also uniform. Hence, the information capacity of a binary symmetric channel with parameter p is

$$C = 1 - h(p) \quad [\text{bits/channel use}]$$

This function is plotted in Fig. 17.8.

17.7 Simple Binary Codes

Shannon's channel coding theorem promises the existence of block codes that allow us to transmit reliably through an unreliable channel at any rate below the channel capacity. Unfortunately, the codes constructed in all known proofs of this fundamental result are impractical in that they do not exhibit any structure which can be employed for an efficient implementation of the encoder and the decoder. This is an important issue, as good codes must have long block lengths and, hence, a large number of codewords. For these codes, simple table lookup encoding and decoding procedures are not feasible. The search for good and practical codes has led to the development of coding theory. Although powerful block codes are, in general, described by sophisticated techniques, the main idea is simple. We collect a number k of information symbols which we wish to transmit, we append r check symbols, and transmit the entire block of $n = k + r$ channel symbols. Assuming that the channel changes a sufficiently small number of symbols within an n -length block, the r check symbols may provide the receiver with sufficient information to detect and/or correct the errors.

Traditionally, good codes have been constructed by sophisticated algebraic schemes. More recent code construction techniques are inspired by Shannon's original work. The idea is to construct the code by making random choices on a suitably defined structure. A key property of the structure is that it leads to codes that may be decoded using powerful iterative techniques. We will demonstrate these two quite distinct concepts by simple examples.

Hamming Codes

For any positive integer m , there is a Hamming code with parameters $k = 2^m - m - 1$ and $n = 2^m - 1$. To illustrate, we consider the $k = 4$, $n = 7$ Hamming code. All operations will be done modulo 2. Consider the set of all nonzero binary vectors of length $m = 3$. Arrange them in columns to form the matrix

$$H = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}$$

TABLE 17.1 Codewords of the (7, 4) Hamming Code

0	0	0	0	0	0	0	1	0	0	0	1	0	1
0	0	0	1	0	1	1	1	0	0	1	1	1	0
0	0	1	0	1	1	0	1	0	1	0	0	1	1
0	0	1	1	1	0	1	1	0	1	1	0	0	0
0	1	0	0	1	1	1	1	1	0	0	0	1	0
0	1	0	1	1	0	0	1	1	0	1	0	0	1
0	1	1	0	0	0	1	1	1	1	0	1	0	0
0	1	1	1	0	1	0	1	1	1	1	1	1	1

The row space of H is a vector space of binary 7-tuples of dimension $m = 3$. The $k = 4$, $n = 7$ Hamming code is the null space of H , that is, the vector space of dimension $n - m = 4$ consisting of all binary 7-tuples c such that $cH^T = 0$. Hence, it contains the $M = 2^k = 16$ codewords shown in Table 17.1 and its rate is $R = (\log M)/n = 4/7$. If c is transmitted and u is received, then the error is the unique binary n -tuple e such that $u = c + e$, where addition is component-wise modulo 2. The decoder performs the operation

$$uH^T = (c + e)H^T = cH^T + eH^T = eH^T$$

If there is a single error at position i , that is, if e is zero except for the i th component (which is one), then uH^T is the i th row of H^T . This tells us the error location. If e contains 2 ones (channel errors), then uH^T is the sum of two rows of H^T . Since this cannot be zero, two channel errors are detectable. They are not correctable, however, since, as one can easily verify when two channel errors occur, there is always a codeword that agrees with the received word in $n - 1$ positions. This is the codeword that would be selected by the decoder if it were forced to make a decision since the transmitted codeword agrees with the received word in only $n - 2$ positions. A simple encoding procedure can be specified as follows: let G be a $k \times n$ matrix whose rows span the null space of H . Such a matrix is

$$G = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}$$

Then an information k -tuple a can be mapped into a codeword $c = aG$ by a simple matrix multiplication.

Low-Density Parity-Check Codes

Low-density parity-check (LDPC) codes constitute a family of a new breed of coding techniques variably described as “codes on graphs” or “iterative coding techniques.” They were originally introduced by Gallager in his thesis in 1962 (see Gallager [1963]), then long forgotten, and later revived in the wake of the discovery of turbo codes by Berrou et. al. (see Berrou et al. [1993] and MacKay [1999]).

LDPC codes are codes which possess a sparse parity check matrix. Because of this sparseness, they can be decoded very efficiently in an iterative fashion. Although this iterative decoding procedure is, in general, suboptimal, it is sufficiently strong to allow transmission seemingly arbitrarily close to channel capacity.

Consider the code represented by the following parity check matrix.

$$H = \begin{pmatrix} 1110111000 \\ 0011111100 \\ 0110100111 \\ 1001010111 \\ 1101001011 \end{pmatrix}$$

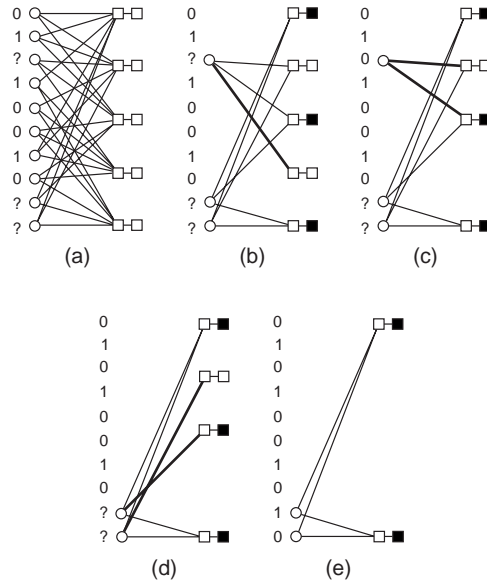

FIGURE 17.9 Iterative decoding.

Note that each row contains exactly 6 ones and that each column contains exactly 3 ones. Such a code is referred to as a (3, 6)-regular LDPC code. A convenient graphical representation of this code is given by means of the bipartite graph shown in Fig. 17.9(a). This graph is usually referred to as Tanner graph. In this graph, each left node (variable node) corresponds to one column of the parity check matrix and each right node (check node) corresponds to one row of H . A left node is connected to a right node if and only if the corresponding position in the parity check matrix contains a 1.

Let $(x = x_0, \dots, x_9)$ be the codeword (0101001010). Assume that we transmit x over a binary erasure channel (BEC) and that the received word is $y = (??01001?10)$ where ? indicates an erasure. Rather than employing a maximum likelihood decoder, we will use the iterative decoding algorithm described in Figs. 17.9(a)–(e). The received word y is written on the left (y_0 on the bottom and y_a on the top). We start by passing all known values from the left to the right along the corresponding edges. We next accumulate at each check the partial sum (mod 2) of all known values and delete all edges along which messages have already been passed. The result is shown in Fig. 17.9(b), where a black box indicates a partial sum equal to 1. Now note that check node one (the second from the bottom) has received already all values except the one from the erased bit seven. Since, by the code constraints, the sum of all values must be equal to zero, we see that we can deduce the value of variable node seven to be equal to zero. This value can now again be propagated to the right and all involved edges be deleted. The result is shown in Fig. 17.9 (d). After one more iteration all erased values are known. (Fig. 17.9(e)).

As we can see, in the above example the given iterative decoding strategy successfully recovered the erased bits. This might seem like a lucky coincidence. Nevertheless, it has been shown that long and suitably defined LDPC codes can achieve capacity on the BEC under iterative decoding (see Luby et. al. [1997]).

Even more, the above iterative decoding strategy, suitably extended, can be used to transmit reliably close to capacity over a wide array of channels (see Richardson et. al. [2001]).

Defining Terms

Binary source code: A mapping from a set of messages into binary strings.

Channel capacity: The highest rate at which information can be transmitted reliably across a channel.

Discrete memoryless channel: A channel model characterized by discrete input and output alphabets and a probability mass function on the output conditioned on the input.

Entropy: A measure of the average uncertainty of a random variable. For a random variable with distribution $p(x)$, the entropy $H(X)$ is defined as $-\sum_x p(x)\log p(x)$.

Huffman coding: A procedure that constructs a code of minimum average length for a random variable.

Lempel-Ziv coding: A procedure for coding that does not use the probability distribution of the source but nevertheless is asymptotically optimal.

Mutual information: A measure for the amount of information that a random variable gives about another.

Rate distortion function: The minimum rate at which a source can be described to the given average distortion.

18.1 Introduction

In this section we examine some fundamental tradeoffs among bandwidth, power, and error performance of digital communication systems. The criteria for choosing modulation and coding schemes, based on whether a system is bandwidth limited or power limited, are reviewed for several system examples. Emphasis is placed on the subtle but straightforward relationships we encounter when transforming from data-bits to channel-bits to symbols to chips.

The design or definition of any digital communication system begins with a description of the communication link. The *link* is the name given to the communication transmission path from the modulator and transmitter, through the channel, and up to and including the receiver and demodulator. The *channel* is the name given to the propagating medium between the transmitter and receiver. A link description quantifies the average signal power that is received, the available bandwidth, the noise statistics, and other

^{1*} A version of this chapter has appeared as a paper in the *IEEE Communications Magazine*, November 1993, under the title “Defining, Designing, and Evaluating Digital Communication Systems.”

impairments, such as fading. Also needed to define the system are basic requirements, such as the data rate to be supported and the error performance.

The Channel

For radio communications, the concept of *free space* assumes a channel region free of all objects that might affect radio frequency (RF) propagation by absorption, reflection, or refraction. It further assumes that the atmosphere in the channel is perfectly uniform and nonabsorbing and that the earth is infinitely far away or its reflection coefficient is negligible. The RF energy arriving at the receiver is assumed to be a function of distance from the transmitter (simply following the inverse-square law as used in optics). In practice, of course, propagation in the atmosphere and near the ground results in refraction, reflection, and absorption, which modify the free space transmission.

The Link

A radio transmitter is characterized by its average output signal power P_t and the gain of its transmitting antenna G_t . The name given to the product $P_t G_t$, with reference to an isotropic antenna, is *effective radiated power (EIRP)* in watts (or dBW). The average signal power S arriving at the output of the receiver antenna can be described as a function of the *EIRP*, the gain of the receiving antenna G_r , the path loss (or space loss) L_s , and other losses, L_o , as follows [1,2]:

$$S = \frac{EIRP G_r}{L_s L_o} \quad (18.1)$$

The path loss L_s can be written as follows [2]:

$$L_s = \left(\frac{4\pi d}{\lambda} \right)^2 \quad (18.2)$$

where d is the distance between the transmitter and receiver and λ is the wavelength.

We restrict our discussion to those links distorted by the mechanism of additive white Gaussian noise (AWGN) only. Such a noise assumption is a very useful model for a large class of communication systems. A valid approximation for average received noise power N that this model introduces is written as follows [3,4]:

$$N \cong kT^\circ W \quad (18.3)$$

where k is Boltzmann's constant (1.38×10^{-23} joule/K), T° is system effective temperature in kelvin, and W is bandwidth in hertz. Dividing Eq. (18.3) by bandwidth enables us to write the received noise-power spectral density N_0 as follows:

$$N_0 = \frac{N}{W} = kT^\circ \quad (18.4)$$

Dividing Eq. (18.1) by N_0 yields the received average signal-power to noise-power spectral density S/N_0 as

$$\frac{S}{N_0} = \frac{EIRP G_r / T^\circ}{kL_s L_o} \quad (18.5)$$

where G_r/T° is often referred to as the receiver figure of merit. A link budget analysis is a compilation of the power gains and losses throughout the link; it is generally computed in decibels and thus takes on the bookkeeping appearance of a business enterprise, highlighting the assets and liabilities of the link. Once the value of S/N_0 is specified or calculated from the link parameters, we then shift our attention to optimizing the choice of signalling types for meeting system bandwidth and error performance requirements.

In Eq. (18.4), N_0 characterizes all the noise in the receiving system since T° is the system effective temperature; thus, S/N_0 is referenced to the predetection point in the receiver [2]. Then we can write the ratio of bit energy-to- N_0 (E_b/N_0) at this point, for any data rate R , as

$$\frac{E_b}{N_0} = \frac{ST_b}{N_0} = \frac{S}{N_0} \left(\frac{1}{R} \right) \quad (18.6)$$

Equation(18.6) follows from the basic definitions that received bit energy is equal to received average signal power times the bit duration and that bit rate is the reciprocal of bit duration. Received E_b/N_0 is a key parameter in defining a digital communication system. Its value indicates the apportionment of the received waveform energy among the bits that the waveform represents. At first glance, one might think that a system specification should entail the symbol-energy to noise-power spectral density E_s/N_0 associated with the arriving waveforms. We will show, however, that for a given S/N_0 , the value of E_s/N_0 is a function of the modulation and coding. The reason for defining systems in terms of E_b/N_0 stems from the fact that E_b/N_0 depends only on S/N_0 and R and is unaffected by any system design choices, such as modulation and coding.

18.2 Bandwidth and Power Considerations

Two primary communications resources are the received power and the available transmission bandwidth. In many communication systems, one of these resources may be more precious than the other and, hence, most systems can be classified as either bandwidth limited or power limited. In bandwidth-limited systems, spectrally efficient modulation techniques can be used to save bandwidth at the expense of power; in power-limited systems, power efficient modulation techniques can be used to save power at the expense of bandwidth. In both bandwidth- and power-limited systems, error-correction coding (often called channel coding) can be used to save power or to improve error performance at the expense of bandwidth. Recently, trellis-coded modulation (TCM) schemes have been used to improve the error performance of bandwidth-limited channels without any increase in bandwidth [5], but these methods are beyond the scope of this chapter.

The Bandwidth Efficiency Plane

Figure 18.1 shows the abscissa as the ratio of bit-energy to noise-power spectral density E_b/N_0 (in decibels) and the ordinate as the ratio of throughput, R (in bits per second), that can be transmitted per hertz in a given bandwidth W . The ratio R/W is called bandwidth efficiency since it reflects how efficiently the bandwidth resource is utilized. The plot stems from the Shannon–Hartley capacity theorem [2,6,7], which can be stated as

$$C = W \log_2 \left(1 + \frac{S}{N} \right) \quad (18.7)$$

where S/N is the ratio of received average signal power to noise power. When the logarithm is taken to the base 2, the capacity C is given in bits per second. The capacity of a channel defines the maximum number of bits that can be reliably sent per second over the channel. For the case where the data (information) rate R is equal to C , the curve separates a region of practical communication systems from a region where such communication systems cannot operate reliably [2,6].

M-ary Signalling

Each symbol in an M -ary alphabet can be related to a unique sequence of m bits, expressed as

$$M = 2^m \quad \text{or} \quad m = \log_2 M \quad (18.8)$$

FIGURE 18.1 Bandwidth-efficiency plane.

where M is the size of the alphabet. In the case of digital transmission, the term symbol refers to the member of the M -ary alphabet that is transmitted during each symbol duration T_s . To transmit the symbol, it must be mapped onto an electrical voltage or current waveform. Because the waveform represents the symbol, the terms symbol and waveform are sometimes used interchangeably. Since one of M symbols or waveforms is transmitted during each symbol duration T_s , the data rate R in bits per second can be expressed as

$$R = \frac{m}{T_s} = \frac{\log_2 M}{T_s} \quad (18.9)$$

Data-bit-time duration is the reciprocal of data rate. Similarly, symbol-time duration is the reciprocal of symbol rate. Therefore, from Eq. (18.9), we write that the effective time duration T_b of each bit in terms of the symbol duration T_s or the symbol rate R_s is

$$T_b = \frac{1}{R} = \frac{T_s}{m} = \frac{1}{m R_s} \quad (18.10)$$

Then, using Eqs. (18.8) and (18.10) we can express the symbol rate R_s in terms of the bit rate R as follows:

$$R_s = \frac{R}{\log_2 M} \quad (18.11)$$

From Eqs. (18.9) and (18.10), any digital scheme that transmits $m = \log_2 M$ bits in T_s seconds, using a bandwidth of W hertz, operates at a bandwidth efficiency of

$$\frac{R}{W} = \frac{\log_2 M}{W T_s} = \frac{1}{W T_b} \quad (\text{b/s})/\text{Hz} \quad (18.12)$$

where T_b is the effective time duration of each data bit.

Bandwidth-Limited Systems

From Eq. (18.12), the smaller the WT_b product, the more bandwidth efficient will be any digital communication system. Thus, signals with small WT_b products are often used with bandwidth-limited systems. For example, the European digital mobile telephone system known as Global System for Mobile Communications (GSM) uses Gaussian minimum shift keying (GMSK) modulation having a WT_b product equal to 0.3 Hz/(b/s), where W is the 3-dB bandwidth of a Gaussian filter [8].

For uncoded bandwidth-limited systems, the objective is to maximize the transmitted information rate within the allowable bandwidth, at the expense of E_b/N_0 (while maintaining a specified value of bit-error probability P_B). The operating points for coherent M -ary phase-shift keying (MPSK) at $P_B = 10^{-5}$ are plotted on the bandwidth-efficiency plane of Fig. 18.1. We assume Nyquist (ideal rectangular) filtering at baseband [9]. Thus, for MPSK, the required double-sideband (DSB) bandwidth at an intermediate frequency (IF) is related to the symbol rate as follows:

$$W = \frac{1}{T_s} = R_s \quad (18.13)$$

where T_s is the symbol duration and R_s is the symbol rate. The use of Nyquist filtering results in the minimum required transmission bandwidth that yields zero intersymbol interference; such ideal filtering gives rise to the name Nyquist minimum bandwidth.

From Eqs. (18.12) and (18.13), the bandwidth efficiency of MPSK modulated signals using Nyquist filtering can be expressed as

$$R/W = \log_2 M \quad (\text{b/s})/\text{Hz} \quad (18.14)$$

The MPSK points in Fig. 18.1 confirm the relationship shown in Eq. (18.14). Note that MPSK modulation is a bandwidth-efficient scheme. As M increases in value, R/W also increases. MPSK modulation can be used for realizing an improvement in bandwidth efficiency at the cost of increased E_b/N_0 . Although beyond the scope of this chapter, many highly bandwidth-efficient modulation schemes have been investigated [10].

Power-Limited Systems

Operating points for noncoherent orthogonal M -ary FSK (MFSK) modulation at $P_B = 10^{-5}$ are also plotted in Fig. 18.1. For MFSK, the IF minimum bandwidth is as follows [2]:

$$W = \frac{M}{T_s} = MR_s \quad (18.15)$$

where T_s is the symbol duration and R_s is the symbol rate. With MFSK, the required transmission bandwidth is expanded M -fold over binary FSK since there are M different orthogonal waveforms, each requiring a bandwidth of $1/T_s$. Thus, from Eqs. (18.12) and (18.15), the bandwidth efficiency of noncoherent orthogonal MFSK signals can be expressed as

$$\frac{R}{W} = \frac{\log_2 M}{M} \quad (\text{b/s})/\text{Hz} \quad (18.16)$$

The MFSK points plotted in Fig. 18.1 confirm the relationship shown in Eq. (18.16). Note that MFSK modulation is a bandwidth-expansive scheme. As M increases, R/W decreases. MFSK modulation can be used for realizing a reduction in required E_b/N_0 at the cost of increased bandwidth.

In Eqs. (18.13) and (18.14) for MPSK and Eqs. (18.15) and (18.16) for MFSK, and for all the points plotted in Fig. 18.1, ideal filtering has been assumed. Such filters are not realizable! For realistic channels

TABLE 18.1 Symbol Rate, Minimum Bandwidth, Bandwidth Efficiency, and Required E_b/N_0 for MPSK and Noncoherent Orthogonal MFSK Signalling at 9600 bit/s

and waveforms, the required transmission bandwidth must be increased in order to account for realizable filters.

In the examples that follow, we will consider radio channels that are disturbed only by additive white Gaussian noise (AWGN) and have no other impairments, and for simplicity, we will limit the modulation choice to constant-envelope types, i.e., either MPSK or noncoherent orthogonal MFSK. For an uncoded system, MPSK is selected if the channel is bandwidth limited, and MFSK is selected if the channel is power limited. When error-correction coding is considered, modulation selection is not as simple, because coding techniques can provide power-bandwidth tradeoffs more effectively than would be possible through the use of any M -ary modulation scheme considered in this chapter [11].

In the most general sense, M -ary signalling can be regarded as a waveform-coding procedure, i.e., when we select an M -ary modulation technique instead of a binary one, we in effect have replaced the binary waveforms with better waveforms—either better for bandwidth performance (MPSK) or better for power performance (MFSK). Even though orthogonal MFSK signalling can be thought of as being a coded system, i.e., a first-order Reed-Muller code [12], we restrict our use of the term coded system to those traditional error-correction codes using redundancies, e.g., block codes or convolutional codes.

Minimum Bandwidth Requirements for MPSK and MFSK Signalling

The basic relationship between the symbol (or waveform) transmission rate R_s and the data rate R was shown in Eq. (18.11). Using this relationship together with Eqs. (18.13–18.16) and $R = 9600$ b/s, a summary of symbol rate, minimum bandwidth, and bandwidth efficiency for MPSK and noncoherent orthogonal MFSK was compiled for $M = 2, 4, 8, 16,$ and 32 (Table 18.1). Values of E_b/N_0 required to achieve a bit-error probability of 10^{-5} for MPSK and MFSK are also given for each value of M . These entries (which were computed using relationships that are presented later in this chapter) corroborate the tradeoffs shown in Fig. 18.1. As M increases, MPSK signalling provides more bandwidth efficiency at the cost of increased E_b/N_0 , whereas MFSK signalling allows for a reduction in E_b/N_0 at the cost of increased bandwidth.

18.3 Example 1: Bandwidth-Limited Uncoded System

Suppose we are given a bandwidth-limited AWGN radio channel with an available bandwidth of $W = 4000$ Hz. Also, suppose that the link constraints (transmitter power, antenna gains, path loss, etc.) result in the ratio of received average signal-power to noise-power spectral density S/N_0 being equal to 53 dB-Hz. Let the required data rate R be equal to 9600 b/s, and let the required bit-error performance P_B be at most 10^{-5} . The goal is to choose a modulation scheme that meets the required performance. In general, an error-correction coding scheme may be needed if none of the allowable modulation schemes can meet the requirements. In this example, however, we shall find that the use of error-correction coding is not necessary.

Solution to Example 1

For any digital communication system, the relationship between received S/N_0 and received bit-energy to noise-power spectral density, E_b/N_0 was given in Eq. (18.6) and is briefly rewritten as

$$\frac{S}{N_0} = \frac{E_b}{N_0} R \quad (18.17)$$

Solving for E_b/N_0 in decibels, we obtain

$$\begin{aligned} \frac{E_b}{N_0} \text{ (dB)} &= \frac{S}{N_0} \text{ (dB-Hz)} - R \text{ (dB-b/s)} \\ &= 53 \text{ dB-Hz} - (10 \times \log_{10} 9600) \text{ dB-b/s} \\ &= 13.2 \text{ dB (or 20.89)} \end{aligned} \quad (18.18)$$

Since the required data rate of 9600 b/s is much larger than the available bandwidth of 4000Hz, the channel is bandwidth limited. We therefore select MPSK as our modulation scheme. We have confined the possible modulation choices to be constant-envelope types; without such a restriction, we would be able to select a modulation type with greater bandwidth efficiency. To conserve power, we compute the *smallest possible* value of M such that the MPSK minimum bandwidth does not exceed the available bandwidth of 4000 Hz. Table 18.1 shows that the smallest value of M meeting this requirement is $M = 8$. Next we determine whether the required bit-error performance of $P_B \leq 10^{-5}$ can be met by using 8-PSK modulation alone or whether it is necessary to use an error-correction coding scheme. Table 18.1 shows that 8-PSK alone will meet the requirements, since the required E_b/N_0 listed for 8-PSK is less than the received E_b/N_0 derived in Eq. (18.18). Let us imagine that we do not have Table 18.1, however, and evaluate whether or not error-correction coding is necessary.

Figure 18.2 shows the basic modulator/demodulator (MODEM) block diagram summarizing the functional details of this design. At the modulator, the transformation from data bits to symbols yields an output symbol rate R_s , that is, a factor $\log_2 M$ smaller than the input data-bit rate R , as is seen in Eq. (18.11). Similarly, at the input to the demodulator, the symbol-energy to noise-power spectral density E_s/N_0 is a factor $\log_2 M$ larger than E_b/N_0 , since each symbol is made up of $\log_2 M$ bits. Because E_s/N_0 is larger than E_b/N_0 by the same factor that R_s is smaller than R , we can expand Eq. (18.17), as

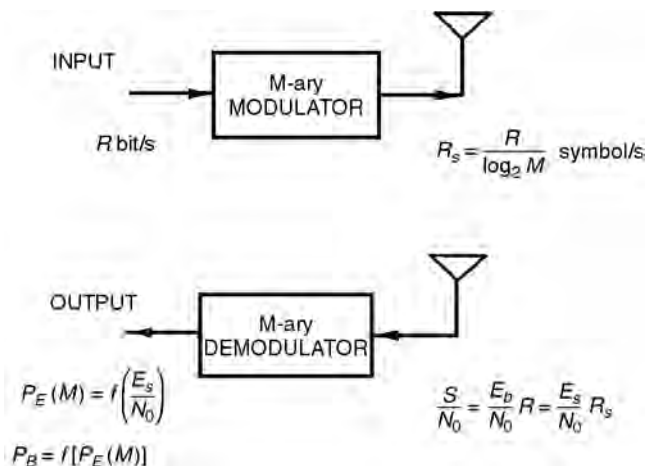

FIGURE 18.2 Basic modulator/demodulator (MODEM) without channel coding.

follows:

$$\frac{S}{N_0} = \frac{E_b}{N_0} R = \frac{E_s}{N_0} R_s \quad (18.19)$$

The demodulator receives a waveform (in this example, one of $M = 8$ possible phase shifts) during each time interval T_s . The probability that the demodulator makes a symbol error $P_E(M)$ is well approximated by the following equation for $M > 2$ [13]:

$$P_E(M) \cong 2Q \left[\sqrt{\frac{2E_s}{N_0}} \sin \left(\frac{\pi}{M} \right) \right] \quad (18.20)$$

where $Q(x)$, sometimes called the complementary error function, represents the probability under the tail of a zero-mean unit-variance Gaussian density function. It is defined as follows [14]:

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty \exp \left(-\frac{u^2}{2} \right) du \quad (18.21)$$

A good approximation for $Q(x)$, valid for $x > 3$, is given by the following equation [15]:

$$Q(x) \cong \frac{1}{x\sqrt{2\pi}} \exp \left(-\frac{x^2}{2} \right) \quad (18.22)$$

In Fig. 18.2 and all of the figures that follow, rather than show explicit probability relationships, the generalized notation $f(x)$ has been used to indicate some functional dependence on x .

A traditional way of characterizing communication efficiency in digital systems is in terms of the received E_b/N_0 in decibels. This E_b/N_0 description has become standard practice, but recall that there are no bits at the input to the demodulator; there are only waveforms that have been assigned bit meanings. The received E_b/N_0 represents a bit-apportionment of the arriving waveform energy.

To solve for $P_E(M)$ in Eq. (18.20), we first need to compute the ratio of received symbol-energy to noise-power spectral density E_s/N_0 . Since, from Eq. (18.18),

$$\frac{E_b}{N_0} = 13.2 \text{ dB (or 20.89)}$$

and because each symbol is made up of $\log_2 M$ bits, we compute the following using $M = 8$:

$$\frac{E_s}{N_0} = (\log_2 M) \frac{E_b}{N_0} = 3 \times 20.89 = 62.67 \quad (18.23)$$

Using the results of Eq. (18.23) in Eq. (18.20) yields the symbol-error probability $P_E = 2.2 \times 10^{-5}$. To transform this to bit-error probability, we use the relationship between bit-error probability P_B and symbol-error probability P_E , for multiple-phase signalling [12] $P_E \ll 1$ as follows:

$$P_B \cong \frac{P_E}{\log_2 M} = \frac{P_E}{m} \quad (18.24)$$

which is a good approximation when Gray coding is used for the bit-to-symbol assignment [13]. This last computation yields $P_B = 7.3 \times 10^{-6}$, which meets the required bit-error performance. No error-correction coding is necessary, and 8-PSK modulation represents the design choice to meet the requirements of the bandwidth-limited channel, which we had predicted by examining the required E_b/N_0 values in Table 18.1.

18.4 Example 2: Power-Limited Uncoded System

Now, suppose that we have exactly the same data rate and bit-error probability requirements as in Example 1, but let the available bandwidth W be equal to 45 kHz and the available S/N_0 be equal to 48 dB-Hz. The goal is to choose a modulation or modulation/coding scheme that yields the required performance. We shall again find that error-correction coding is not required.

Solution to Example 2

The channel is clearly not bandwidth limited since the available bandwidth of 45kHz is more than adequate for supporting the required data rate of 9600 bit/s. We find the received E_b/N_0 from Eq. (18.18), as follows:

$$\frac{E_b}{N_0} \text{ (dB)} = 48 \text{ dB-Hz} - (10 \times \log_{10} 9600) \text{ dB-b/s} = 8.2 \text{ dB (or 6.61)} \quad (18.25)$$

Since there is abundant bandwidth but a relatively small E_b/N_0 for the required bit-error probability, we consider that this channel is power limited and choose MFSK as the modulation scheme. To conserve power, we search for the *largest possible* M such that the MFSK minimum bandwidth is not expanded beyond our available bandwidth of 45 kHz. A search results in the choice of $M = 16$ (Table 18.1). Next, we determine whether the required error performance of $P_B \leq 10^{-5}$ can be met by using 16-FSK alone, i.e., without error-correction coding. Table 18.1 shows that 16-FSK alone meets the requirements, since the required E_b/N_0 listed for 16-FSK is less than the received E_b/N_0 derived in Eq. (18.25). Let us imagine again that we do not have Table 18.1 and evaluate whether or not error-correction coding is necessary.

The block diagram in Fig. 18.2 summarizes the relationships between symbol rate R_s and bit rate R , and between E_s/N_0 and E_b/N_0 , which is identical to each of the respective relationships in Example 1. The 16-FSK demodulator receives a waveform (one of 16 possible frequencies) during each symbol time interval T_s . For noncoherent orthogonal MFSK, the probability that the demodulator makes a symbol error $P_E(M)$ is approximated by the following upper bound [16]:

$$P_E(M) \leq \frac{M-1}{2} \exp\left(-\frac{E_s}{2N_0}\right) \quad (18.26)$$

To solve for $P_E(M)$ in Eq. (18.26), we compute E_s/N_0 , as in Example 1. Using the results of Eq. (18.25) in Eq. (18.23), with $M = 16$, we get

$$\frac{E_s}{N_0} = (\log_2 M) \frac{E_b}{N_0} = 4 \times 6.61 = 26.44 \quad (18.27)$$

Next, using the results of Eq. (18.27) in Eq. (18.26) yields the symbol-error probability $P_E = 1.4 \times 10^{-5}$. To transform this to bit-error probability, P_B , we use the relationship between P_B and P_E for orthogonal signalling [16], given by

$$P_B = \frac{2^{m-1}}{(2^m - 1)} P_E \quad (18.28)$$

This last computation yields $P_B = 7.3 \times 10^{-6}$, which meets the required bit-error performance. Thus, we can meet the given specifications for this power-limited channel by using 16-FSK modulation, without any need for error-correction coding, as we had predicted by examining the required E_b/N_0 values in Table 18.1.

18.5 Example 3: Bandwidth-Limited and Power-Limited Coded System

We start with the same channel parameters as in Example 1 ($W = 4000$ Hz, $S/N_0 = 53$ dB-Hz, and $R = 9600$ b/s), with one exception.

In this example, we specify that P_B must be at most 10^{-9} . Table 18.1 shows that the system is both bandwidth limited and power limited, based on the available bandwidth of 4000 Hz and the available E_b/N_0 of 20.2 dB, from Eq. (18.18); 8-PSK is the only possible choice to meet the bandwidth constraint; however, the available E_b/N_0 of 20.2 dB is certainly insufficient to meet the required P_B of 10^{-9} . For this small value of P_B , we need to consider the performance improvement that error-correction coding can provide within the available bandwidth. In general, one can use convolutional codes or block codes.

The Bose–Chaudhuri–Hocquenghem (BCH) codes form a large class of powerful error-correcting cyclic (block) codes [17]. To simplify the explanation, we shall choose a block code from the BCH family. Table 18.2 presents a partial catalog of the available BCH codes in terms of n , k , and t , where k represents the number of information (or data) bits that the code transforms into a longer block of n coded bits (or channel bits), and t represents the largest number of incorrect channel bits that the code can correct within each n -sized block. The rate of a code is defined as the ratio k/n ; its inverse represents a measure of the code's redundancy [17].

Solution to Example 3

Since this example has the same bandwidth-limited parameters given in Example 1, we start with the same 8-PSK modulation used to meet the stated bandwidth constraint. We now employ error-correction coding, however, so that the bit-error probability can be lowered to $P_B \leq 10^{-9}$.

To make the optimum code selection from Table 18.2, we are guided by the following goals.

1. The output bit-error probability of the combined modulation/coding system must meet the system error requirement.

2. The rate of the code must not expand the required transmission bandwidth beyond the available channel bandwidth.
3. The code should be as simple as possible. Generally, the shorter the code, the simpler will be its implementation.

The uncoded 8-PSK minimum bandwidth requirement is 3200 Hz (Table 18.1) and the allowable channel bandwidth is 4000 Hz, and so the uncoded signal bandwidth can be increased by no more than a factor of 1.25 (i.e., an expansion of 25%). The very first step in this (simplified) code selection example is to eliminate the candidates in Table 18.2 that would expand the bandwidth by more than 25%. The remaining entries form a much reduced set of bandwidth-compatible codes (Table 18.3).

In Table 18.3, a column designated Coding Gain G (for MPSK at $P_B = 10^{-9}$) has been added. Coding gain in decibels is defined as follows:

$$G = \left(\frac{E_b}{N_0} \right)_{\text{uncoded}} - \left(\frac{E_b}{N_0} \right)_{\text{coded}} \quad (18.29)$$

G can be described as the reduction in the required E_b/N_0 (in decibels) that is needed due to the error-performance properties of the channel coding. G is a function of the modulation type and bit-error probability, and it has been computed for MPSK at $P_B = 10^{-9}$ (Table 18.3). For MPSK modulation, G is relatively independent of the value of M . Thus, for a particular bit-error probability, a given code will provide about the same coding gain when used with any of the MPSK modulation schemes. Coding gains were calculated using a procedure outlined in the subsequent Calculating Coding Gain section.

A block diagram summarizes this system, which contains both modulation and coding (Fig. 18.3). The introduction of encoder/decoder blocks brings about additional transformations. The relationships that exist when transforming from R b/s to R_c channel-b/s to R_s symbol/s are shown at the encoder/modulator. Regarding the channel-bit rate R_c , some authors prefer to use the units of channel-symbol/s (or code-symbol/s). The benefit is that error-correction coding is often described more efficiently with nonbinary digits. We reserve the term symbol for that group of bits mapped onto an electrical waveform for transmission, and we designate the units of R_c to be channel-b/s (or coded-b/s).

We assume that our communication system cannot tolerate any message delay, so that the channel-bit rate R_c must exceed the data-bit rate R by the factor n/k . Further, each symbol is made up of $\log_2 M$ channel bits, and so the symbol rate R_s is less than R_c by the factor $\log_2 M$. For a system containing both modulation and coding, we summarize the rate transformations as follows:

$$R_c = \left(\frac{n}{k} \right) R \quad (18.30)$$

$$R_s = \frac{R_c}{\log_2 M} \quad (18.31)$$

At the demodulator/decoder in Fig. 18.3, the transformations among data-bit energy, channel-bit energy, and symbol energy are related (in a reciprocal fashion) by the same factors as shown among the rate

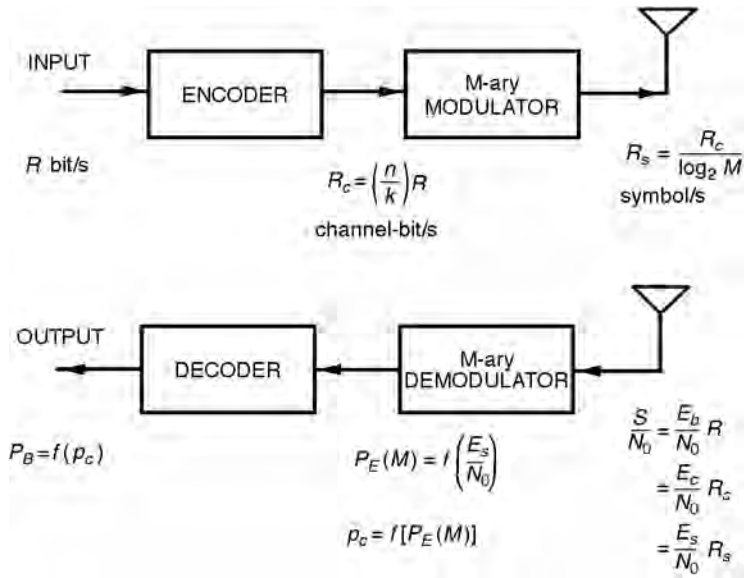

FIGURE 18.3 MODEM with channel coding.

transformations in Eqs. (18.30) and (18.31). Since the encoding transformation has replaced k data bits with n channel bits, then the ratio of channel-bit energy to noise-power spectral density E_c/N_0 is computed by decrementing the value of E_b/N_0 by the factor k/n . Also, since each transmission symbol is made up of $\log_2 M$ channel bits, then E_s/N_0 , which is needed in Eq. (18.20) to solve for P_E , is computed by incrementing E_c/N_0 by the factor $\log_2 M$. For a system containing both modulation and coding, we summarize the energy to noise-power spectral density transformations as follows:

$$\frac{E_c}{N_0} = \left(\frac{k}{n}\right) \frac{E_b}{N_0} \quad (18.32)$$

$$\frac{E_s}{N_0} = (\log_2 M) \frac{E_c}{N_0} \quad (18.33)$$

Using Eqs. (18.30) and (18.31), we can now expand the expression for S/N_0 in Eq. (18.19) as follows (see [Appendix](#)):

$$\frac{S}{N_0} = \frac{E_b}{N_0} R = \frac{E_c}{N_0} R_c = \frac{E_s}{N_0} R_s \quad (18.34)$$

As before, a standard way of describing the link is in terms of the received E_b/N_0 in decibels. However, there are no data bits at the input to the demodulator, and there are no channel bits; there are only waveforms that have bit meanings and, thus, the waveforms can be described in terms of bit-energy apportionments.

Since S/N_0 and R were given as 53 dB-Hz and 9600 b/s, respectively, we find as before, from Eq. (18.18), that the received $E_b/N_0 = 13.2$ dB. The received E_b/N_0 is fixed and independent of n , k , and t (see [Appendix](#)). As we search in [Table 18.3](#) for the ideal code to meet the specifications, we can iteratively repeat the computations suggested in [Fig. 18.3](#). It might be useful to program on a personal computer (or calculator) the

following four steps as a function of n , k , and t . Step 1 starts by combining Eqs. (18.32) and (18.33), as follows.

Step 1:

$$\frac{E_s}{N_0} = (\log_2 M) \frac{E_c}{N_0} = (\log_2 M) \binom{k}{n} \frac{E_b}{N_0} \quad (18.35)$$

Step 2:

$$P_E(M) \cong 2Q \left[\sqrt{\frac{2E_s}{N_0}} \sin \left(\frac{\pi}{M} \right) \right] \quad (18.36)$$

which is the approximation for symbol-error probability P_E rewritten from Eq. (18.20). At each symbol-time interval, the demodulator makes a symbol decision, but it delivers a channel-bit sequence representing that symbol to the decoder. When the channel-bit output of the demodulator is quantized to two levels, 1 and 0, the demodulator is said to make hard decisions. When the output is quantized to more than two levels, the demodulator is said to make soft decisions [2]. Throughout this paper, we shall assume hard-decision demodulation.

Now that we have a decoder block in the system, we designate the channel-bit-error probability out of the demodulator and into the decoder as p_c and we reserve the notation P_B for the bit-error probability out of the decoder. We rewrite Eq. (18.24) in terms of p_c for $P_E \ll 1$ as follows.

Step 3:

$$p_c \cong \frac{P_E}{\log_2 M} = \frac{P_E}{m} \quad (18.37)$$

relating the channel-bit-error probability to the symbol-error probability out of the demodulator, assuming Gray coding, as referenced in Eq. (18.24).

For traditional channel-coding schemes and a given value of received S/N_0 , the value of E_s/N_0 with coding will always be less than the value of E_s/N_0 without coding. Since the demodulator with coding receives less E_s/N_0 , it makes more errors! When coding is used, however, the system error-performance does not only depend on the performance of the demodulator, it also depends on the performance of the decoder. For error-performance improvement due to coding, the decoder must provide enough error correction to more than compensate for the poor performance of the demodulator.

The final output decoded bit-error probability P_B depends on the particular code, the decoder, and the channel-bit-error probability p_c . It can be expressed by the following approximation [18].

Step 4:

$$P_B \cong \frac{1}{n} \sum_{j=t+1}^n j \binom{n}{j} p_c^j (1-p_c)^{n-j} \quad (18.38)$$

where t is the largest number of channel bits that the code can correct within each block of n bits. Using Eqs. (18.35–18.38) in the four steps, we can compute the decoded bit-error probability P_B as a function of n , k , and t for each of the codes listed in Table 18.3. The entry that meets the stated error requirement with the largest possible code rate and the smallest value of n is the double-error correcting (63, 51) code. The computations are as follows.

Step 1:

$$\frac{E_s}{N_0} = 3 \left(\frac{51}{63} \right) 20.89 = 50.73$$

where $M = 8$, and the received $E_b/N_0 = 13.2$ dB (or 20.89).

Step 2:

$$P_E \cong 2Q\left[\sqrt{101.5} \times \sin\left(\frac{\pi}{8}\right)\right] = 2Q(3.86) = 1.2 \times 10^{-4}$$

Step 3:

$$p_c \cong \frac{1.2 \times 10^{-4}}{3} = 4 \times 10^{-5}$$

Step 4:

$$\begin{aligned} P_B &\cong \frac{3}{63} \binom{63}{3} (4 \times 10^{-5})^3 (1 - 4 \times 10^{-5})^{60} \\ &\quad + \frac{4}{63} \binom{63}{4} (4 \times 10^{-5})^4 (1 - 4 \times 10^{-5})^{59} + \dots \\ &= 1.2 \times 10^{-10} \end{aligned}$$

where the bit-error-correcting capability of the code is $t = 2$. For the computation of P_B in step 4, we need only consider the first two terms in the summation of Eq. (18.38) since the other terms have a vanishingly small effect on the result. Now that we have selected the (63, 51) code, we can compute the values of channel-bit rate R_c and symbol rate R_s using Eqs. (18.30) and (18.31), with $M = 8$,

$$\begin{aligned} R_c &= \binom{n}{k} R = \binom{63}{51} 9600 \approx 11,859 \text{ channel-b/s} \\ R_s &= \frac{R_c}{\log_2 M} = \frac{11859}{3} = 3953 \text{ symbol/s} \end{aligned}$$

Calculating Coding Gain

Perhaps a more direct way of finding the simplest code that meets the specified error performance is to first compute how much coding gain G is required in order to yield $P_B = 10^{-9}$ when using 8-PSK modulation alone; then, from [Table 18.3](#), we can simply choose the code that provides this performance improvement. First, we find the uncoded E_s/N_0 that yields an error probability of $P_B = 10^{-9}$, by writing from Eqs. (18.24) and (18.36), the following:

$$P_B \cong \frac{P_E}{\log_2 M} \cong \frac{2Q\left[\sqrt{\frac{2E_s}{N_0}} \sin\left(\frac{\pi}{M}\right)\right]}{\log_2 M} = 10^{-9} \quad (18.39)$$

At this low value of bit-error probability, it is valid to use Eq. (18.22) to approximate $Q(x)$ in Eq. (18.39). By trial and error (on a programmable calculator), we find that the uncoded $E_s/N_0 = 120.67 = 20.8$ dB, and since each symbol is made up of $\log_2 8 = 3$ bits, the required $(E_b/N_0)_{\text{uncoded}} = 120.67/3 = 40.22 = 16$ dB. From the given parameters and Eq. (18.18), we know that the received $(E_b/N_0)_{\text{coded}} = 13.2$ dB. Using Eq. (18.29), the required coding gain to meet the bit-error performance of $P_B = 10^{-9}$ in decibels is

$$G = \left(\frac{E_b}{N_0}\right)_{\text{uncoded}} - \left(\frac{E_b}{N_0}\right)_{\text{coded}} = 16 - 13.2 = 2.8$$

To be precise, each of the E_b/N_0 values in the preceding computation must correspond to exactly the same value of bit-error probability (which they do not). They correspond to $P_B = 10^{-9}$ and $P_B = 1.2 \times 10^{-10}$, respectively. At these low probability values, however, even with such a discrepancy, this computation still provides a good approximation of the required coding gain. In searching Table 18.3 for the simplest code that will yield a coding gain of at least 2.8 dB, we see that the choice is the (63, 51) code, which corresponds to the same code choice that we made earlier.

18.6 Example 4: Direct-Sequence (DS) Spread-Spectrum Coded System

Spread-spectrum systems are not usually classified as being bandwidth or power limited. They are generally perceived to be power-limited systems, however, because the bandwidth occupancy of the information is much larger than the bandwidth that is intrinsically needed for the information transmission. In a direct-sequence spread-spectrum (DS/SS) system, spreading the signal bandwidth by some factor permits lowering the signal-power spectral density by the same factor (the total average signal power is the same as before spreading). The bandwidth spreading is typically accomplished by multiplying a relatively narrowband data signal by a wideband spreading signal. The spreading signal or spreading code is often referred to as a pseudorandom code or PN code.

Processing Gain

A typical DS/SS radio system is often described as a two-step BPSK modulation process. In the first step, the carrier wave is modulated by a bipolar data waveform having a value +1 or -1 during each data-bit duration; in the second step, the output of the first step is multiplied (modulated) by a bipolar PN-code waveform having a value +1 or -1 during each PN-code-bit duration. In reality, DS/SS systems are usually implemented by first multiplying the data waveform by the PN-code waveform and then making a single pass through a BPSK modulator. For this example, however, it is useful to characterize the modulation process in two separate steps—the outer modulator/demodulator for the data, and the inner modulator/demodulator for the PN code (Fig. 18.4).

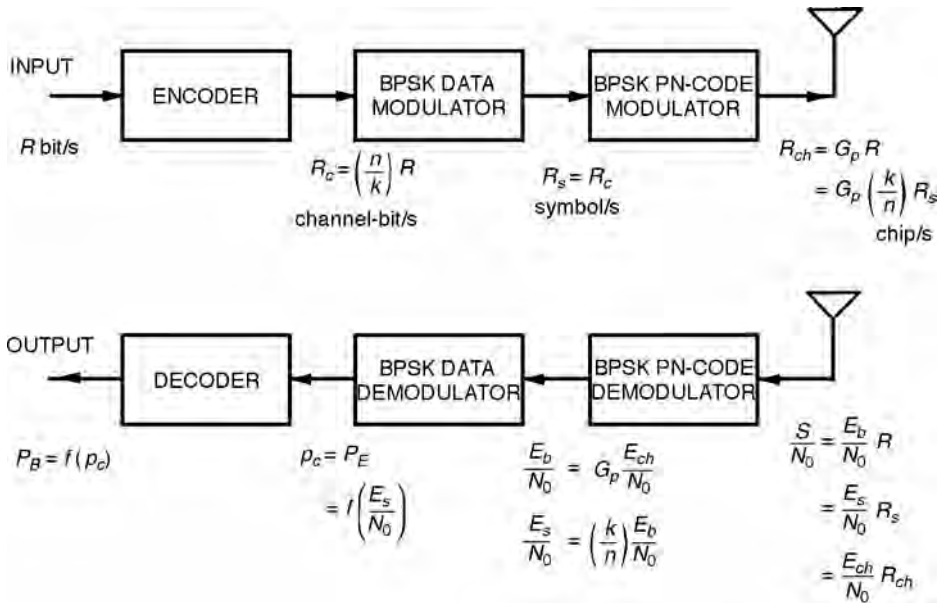

FIGURE 18.4 Direct-sequence spread-spectrum MODEM with channel coding.

A spread-spectrum system is characterized by a processing gain G_p that is defined in terms of the spread-spectrum bandwidth W_{ss} and the data rate R as follows [19]:

$$G_p = \frac{W_{ss}}{R} \quad (18.40)$$

For a DS/SS system, the PN-code bit has been given the name chip, and the spread-spectrum signal bandwidth can be shown to be about equal to the chip rate R_{ch} as follows:

$$G_p = \frac{R_{ch}}{R} \quad (18.41)$$

Some authors define processing gain to be the ratio of the spread-spectrum bandwidth to the symbol rate. This definition separates the system performance that is due to bandwidth spreading from the performance that is due to error-correction coding. Since we ultimately want to relate all of the coding mechanisms relative to the information source, we shall conform to the most usually accepted definition for processing gain, as expressed in Eqs. (18.40) and (18.41).

A spread-spectrum system can be used for interference rejection and for multiple access (allowing multiple users to access a communications resource simultaneously). The benefits of DS/SS signals are best achieved when the processing gain is very large; in other words, the chip rate of the spreading (or PN) code is much larger than the data rate. In such systems, the large value of G_p allows the signalling chips to be transmitted at a power level well below that of the thermal noise. We will use a value of $G_p = 1000$. At the receiver, the despreading operation correlates the incoming signal with a synchronized copy of the PN code and, thus, accumulates the energy from multiple (G_p) chips to yield the energy per data bit. The value of G_p has a major influence on the performance of the spread-spectrum system application. We shall see, however, that the value of G_p has no effect on the received E_b/N_0 . In other words, spread spectrum techniques offer no error-performance advantage over thermal noise. For DS/SS systems, there is no disadvantage either! Sometimes such spread-spectrum radio systems are employed only to enable the transmission of very small power-spectral densities and thus avoid the need for FCC licensing [20].

Channel Parameters for Example 4

Consider a DS/SS radio system that uses the same (63, 51) code as in the previous example. Instead of using MPSK for the data modulation, we shall use BPSK. Also, we shall use BPSK for modulating the PN-code chips. Let the received $S/N_0 = 48$ dB-Hz, the data rate $R = 9600$ b/s, and the required $P_B \leq 10^{-6}$. For simplicity, assume that there are no bandwidth constraints. Our task is simply to determine whether or not the required error performance can be achieved using the given system architecture and design parameters. In evaluating the system, we will use the same type of transformations used in the previous examples.

Solution to Example 4

A typical DS/SS system can be implemented more simply than the one shown in Fig. 18.4. The data and the PN code would be combined at baseband, followed by a single pass through a BPSK modulator. We will, however, assume the existence of the individual blocks in Fig. 18.4 because they enhance our understanding of the transformation process. The relationships in transforming from data bits, to channel bits, to symbols, and to chips, shown in Fig. 18.4, have the same pattern of subtle but straightforward transformations in rates and energies as previous relationships (Figs. 18.2 and 18.3). The values of R_c , R_s , and R_{ch} can now be calculated immediately since the (63, 51) BCH code has already been selected. From Eq. (18.30) we write

$$R_c = \left(\frac{n}{k}\right)R = \left(\frac{63}{51}\right)9600 \approx 11,859 \text{ channel-b/s}$$

Since the data modulation considered here is BPSK, then from Eq. (18.31) we write

$$R_s = R_c \approx 11,859 \text{ symbol/s}$$

and from Eq. (18.41), with an assumed value of $G_p = 1000$

$$R_{\text{ch}} = G_p R = 1000 \times 9600 = 9.6 \times 10^6 \text{ chip/s}$$

Since we have been given the same S/N_0 and the same data rate as in Example 2, we find the value of received E_b/N_0 from Eq. (18.25) to be 8.2 dB (or 6.61). At the demodulator, we can now expand the expression for S/N_0 in Eq. (18.34) and the Appendix as follows:

$$\frac{S}{N_0} = \frac{E_b}{N_0} R = \frac{E_c}{N_0} R_c = \frac{E_s}{N_0} R_s = \frac{E_{\text{ch}}}{N_0} R_{\text{ch}} \quad (18.42)$$

Corresponding to each transformed entity (data bit, channel bit, symbol, or chip) there is a change in rate and, similarly, a reciprocal change in energy-to-noise spectral density for that received entity. Equation (18.42) is valid for any such transformation when the rate and energy are modified in a reciprocal way. There is a kind of *conservation of power* (or energy) phenomenon that exists in the transformations. The total received average power (or total received energy per symbol duration) is fixed regardless of how it is computed, on the basis of data bits, channel bits, symbols, or chips.

The ratio E_{ch}/N_0 is much lower in value than E_b/N_0 . This can be seen from Eqs. (18.42) and (18.41), as follows:

$$\frac{E_{\text{ch}}}{N_0} = \frac{S}{N_0} \left(\frac{1}{R_{\text{ch}}} \right) = \frac{S}{N_0} \left(\frac{1}{G_p R} \right) = \left(\frac{1}{G_p} \right) \frac{E_b}{N_0} \quad (18.43)$$

But, even so, the despreading function (when properly synchronized) accumulates the energy contained in a quantity G_p of the chips, yielding the same value $E_b/N_0 = 8.2$ dB, as was computed earlier from Eq. (18.25). Thus, the DS spreading transformation has no effect on the error performance of an AWGN channel [2], and the value of G_p has no bearing on the value of P_B in this example.

From Eq. (18.43), we can compute, in decibels,

$$\begin{aligned} \frac{E_{\text{ch}}}{N_0} &= E_b/N_0 - G_p \\ &= 8.2 - (10 \times \log_{10} 1000) \\ &= -21.8 \end{aligned} \quad (18.44)$$

The chosen value of processing gain ($G_p = 1000$) enables the DS/SS system to operate at a value of chip energy well below the thermal noise, with the same error performance as without spreading.

Since BPSK is the data modulation selected in this example, each message symbol therefore corresponds to a single channel bit, and we can write

$$\frac{E_s}{N_0} = \frac{E_c}{N_0} = \left(\frac{k}{n} \right) \frac{E_b}{N_0} = \left(\frac{51}{63} \right) \times 6.61 = 5.35 \quad (18.45)$$

where the received $E_b/N_0 = 8.2$ dB (or 6.61). Out of the BPSK data demodulator, the symbol-error probability P_E (and the channel-bit error probability p_c) is computed as follows [2]:

$$p_c = P_E = Q \left(\sqrt{\frac{2E_c}{N_0}} \right) \quad (18.46)$$

Using the results of Eq. (18.45) in Eq. (18.46) yields

$$p_c = Q(3.27) = 5.8 \times 10^{-4}$$

Finally, using this value of p_c in Eq. (18.38) for the (63, 51) double-error correcting code yields the output bit-error probability of $P_B = 3.6 \times 10^{-7}$. We can, therefore, verify that for the given architecture and design parameters of this example, the system does, in fact, achieve the required error performance.

18.7 Conclusion

The goal of this chapter has been to review fundamental relationships used in evaluating the performance of digital communication systems. First, we described the concept of a link and a channel and examined a radio system from its transmitting segment up through the output of the receiving antenna. We then examined the concept of bandwidth-limited and power-limited systems and how such conditions influence the system design when the choices are confined to MPSK and MFSK modulation. Most important, we focused on the definitions and computations involved in transforming from data bits to channel bits to symbols to chips. In general, most digital communication systems share these concepts; thus, understanding them should enable one to evaluate other such systems in a similar way.

Appendix: Received E_b/N_0 Is Independent of the Code Parameters

Starting with the basic concept that the received average signal power S is equal to the received symbol or waveform energy, E_s , divided by the symbol-time duration, T_s (or multiplied by the symbol rate, R_s), we write

$$\frac{S}{N_0} = \frac{E_s/T_s}{N_0} = \frac{E_s}{N_0} R_s \quad (\text{A18.1})$$

where N_0 is noise-power spectral density characterizing all the noise in the receiving system.

Using Eqs. (18.27) and (18.25), rewritten as

$$\frac{E_s}{N_0} = (\log_2 M) \frac{E_c}{N_0} \quad \text{and} \quad R_s = \frac{R_c}{\log_2 M}$$

let us make substitutions into Eq. (A18.1), which yields

$$\frac{S}{N_0} = \frac{E_c}{N_0} R_c \quad (\text{A18.2})$$

Next, using Eqs. (18.26) and (18.24), rewritten as

$$\frac{E_c}{N_0} = \left(\frac{k}{n}\right) \frac{E_b}{N_0} \quad \text{and} \quad R_c = \left(\frac{n}{k}\right) R$$

let us now make substitutions into Eq. (A18.2), which yields the relationship expressed in Eq. (18.11)

$$\frac{S}{N_0} = \frac{E_b}{N_0} R \quad (\text{A18.3})$$

Hence, the received E_b/N_0 is only a function of the received S/N_0 and the data rate R . It is independent of the code parameters n , k , and t . These results are summarized in [Fig. 18.3](#).

19.1 Introduction

Etymologically, the word synchronization refers to the process of making two or more events occur at the same time, or, by duality, at the same frequency. In a digital communication context, various levels of synchronization must be established before data decoding can take place, including *carrier synchronization*, *symbol synchronization*, and *frame synchronization*.

In radio frequency communications, carrier synchronization refers to the process of generating a sinusoidal signal that closely tracks the *phase* and *frequency* of a received noisy carrier, transmitted by a possibly distant transmitter. Thus, carrier synchronization in general refers to both frequency and phase acquisition and tracking. Of the two, in many cases the more difficult problem is extracting carrier phase, which is often a much faster varying process compared to frequency offset. This is especially so since the advent of highly stable crystal oscillators operating in the UHF or lower frequency bands, although the problem is still prevalent at the higher, microwave frequencies where crystal oscillators are not available. Frequency acquisition is also a problem in mobile radio applications where, due to the Doppler effect, there is an offset in the frequency of the received carrier.

Communication systems that have available, or somehow extract and make use of, good (theoretically perfect) carrier frequency and phase information are known as *coherent systems*, in contrast to *incoherent systems* that neglect the carrier phase. Systems that attempt to acquire phase information but do not do a perfect job are known as *partially coherent systems*. Coherent systems are known to perform better than incoherent ones, at the price, however, of more complexity required for carrier synchronization. This chapter will look at some of the classical techniques for carrier acquisition as well as some of the modern techniques, which often involve operating on sampled instead of analog data.

Symbol synchronization is the process of deriving at the receiver timing signals that indicate where in time the transmitted symbols are located. The decision part of the receiver subsequently uses this information in order to decide what the symbols are. As with carrier synchronization, the data available to the receiver for making timing estimates is noisy. Thus, perfect timing information cannot be obtained in practice, although practical systems come close.

Once symbol synchronization is achieved, the next highest synchronization level is frame synchronization. Frame synchronization is necessary in systems for which the unit of information is not a symbol, but rather a sequence of symbols. Such systems are, for example, coded systems where the unit of information is a codeword which consists of a number of symbols. In this case, it is clear that knowing where the symbols are is not enough, and a further knowledge of where the codewords are is needed. It is easily seen that the existence of frame synchronization automatically implies symbol synchronization, but the converse is not true. Thus, one might be tempted to attempt frame synchronization before symbol synchronization is achieved, thereby achieving both at once. Such an approach, although in theory resulting in better performance, has the disadvantage of requiring more complex processing than the approach of first achieving lower level synchronization before higher levels are attempted. In practice, almost invariably the latter approach is followed. A rather standard approach to achieving frame synchronization is for the transmitter to insert at the start of every frame a special synchronization pattern, whose detection at the receiver locates frame boundaries. We will look at the optimal frame synchronization processing as well as some of the desirable characteristics of synchronization sequences later.

There are two general methodologies for achieving the various synchronization levels needed by the receiver. One way is to provide at the receiver side an unmodulated carrier, or a carrier modulated by a known sequence, which can be used solely for the purpose of synchronization. This approach has the advantage of decoupling the problem of data detection and synchronization and makes the synchronization system design easier. On the other hand, the overall communication efficiency suffers since signal energy and time is used but no information is sent. A second approach, which is often preferred, is to derive synchronization from the data-modulated carrier, the same signal used for symbol decisions. In this way, no efficiency is sacrificed, but the processing becomes somewhat more involved. In the sequel, we will only consider algorithms that utilize a modulated received signal to derive synchronization. We first start with a look at carrier synchronization algorithms. Excellent general treatments of this and the other synchronization problems studied later can be found in the classic texts of Stiffler [1] and Lindsey and Simon [2], and more recently by Meyr [3, 16] and Mengali and D'Andrea [17].

19.2 Carrier Synchronization

Carrier Frequency Synchronization

The objective of a carrier frequency synchronization system consists of estimating and compensating the carrier frequency offset that may be induced at the receiver by oscillator instabilities and/or Doppler shifts. According to the degree of knowledge of the transmitted symbols, carrier frequency synchronizers are classified into three main categories: data-aided (DA), decision-directed (DD) and non-data aided (NDA) or blind methods. DA methods assume perfect knowledge of the transmitted symbols, while NDA methods do not require such knowledge. Being more spectrally efficient, the NDA methods are well suited for burst applications. As an intermediate category between the DA and NDA methods, the DD methods rely on knowledge of the symbols obtained at the output of a symbol-by-symbol decoder. According to the magnitude of the carrier frequency offset that they can cope with, carrier frequency synchronizers may be classified in two classes:

1. Carrier frequency synchronizers that can compensate frequency offsets much smaller than the symbol rate ($1/T$), in general less than 10% of the symbol rate.
2. Carrier frequency synchronizers that can compensate large frequency offsets on the order of the symbol rate ($1/T$).

During initial carrier frequency acquisition, the second class of carrier synchronizers is employed in order to reduce large carrier frequency offsets to a small percentage of the symbol rate and to facilitate other carrier or symbol synchronization operations. Compensation of large frequency offsets with magnitudes in the range of 100% of the symbol rate can be performed using either closed-loop (feedback) or open-loop (feedforward) frequency synchronizers. Within the class of closed-loop frequency synchronizers, the most

used carrier recovery systems are the approximate maximum likelihood (ML) frequency error detectors [23, 25], quadricorrelators [24, 26, 33, 34], and dual filter detectors [21, 33], which were shown to be equivalent in [22]. Open-loop frequency recovery schemes [27, 28], referred to also as delay-and-multiply methods, present shorter acquisition time and are simpler to implement than the closed-loop frequency recovery methods. They also exhibit comparable performance to the approximate ML frequency error detectors [23, 25]. Due to these features, open-loop carrier recovery schemes are used in spontaneous packet transmissions, where the frequency synchronization must be performed within a fixed time interval.

Once that the compensation of the large carrier frequency offsets has been accomplished and the receiver operates under steady-state conditions, carrier frequency recovery systems that can track and compensate carrier frequency offsets of magnitude much less than the symbol rate are usually employed. Compensation of frequency offsets with magnitudes in the range of 10% of the symbol rate can be performed by employing DA methods, such as those proposed by Fitz [30, 31], Luise and Reggiannini [32], and the approximate ML estimator [17, 28]. These methods appear to be the best methods available in the literature in terms of implementation complexity and performance. All these methods practically achieve the Cramer–Rao bound at a signal-to-noise ratio (SNR) of zero dB. For burst mode applications, open-loop NDA frequency recovery schemes have been proposed for arbitrary QAM and M-ary PSK input symbol constellations [29]. Open-loop NDA frequency recovery schemes estimate the frequency offset based on certain higher-order statistics computed from the received samples and present limited performance due to the self-noise that is induced by computing the associated higher-order statistics.

Carrier Phase Synchronization

This section will formulate the carrier synchronization problem in mathematical terms as an estimation problem and will then see how the optimal equations derived can be practically implemented through appropriate approximations. Our optimality criterion is in the sense of maximum-likelihood, under which estimates maximize with respect to the parameter to be estimated, the conditional probability density of the data given the parameter (see, for example, [4]). As pointed out in the introduction, carrier synchronization may be achieved rather easily by tracking the phase of an unmodulated carrier that is frequency multiplexed with the modulated carrier. In this case, we need not worry about the noise (uncertainty) introduced by the random modulation. On the other hand, the resulting system is inefficient since part of the transmitter power carries no information and is used solely for carrier phase estimation. Although we will look at such synchronizers, our emphasis will be on the more efficient carrier synchronizers that derive their carrier phase estimates from suppressed carrier signals.

Unmodulated Carrier

The received unmodulated signal $r(t)$ is

$$r(t) = s(t; \phi) + n(t), \quad t \in T_0 \quad (19.1)$$

where $s(t, \phi) = A \cos(2\pi f_c t - \phi)$ is the transmitted (unmodulated) signal, ϕ is the carrier phase, and $n(t)$ is a zero-mean, white Gaussian noise process with spectral density $N_0/2$. The maximum-likelihood (ML) estimate of the received noisy carrier is the value of ϕ that maximizes the likelihood function, given by (see, for example, [4])

$$L(\phi) = \exp \left[\frac{2}{N_0} \int_{T_0} r(t)s(t; \phi) dt - \frac{1}{N_0} \int_{T_0} s^2(t; \phi) dt \right] \quad (19.2)$$

Since the second integral above is not a function of ϕ , it can be dropped. Taking the logarithm of the resulting expression, we can equivalently maximize the log-likelihood function given by

$$\ell(\phi) = \frac{2}{N_0} \int_{T_0} r(t)s(t; \phi) dt \quad (19.3)$$

FIGURE 19.1 ML synchronizer: open-loop.

FIGURE 19.2 Phase-locked loop estimator.

Differentiating with respect to ϕ and setting to zero, we obtain the following necessary condition for the maximum-likelihood estimate $\hat{\phi}$:

$$\int_{T_0} r(t) \sin(2\pi f_c t - \hat{\phi}) dt = 0 \tag{19.4}$$

Solving for $\hat{\phi}$ we obtain

$$\hat{\phi} = \tan^{-1} \left[\frac{\int_{T_0} r(t) \sin(2\pi f_c t) dt}{\int_{T_0} r(t) \cos(2\pi f_c t) dt} \right]$$

Figure 19.1 shows how the above estimator can be implemented in block-diagram form in what is referred to as an *open-loop* realization.

A *closed-loop* or tracking synchronizer that uses the optimality condition in Eq. (19.4) in a tracking loop referred to as a *phase-locked loop* (PLL) is shown in Fig. 19.2. In this figure, VCO stands for Voltage Controlled Oscillator and is a device that produces a sinusoid at the carrier frequency f_c and has an instantaneous frequency which is proportional to its input (or, equivalently, a phase that is the integral of its input). The integrator in Fig. 19.2 over the interval T_0 is a linear filter that, in general, can be modeled by an impulse response $g(t)$ or a transfer function $G(s)$ and is referred to as the *loop filter*.

Let us now investigate the performance of the PLL synchronizer. We have the following equation describing the PLL in Fig. 19.2:

$$\frac{d\hat{\phi}(t)}{dt} = \left\{ r(t) \sin[2\pi f_c t + \hat{\phi}(t)] \right\} * g(t) \tag{19.5}$$

where $*$ represents convolution. Substituting for $r(t)$ from Eq. (19.1) the product term becomes

$$r(t) \sin[2\pi f_c t + \hat{\phi}(t)] = \frac{A}{2} \left\{ \sin[4\pi f_c t + \hat{\phi}(t) + \phi] + \sin[\hat{\phi}(t) - \phi] \right\} + n'(t) \tag{19.6}$$

FIGURE 19.3 Equivalent PLL model for performance analysis.

FIGURE 19.4 Linearized PLL model for performance computation.

where $n'(t)$ can be argued to be white and Gaussian with zero mean and spectral density $N_0/4$. Dropping the double-frequency term in Eq. (19.6), since it will be filtered out by the much lower bandwidth of the loop, we obtain the following model for the PLL

$$\frac{d\phi(t)}{dt} = \left[\frac{A}{2} \sin[\hat{\phi}(t) - \phi] + n'(t) \right] * g(t) \quad (19.7)$$

Equation (19.7) is a nonlinear stochastic differential equation that describes the evolution of the phase estimate and is modeled in Fig. 19.3. If we let $e(t) = [\hat{\phi}(t) - \phi]$ be the phase error, then it is easily seen (since ϕ is not a function of time) that the phase-error is described by

$$\frac{de(t)}{dt} = \left[\frac{A}{2} \sin[e(t)] + n'(t) \right] * g(t) \quad (19.8)$$

An analytical solution for the density of the error $e(t)$ in steady-state has been derived (see Viterbi [5]) for the special case when $G(s) = 1$ and is given by the *Tichonov density function*

$$p(e) = \frac{\exp[\alpha \cos(e)]}{2\pi I_0(\alpha)}, \quad -\pi \leq e \leq \pi \quad (19.9)$$

where $\alpha = 4A/N_0$ and $I_0(\cdot)$ is the zero-order modified Bessel function. For large α , i.e., large signal-to-noise ratios (SNRs), the variance of the phase-error computed from Eq. (19.9) can be approximated by $\sigma_e^2 \cong 1/\alpha$. Further, for large SNRs, the error will be small on the average, and so, in Eq. (19.8), $\sin(e) \cong e$. Under this approximation, Eq. (19.8) (and, consequently, Eq. (19.7)) become linear. Figure 19.4 shows the linearized model for a PLL.

For the linear model in Fig. 19.4, an expression for the variance of the estimation error in steady-state can be derived easily by computing the variance of the output ϕ when the input is just the noise $n'(t)$. The following expression for the variance of the estimation error can be derived (which is a good approximation to the actual variance at high SNRs when the linearized model is valid)

$$\sigma_e^2 = \frac{2N_0B_L}{A^2}, \quad (19.10)$$

where the parameter B_L is known as the (one-sided) *loop noise equivalent bandwidth* and is given by

$$B_L = \frac{1}{\max |H(f)|^2} \int_0^\infty |H(f)|^2 df. \quad (19.11)$$

In Eq. (19.11), $H(s)$ is the closed-loop transfer function of the (linearized) loop and is given by

$$H(s) = \frac{AG(s)}{2s + AG(s)}. \quad (19.12)$$

A simple computation of the variance given by Eq. (19.9) for the special case when $G(s) = 1$ yields $1/\alpha$, as expected. The advantage of Eq. (19.10) is that it can be used for general $G(s)$, provided the signal-to-noise ratio is large enough for the linear approximation to hold. Note also that the estimation error becomes smaller with decreasing bandwidth B_L . Thus, one might be tempted to reduce B_L to zero. The problem in this case is that the transient performance of the loop degrades to the extent that it may take a longer period of time to achieve a small error. Also, in practice, the input phase ϕ is time-varying, in which case the loop bandwidth should be large enough so that the loop can track the changes in the input. We now turn our attention to finding the performance of the ML carrier synchronizer in Fig. 19.1.

We make use of the Cramer–Rao lower bound [4] that states that under some conditions, the variance of the estimation error for *any* unbiased estimate of a parameter ϕ is lower-bounded by

$$\sigma_e^2 = \frac{-1}{E \left[\frac{\partial^2 \ln p(r|\phi)}{\partial \phi^2} \right]}, \quad (19.13)$$

where $\ln p(r|\phi)$ is the log-likelihood function given by Eq. (19.3) for the phase estimation problem. Using Eq. (19.13), we obtain

$$\sigma_e^2 \geq \left\{ \frac{2A}{N_0} \int_{T_0} E[r(t)] \cos(2\pi f_c t + \phi) dt \right\} = \frac{2N_0}{A^2} \frac{1}{2T_0}. \quad (19.14)$$

A brief computation shows that $1/T_0$ corresponds to the equivalent noise bandwidth of the integrator. Thus, if the equivalent noise bandwidths in Eqs. (19.10) and (19.14) are the same, the performances of the ML and the PLL synchronizers are the same (assuming that the bound in Eq. (19.14) is achieved closely). Next, we address carrier extraction from a modulated carrier, which, as pointed out earlier, is, in practice, the preferred approach for efficiency reasons.

Synchronization from a Modulated Carrier

A suboptimal approach, often used in practice, to extract carrier synchronization from a modulated signal is to first nonlinearly preprocess the signal to “wipe off” the modulation, and then follow that by, for example, a PLL, as described above. For M -ary phase-shift keying (PSK), the nonlinear preprocessing involves taking the M th power of the signal. This has the effect of multiplying the carrier phase by M , and thus a subsequent division by M is needed to match the original carrier phase. For PSK signaling, a side effect of the power-law nonlinearity is to introduce a phase ambiguity, which must be resolved either by using pilot symbols or through the use of *differential encoding* of the data (information is conveyed by the change in the phase relative to the previous baud interval, rather than absolute phase), which is the case in practice.

Besides the suboptimal power-law technique, ML estimation can be used to suggest the optimal processing and possible approximations, which we study next. Let the modulated data be

$$r(t) = s(t; d, \phi) + n(t) \quad (19.15)$$

where d is a sequence of N modulation symbols. For simplicity, we will assume binary antipodal signals in which case each component, d_k , of d is either 1 or -1 . If we let the baud rate be $1/T$ symbols/s, then the signal part in Eq. (19.15) can be expressed as

$$s(t; d, \phi) = A \sum_{k=0}^{N-1} d_k \cos(2\pi f_c t + \phi) p(t - kT), \quad (19.16)$$

where $p(t)$ is a baseband pulse which determines to a large extent the spectral content of the transmitted signal, and we are assuming a data window of length N . For simplicity, we will assume a unit height rectangular pulse next, but the results can be generalized to any arbitrary pulse shape. Assuming for the moment that the modulation sequence d is known, we have the following conditional likelihood function:

$$L(\phi) = \exp\left[\frac{2}{N_0} \int_0^{NT} r(t) s(t; d, \phi) dt\right] = \exp\left[\frac{2A}{N_0} \sum_{k=0}^{N-1} d_k \int_{kT}^{(k+1)T} r(t) \cos(2\pi f_c t + \phi) dt\right]. \quad (19.17)$$

All we need to do now is take the expectation of the conditional likelihood function in Eq. (19.17) with respect to the random modulation sequence. Assuming that each binary symbol occurs with probability $1/2$ and that symbols are independent, we obtain the following log-likelihood function after dropping terms that are not functions of ϕ and taking the logarithm of the resulting expression:

$$\Lambda(\phi) = \sum_{k=0}^{N-1} \ln \cosh\left[\frac{2A}{N_0} \int_{kT}^{(k+1)T} r(t) \cos(2\pi f_c t + \phi) dt\right]. \quad (19.18)$$

A maximum likelihood estimator maximizes the above expression with respect to the phase ϕ . In practice, to reduce complexity we use the following substitutions, $\ln \cosh(x) \approx x^2$ and $\ln \cosh(x) \approx |x|$, valid for small and large signal-to-noise ratios, respectively. In the case of small SNRs, the log-likelihood simplifies to

$$\ell(\phi) = \sum_{k=0}^{N-1} \left[\int_{kT}^{(k+1)T} r(t) \cos(2\pi f_c t + \phi) dt \right]^2. \quad (19.19)$$

Taking the derivative of Eq. (19.19) with respect to ϕ , we obtain the following necessary condition for the ML estimate $\hat{\phi}$ of ϕ

$$\sum_{k=0}^{N-1} \int_{kT}^{(k+1)T} r(t) \cos(2\pi f_c t + \hat{\phi}) dt \times \int_{kT}^{(k+1)T} r(t) \sin(2\pi f_c t + \hat{\phi}) dt = 0. \quad (19.20)$$

A tracking loop that dynamically forces the condition in Eq. (19.20) is shown in Fig. 19.5. Note that the product of the two integrals effectively removes the modulation. In practice, the summation operator may be replaced by a digital filter that applies different weights to the past and present data in order to improve response.

To Explore Further: Carrier Acquisition for QAM Constellations

The need for high throughputs required by several high-speed applications (such as digital TV) has pushed system designers towards more throughput-efficient modulation schemes. Because of their relatively good performance, large QAM constellations are being used in many of these applications. One of the problems associated with their use is that of carrier acquisition, which, for efficiency reasons, must

FIGURE 19.5 Carrier synchronization from modulated data.

often be done without the use of a preamble. The problem is further complicated for cross QAM constellations, for which the high SNR corner points used by some simple carrier phase estimators are not available. Clearly, due to the phase symmetry of QAM constellations, only phase offsets modulo $\pi/2$ are detectable, and differential encoding is used to resolve the ambiguity.

The phase synchronization problem is invariably divided into an acquisition and a tracking part. In many practical systems, tracking is done simply and efficiently in a decision-directed (DD) mode after acquisition has been established, and it is the acquisition problem that is the most troublesome, especially in applications where no preamble is allowed. For square QAM constellations, a simple technique for phase acquisition is based on detecting the signals at the four corners and using them to produce an estimate of the phase-offset which can be averaged in time to converge to a reliable estimate. The problem is more complicated for cross constellations which do not have the corner points.

We first look at the ML carrier phase estimator. Let

$$r_k = d_k e^{j\theta} + n_k$$

be the baud-rate samples of the output of a matched filter, where d_k is a complex number denoting the transmitted QAM symbol at time kT ($1/T$ is the signaling rate), and θ denotes the unknown phase-offset to be estimated; the n_k are complex, independent identically distributed (i.i.d.), zero-mean, Gaussian random variables with independent real and imaginary parts of variance σ^2 , modeling the effects of noise. Without loss of generality, we assume that $E[d_k^2] = 1$ (i.e., a unit average energy constellation), in which case the signal-to-noise ratio per symbol is $\text{SNR} = 1/2\sigma^2$. Then the ML phase estimate of θ from data over a window of length N is easily obtained as the value of ϕ that maximizes the log-likelihood function

$$L(\phi) = \sum_{k=0}^N \ln \left[\sum_d \exp \left(-\frac{1}{2\sigma^2} |r_k - d \cdot e^{j\theta}|^2 \right) \right],$$

where the inner summation is performed with respect to the data d present in the constellation. The complexity of the ML algorithm is due in part to this inner summation, which, even for small constellations, will require more computations than possible, especially for high-speed systems. Another complication in implementing the ML estimator is the need to solve a nonlinear maximization problem in order to find the ML estimate of ϕ . Some simplifications of the ML estimator can be obtained for square constellations, but they are not sufficient to bring the ML estimator into a practical form.

For square constellations, a simple algorithm can be used to extract the carrier phase by detecting the presence of one of the four corner points in the constellation. These points can be detected by setting an amplitude threshold between the peak amplitude of the corner points and the second largest amplitude. The angles of these four points can be expressed as

$$\phi^i = \frac{\pi}{4} + i \cdot \frac{\pi}{2}, \quad i = 0, 1, 2, 3.$$

Thus,

$$\phi^i = \frac{\pi}{4} \bmod \left(\frac{\pi}{2} \right).$$

Since only phase rotations modulo $\pi/2$ are required, a simple estimator looks at the angle of the received sample r_k modulo $\pi/2$ and subtracts it from $\pi/4$. The result is the required estimate, which can be refined in time as more data are observed.

Another often used algorithm, which has been shown in [6] to be asymptotically the ML estimator in the limit of small SNRs, is the M th power-law estimator, where $M = 4$ for QAM constellations, and it equals the size of the constellation for PSK signaling. For QAM signaling, the 4th power estimator extracts a phase estimate according to

$$\hat{\phi} = \frac{1}{4} \arg \left[E[d^{*4}] \cdot \sum_{k=1}^N r_k^4 \right].$$

The approximate mean-square error performance of the above estimator was also obtained in [6]. More recently, another algorithm that seems to work well for both square and cross constellations has been reported in [7]. The algorithm referred to as the histogram algorithm (HA) does the following: (1) For each received sample r_k it finds the set of signals whose magnitude is closest to $|r_k|$. (2) Compute the angle of the subset of signals from step 1 belonging to the first quadrant. (3) Subtract each of the angles computed at step 2 from the angle of r_k . (4) Uniformly quantize the angle interval from 0 to 90 degrees into L bins, and associate a counter with each; increment the counters corresponding to the quantization intervals where the angles computed at step 3 fall in. (5) Repeat this process for new data r_k as they arrive. (6) When enough data is received, find the bin that has the largest counter value. The angle corresponding to this bin is produced as the phase estimate.

Figure 19.6 compares the performance of the ML and HA algorithms obtained through simulation to the Cramer–Rao bound for the 128-QAM (cross) constellation. Results for the 4th power estimator are shown separately in Fig. 19.7 since the performance of this estimator is about two orders of magnitude worse than the ML and HA algorithms. The reason behind the bad performance of the 4th power estimator is the existence of large self-noise, partly due to the absence of the corner points. These results indicate that the 4th power estimator is not an option for cross constellations, at least not for sizes greater than or equal to 128.

FIGURE 19.6 Mean square error for the various algorithms and 128-QAM.

FIGURE 19.7 The performance of the 4th power estimator for 128-QAM.

FIGURE 19.8 The HA vs. the 4th power algorithms for 256-QAM.

Figure 19.8 compares the HA and the 4th power estimators for the 256-QAM (square) constellation. As can be seen, the 4th power estimator performs much better with square constellations, and, in fact, it outperforms the HA for a range of data sequence lengths at 25dB SNR. As the SNR increases, however, the self-noise dominates and the performance of the 4th power estimator degrades.

In closing this section, we mention that an algorithm for joint estimation of carrier phase and frequency for 16-QAM input constellations has been proposed in [18] and shown to achieve the Cramer–Rao bound for SNRs greater than 15 dB.

19.3 Symbol Synchronization

We first investigate symbol synchronizers that are optimal in a maximum-likelihood sense. The ML symbol synchronizer can be used to suggest suboptimal but more easily implementable algorithms and provides a benchmark against which the performance of other synchronizers can be compared. Let T be the symbol duration and $r(t)$ be the received data. We assume an additive white Gaussian noise channel,

so $r(t)$ is modeled by

$$r(t) = s(t; d, \tau) + n(t), \quad (19.21)$$

where $n(t)$ is zero-mean white Gaussian noise having spectral density $N_0/2$, d is a sequence of modulation symbols d_k , $k = \dots, -1, 0, 1, \dots$, and τ is the timing-error. Assuming pulse-amplitude modulation (PAM), the signal can be described explicitly by

$$s(t; d, \tau) = \sum_k d_k p(t - kT - \tau), \quad (19.22)$$

where $p(t)$ is a baseband pulse. Our problem is to process the received signal $r(t)$ in order to obtain an estimate of the timing-error τ . To avoid loss in communication efficiency, we will do this in the presence of modulation symbols. For simplicity, we will assume a binary system with antipodal signals (one signal is just the negative of the other), in which case $d_k \in \{1, -1\}$.

As previously for carrier phase estimation, ML synchronization requires the probability density function of the data given the timing-error τ . Conditioned on knowing the data sequence d , the likelihood-function is given by Eq. (19.2) (with the signal part now given by Eq. (19.22)). Since the quadratic term does not depend on τ , the ML function can be reduced to

$$L(\tau, d) = \exp \left[\frac{2}{N_0} \sum_k d_k \int_{-\infty}^{\infty} r(t) p(t - kT - \tau) dt \right]. \quad (19.23)$$

All we need to do now is take the expectation of the above conditional likelihood function with respect to the data sequence to obtain the likelihood function. Performing the expectation and assuming independent and equiprobable data, we obtain (after taking the logarithm of the resulting expression) the required log-likelihood function

$$\ell(\tau) = \sum_k \ln \cosh \left[\frac{2q_k(\tau)}{N_0} \right], \quad (19.24)$$

where

$$q_k(\tau) = \int_{-\infty}^{\infty} r(t) p(t - kT - \tau) dt. \quad (19.25)$$

A maximum-likelihood synchronizer finds the estimate $\hat{\tau}$, which maximizes the log-likelihood function in Eq. (19.24) based on the received data. Several problems arise as we try to implement this optimal synchronizer: (1) obtaining an ML estimate requires maximizing in real-time Eq. (19.24), an impossible task in most practical cases; (2) implementation of Eq. (19.24) requires knowledge of the signal-to-noise ratio, which is not readily available and must be estimated; and (3) there is no simple way to exploit Eq. (19.24) to extract timing estimates in real-time. The problem associated with (1) above can be partly alleviated by approximating the $\ln \cosh(\cdot)$ function for large and small SNRs, as was done before, which results in

$$\begin{aligned} \ell(\tau) &\cong \sum_k q_k^2(\tau), & \text{low SNR,} \\ \ell(\tau) &\cong \sum_k |q_k(\tau)|, & \text{high SNR.} \end{aligned} \quad (19.26)$$

FIGURE 19.9 Closed-loop timing synchronizer.

In addition to simplifying the log-likelihood function, the approximations above also obviate the need for knowing the SNR. The need, however, to maximize a nonlinear function in real-time still exists.

As for the carrier synchronization problem, a number of open-loop realizations of the ML timing estimator exist. Perhaps the more interesting algorithms from a practical viewpoint are the closed-loop algorithms, two of which we motivate next. Taking the derivative of Eq. (19.24) with respect to τ and equating to zero results in an equation whose solution is the ML timing estimate:

$$\frac{\partial \ell(\tau)}{\partial \tau} \Big|_{\tau=\hat{\tau}} = \sum_k \left[\frac{2}{N_0} \int_{-\infty}^{\infty} r(t) \frac{\partial p(t - kT - \tau)}{\partial \tau} dt \right] \times \tanh \left[\frac{2}{N_0} \int_{-\infty}^{\infty} r(t) p(t - kT - \tau) dt \right] = 0, \quad (19.27)$$

where we have assumed that $p(-\infty) = p(\infty) = 0$. Note that if the timing τ is other than the ML estimate τ that makes the left-hand side of Eq. (19.27) equal to zero, the above derivative will be either positive or negative depending on the sign of the error $(\tau - \tau)$. Thus, the derivative can be used in a tracking loop to provide a correcting signal in a system that dynamically produces the ML timing estimate. Such a system is shown in Fig. 19.9, where the timing pulse generator adjusts the phase of the timing depending on the output of the accumulator once every T seconds. In practice, the accumulator may be replaced by a digital filter whose response is such that it puts more emphasis on recent data and less on past data. Clearly, when the timing-jitter is fast changing, better results may be obtained by having a short memory filter. On the other hand, if the timing-jitter is slowly varying, a filter with a long memory (low bandwidth) will yield better results.

Further simplifications to the above tracking synchronizer can be made under the assumptions of low or high signal-to-noise ratios, in which case Eq. (19.26) instead of Eq. (19.24) may be used. If the derivative of the likelihood function with respect to τ is approximated by the difference

$$\frac{\partial \ell(\tau)}{\partial \tau} \cong \frac{\ell(\tau + \delta/2) - \ell(\tau - \delta/2)}{\delta} \quad (19.28)$$

then, under the high SNR approximation (for example), Eq. (19.27) can be replaced by

$$\frac{\partial \ell(\tau)}{\partial \tau} \cong \sum_k \left[\left| \int_{-\infty}^{\infty} r(t) p(t - kT - \tau - \delta/2) dt \right| - \left| \int_{-\infty}^{\infty} r(t) p(t - kT - \tau + \delta/2) dt \right| \right] \quad (19.29)$$

A tracking-loop synchronizer, known as an *early-late gate symbol synchronizer*, implements Eq. (19.29) and is shown in Fig. 19.10. A similar synchronizer for a low SNR approximation can be implemented. The intuitive explanation of how early-late gate symbol synchronizers work is simple and can be easily illustrated for the case of non-return to zero (NRZ) pulses whose pulse shape $p(t)$ and autocorrelation function $a(t)$ are shown in Fig. 19.11.

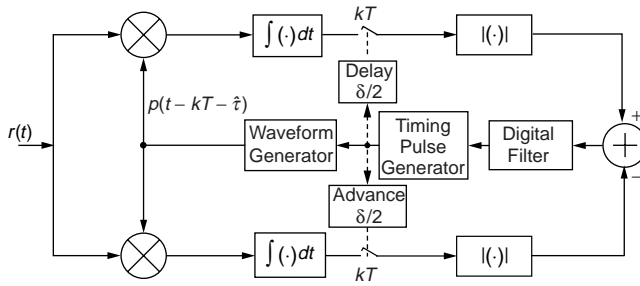

FIGURE 19.10 The early-late gate synchronizer.

FIGURE 19.11 Example for NRZ pulses.

In the absence of timing-error, the receiver samples the output of the matched filter at the times corresponding to the peak of the autocorrelation function of the NRZ pulse (which results in the largest SNR). When a timing error exists, the samples occur at either side of the peak depending on whether the error is positive or negative. In either case, because of the symmetry of the autocorrelation function, the samples are of the same value (on the average). In an early-late gate synchronizer, two samples are taken, separated by δ seconds and centered around the current timing estimate. Depending on whether the error is positive or negative, the difference between the absolute values of these samples will be positive or negative, thus providing a control signal to increase or decrease τ in the desired direction to reduce the error. Notice that on the average, due to the even symmetry of the autocorrelation function, the difference between the absolute values of the two samples is zero at the actual symbol timing phase, i.e., when the timing error is zero. Thus, at least intuitively, the system in Fig. 19.10 is a stable loop for tracking the symbol timing phase. We end this section by noting that a number of practical implementations based on some further simplification of the synchronizers discussed above are used in practice.

To Browse Further

In modern receivers, more and more of the processing is done in the discrete domain, which allows for more complicated algorithms to be accurately implemented compared to analog implementations. For timing recovery, the preferred technique is to process samples taken at the output of a matched (or other suitable) filter at rates as low as the baud rate to a few samples per baud. The advantage of baud-rate sampling is that it uses the same samples that the detector uses to make symbol decisions, and it is the lowest rate possible, making the sampler less costly and the processing of samples faster. The disadvantage is that baud-rate sampling is below the Nyquist rate and, thus, acquisition performance tends to suffer somewhat. For bandlimited signaling, two or more samples per baud are at or above the Nyquist rate and, thus, all information contained in the original analog signal is preserved by the sampling process. This means that the sampler can be free-running without the need to adjust its sampling phase since that can be done in the discrete domain through interpolation.

Perhaps the most well known paper on timing-recovery from baud-rate samples is that by Mueller and Muller [8]. The timing algorithms studied therein are decision-directed (make use of tentative symbol decisions) and use the baud-rate samples in order to estimate the timing error. The timing error information is then used to adjust the phase of the sampler towards reducing the timing error. Other works that consider two or more samples per baud have been reported in [9–11].

19.4 Frame Synchronization

As noted in the introduction, frame synchronization is obtained in practice by locating at the receiver the position of a frame synchronization pattern (referred to also as a *marker*), periodically inserted in the data stream by the transmitter. In most systems, partly for simplicity and partly because the periodicity of the marker insertion makes it easily identifiable when enough frames are processed, the marker is not prevented from appearing in the random data stream. This means that it should be long enough compared to the frame length to make the probability of it appearing in the data small. If we let the synchronization pattern be of length L and the frame size (including the marker) be of length N , then the efficiency of such a system, measured by the number of data symbols per channel symbol, is

$$e = 1 - \frac{L}{N}. \tag{19.30}$$

The efficiency can be made arbitrarily close to one by increasing N for a fixed L or by decreasing L for a fixed N . In both cases, however, the probability of correctly detecting the position of the marker is reduced. In practice, good first pass acquisition probabilities can be achieved with efficiencies of about 97%. Figure 19.12 shows the contents of a frame.

As for the symbol synchronization case, we will first introduce the optimum (ML) frame synchronizer and then investigate some suboptimum synchronizers. For simplicity, we will only look at binary antipodal baseband signaling, although, in qualitative terms, similar results hold for non-binary systems. In the following, we assume that perfect symbol synchronization is present. As usual, we assume an additive white Gaussian noise channel, in which case the sufficient statistic (loosely, the simplest function of the data required by the optimum synchronizer) is the baud-rate samples of the output of a matched filter. Let $r = (r_1, r_2, \dots, r_N)$ be the vector of the observed data obtained by sampling the output of a matched filter (matched to the baseband pulse) at the correct symbol rate and phase (no symbol timing-error), but not necessarily at the correct frame phase. Under a Gaussian noise assumption, the discrete matched filter samples can be modeled by

$$r_k = \sqrt{E}d_k + n_k, \tag{19.31}$$

where E is the signal energy, $d_k \in \{1, -1\}$ is the k th modulation symbol, and the n_k s constitute a sequence of independent and identically distributed (i.i.d.) Gaussian random variables with zero mean and variance σ^2 .

It is clear that since the frame length is N , there is exactly one frame marker within the observation window. Our problem is to locate the position $m \in (0, 1, 2, \dots, N - 1)$ of the marker from the observed data r . If m is the actual position of the marker, then the data vector corresponding to the observed vector r is

$$d = (d_1, d_2, \dots, d_{m-1}, d_m, \dots, d_{m+L-1}, \dots, d_N),$$

where the L -symbol sequence starting at position m is the marker. If we denote the marker by S , this means

$$S = (s_1, s_2, \dots, s_L) = (d_m, d_{m+1}, \dots, d_{m+L-1}).$$

FIGURE 19.12 The composition of a frame.

For maximum-likelihood estimation of m , we need to maximize the following conditional density:

$$p(r|m) = \sum_{d'} p[r|m, d'] \Pr(d') \quad (19.32)$$

where d' is the $(N - L)$ -symbol data sequence that surrounds the marker. Assuming equiprobable symbols, Massey [12] derived the following log-likelihood function:

$$L(m) = \sum_{k=1}^L s_k r_{k+m} - \frac{\sigma^2}{\sqrt{E}} \sum \ln \cosh\left(\frac{\sqrt{E}}{\sigma^2} r_{k+m}\right). \quad (19.33)$$

To account for the periodicity of the marker, indices in Eq. (19.33) are interpreted modulo N . An optimal frame synchronizer computes the above expression for all values of m and chooses as its best estimate of the marker position the value that maximizes $L(m)$.

A few observations are now in order regarding the above likelihood function. First, we note that $L(m)$ is the sum of two terms: a linear term and a nonlinear term. The first term can be recognized as the correlation between the received data r and the known marker; the second term can be interpreted as an energy correction term that accounts for the random data surrounding the marker.

For practical implementation, some approximations of the optimal rule can be obtained easily by approximating $\ln \cosh(\cdot)$. For high SNRs, by replacing $\ln \cosh(x)$ by $|x|$, we obtain

$$L(m) \cong \sum_{k=1}^L s_k r_{k+m} - \sum_{k=1}^L |r_{k+m}|. \quad (19.34)$$

For low SNRs, replacing $\ln \cosh(x)$ by $x^2/2$, the optimal rule becomes

$$L(m) \cong \sum_{k=1}^L s_k r_{k+m} - \frac{\sqrt{E}}{2\sigma^2} \sum_{k=1}^L r_{k+m}^2. \quad (19.35)$$

A further approximation that is quite often used is to drop the second nonlinear term altogether. The resulting rule then becomes

$$L(m) \cong \sum_{k=1}^L s_k r_{k+m}, \quad (19.36)$$

and is known as the *simple correlation rule* for obvious reasons. The high SNR approximation and the simple correlation rule have the added advantage that no knowledge of the SNR is needed for implementation, compared to the optimum and the low SNR approximation rules.

Practical frame synchronizers use the periodicity of the marker in order to improve performance in time and usually include algorithms for detecting loss of synchronization in which re-acquisition is initiated. The above algorithms can be used as the basis for these practical synchronizers in estimating the marker position from a frame's-worth of data. Their performance in correctly identifying the marker position significantly affects the overall performance of the frame synchronizer as measured not only by the probability of correct acquisition, but also by the time it takes for the algorithm to acquire.

Other techniques for marker acquisition (besides those based on the maximum-likelihood principle) can be used as well. For example, in some practical implementations of the simple correlation rule, sequential detection of the marker is often implemented: the correlation of the marker with the data is

computed sequentially for each frame position and the result is compared to some threshold. When for some value of m the computed correlation exceeds the threshold, the frame synchronizer declares a marker presence. Otherwise the search continues. The value of the threshold is critical for performance and it is usually chosen to minimize the time to marker acquisition.

Another important aspect of frame synchronization design is the design of good marker sequences. Although the above algorithms work with any chosen sequence, the resulting performance of the synchronizer depends critically on the sequence used. In general, sequences that have good autocorrelation properties perform well as frame markers. These sequences have the property that their autocorrelation function is uniformly small for all shifts other than the zero shift. Examples of such sequences include the *Barker sequences* [13] and the *Neuman–Hofman sequences* [14]. Barker sequences are binary sequences whose largest side-lobe (nonzero shift correlation) is at most 1. Unfortunately, the largest known Barker sequence is of length 13, and there is proof that no Barker sequences of length between 14 and 6084 exist. In many cases, however, there is a need for larger sequences to improve performance. Neuman–Hofman sequences were specifically designed to maximize performance when a simple correlation rule is used. Thus, these sequences perform somewhat better than Barker sequences when a correlation rule is used. What is more important, though, is that Neuman–Hofman sequences of large length exist. Examples of Barker and Neuman–Hofman sequences of length seven and thirteen are

$$(1, -1, 1, 1, -1, -1, -1), \quad \text{Barker, } L = 7,$$

$$(1, 1, 1, 1, 1, -1, -1, 1, 1, -1, 1, -1, 1), \quad \text{Barker, } L = 13,$$

$$(-1, -1, -1, -1, -1, -1, 1, 1, -1, -1, 1, -1, 1), \quad \text{Neuman–Hofman, } L = 13.$$

Performance

We address briefly the performance of the ML and two suboptimal synchronizers given above, as measured by the probability of erroneous synchronization. First, we look at the question of how well *any* frame synchronizer can perform, as a function of the frame length N , marker length L , and SNR. Clearly, in the limit of infinite SNR we obtain the best performance (smallest probability of erroneous marker detection). In this case, an error can be made when the marker appears randomly in one or more positions in the random data part. For *bifix-free* sequences (i.e., sequences for which no prefix is also a suffix), Nielsen [15] has obtained the following expression for probability of erroneous synchronization in this case:

$$P_{LB} = \sum_{k=1}^R \frac{(-1)^{k+1}}{k+1} \cdot \binom{N-L-k(L-1)}{k} \cdot M^{-kL}, \quad (19.37)$$

where

$$R = \left\lfloor \frac{N-L}{L} \right\rfloor, \quad (19.38)$$

and M is the size of the modulation ($M = 2$ for binary signaling). The bifix-free condition guarantees that no partial overlap of the marker with itself results in a perfect match for the overlapped parts. [Figure 19.13](#) shows simulation results for the performance of the ML, high SNR approximation, and simple-correlation rules of Eqs. (19.33), (19.34) and (19.36), respectively. Also shown is the lower-bound in Eq. (19.37), which is achieved by the ML rule and its high SNR approximation. On the other hand, the simple-correlation rule performs significantly worse.

20.1 Introduction

The goal of a digital communication system is to deliver information represented by a sequence of binary symbols, through a physical channel, to a user. The mapping of these symbols into signals, selected to match the features of the physical channel, is called **digital modulation**.

The digital modulator is the device used to achieve this mapping. The simplest type of modulator has no memory, that is, the mapping of blocks of binary digits into signals is performed independently of the blocks transmitted before or after. If the modulator maps the binary digits 0 and 1 into a set of two different waveforms, then the modulation is called *binary*. Alternatively, the modulator may map symbols formed by h binary digits at a time onto $M = 2^h$ different waveforms. This modulation is called *multilevel*.

The general expression of a signal modulated by a modulator with memory is

$$v(t) = \sum_{n=-\infty}^{\infty} s(t - nT; \xi_n, \sigma_n)$$

where $\{s(t; i, j)\}$ is a set of waveforms, x_n is the symbol emitted by the source at time nT , and \mathfrak{s}_n is the state of the modulator at time n . If the modulator has no memory, then there is no dependence on \mathfrak{s}_n . A *linear* memoryless modulation scheme is one such that $s(t - nT; \mathfrak{x}_n; \mathfrak{s}_n) = x_n s(t - nT)$.

Given a signal set $\{s_i(t)\}_{i=1}^M$ used for modulation, its compact characterization may be given in terms of a **geometric representation**. From the set of M waveforms we first construct a set of $N \leq M$ orthonormal

waveforms $\{\psi_i(t)\}_{i=1}^N$ (the Gram–Schmidt procedure is the appropriate algorithm to do this). Next we express each signal $s_k(t)$ as a linear combination of these waveforms,

$$s_k(t) = \sum_{i=1}^N s_{ki} \psi_i(t)$$

The coefficients of this expansion may be interpreted as the components of M vectors that geometrically represent the original signal set or, equivalently, as the coordinates in a Euclidean N -dimensional space of a set of points called the **signal constellation**.

20.2 The Challenge of Digital Modulation

The selection of a digital modulation scheme should be done by making the best possible use of the resources available for transmission, namely, bandwidth, power, and complexity, in order to achieve the reliability required.

Bandwidth

There is no unique definition of signal bandwidth. Actually, any signal $s(t)$ strictly limited to a time interval T would have an infinite bandwidth if the latter were defined as the support of the Fourier transform of $s(t)$. For example, consider the bandpass linearly modulated signal

$$v(t) = \Re \left[\sum_{n=-\infty}^{\infty} \xi_k s(t - nT) e^{j2\pi f_0 t} \right]$$

where \Re denotes real part, f_0 is the carrier frequency, $s(t)$ is a rectangular pulse with duration T and amplitude 1, and (ξ_k) is a stationary sequence of complex uncorrelated random variables with $E(\xi_n) = 0$ and $E(|\xi_n|^2) = 1$. Then the power density spectrum of $v(t)$ is given by

$$\mathcal{G}(f) = \frac{1}{4} [G(-f - f_0) + G(f - f_0)]$$

where

$$G(f) = T \left[\frac{\sin \pi f T}{\pi f T} \right]^2 \quad (20.1)$$

The function $G(f)$ is shown in [Fig. 20.1](#).

The following are possible definitions of the bandwidth:

- *Half-power bandwidth*. This is the interval between the two frequencies at which the power spectrum is 3 dB below its peak value.
- *Equivalent noise bandwidth*. This is given by

$$B_{\text{eq}} = \frac{1}{2} \frac{\int_{-\infty}^{\infty} \mathcal{G}(f) df}{\max_f \mathcal{G}(f)}$$

This measures the basis of a rectangle whose height is $\max_f \mathcal{G}(f)$ and whose area is one-half of the power of the modulated signal.

- *Null-to-null bandwidth*. This represents the width of the main spectral lobe.

FIGURE 20.1 Power density spectrum of a linearly modulated signal with rectangular waveforms.

- *Fractional power containment bandwidth.* This bandwidth definition states that the occupied bandwidth is the band that contains $(1 - \epsilon)$ of the total signal power.
- *Bounded-power spectral density bandwidth.* This states that everywhere outside this bandwidth the power spectral density must fall at least a certain level (e.g., 35 or 50 dB) below its maximum value.

Although the actual value of the signal bandwidth depends on the definition that has been accepted for the specific application, in general, we can say that

$$B = \frac{\alpha}{T}$$

where T is the duration of one of the waveforms used by the modulator, and α reflects the definition of bandwidth and the selection of waveforms. For example, for Eq. (20.1) the null-to-null bandwidth provides $B = 2/T$, that is, $\alpha = 2$. For 3-dB bandwidth, $\alpha = 0.88$. For equivalent-noise bandwidth, we have $\alpha = 1$.

Shannon Bandwidth

To make it possible to compare different modulation schemes in terms of their bandwidth efficiency, it is useful to consider the following definition of bandwidth. Consider a signal set and its geometric representation based on the orthonormal set of signals $\{\psi_i(t)\}_{i=1}^N$ defined over a time interval with duration T . The value of N is called the *dimensionality* of the signal set. We say that a real signal $x(t)$ with Fourier transform $X(f)$ is time limited to the interval $-T/2 < t < T/2$ at level ϵ if

$$\int_{|t|>T/2} x^2(t) dt < \epsilon$$

and is bandlimited with bandwidth B at level ϵ if

$$\int_{|f|>B} |X(f)|^2 df < \epsilon$$

Then for large BT the space of signals that are time limited and bandlimited at level ϵ has dimensionality $N = 2BT$ [Slepian, 1976]. Consequently, the Shannon bandwidth [Massey, 1995] of the signal set is defined as

$$B = \frac{N}{2T}$$

and is measured in dimensions per second.

Signal-to-Noise Ratio

Assume from now on that the information source emits independent, identically distributed binary digits with rate R_s digits per second, and that the transmission channel adds to the signal a realization of a white Gaussian noise process with power spectral density $N_0/2$.

The rate, in bits per second, that can be accepted by the modulator is

$$R_s = \frac{\log_2 M}{T}$$

where M is the number of signals of duration T available at the modulator, and $1/T$ is the signaling rate. The average signal power is

$$\mathcal{P} = \frac{\mathcal{E}}{T} = \mathcal{E}_b R_s$$

where \mathcal{E} is the average signal energy and $\mathcal{E}_b = \mathcal{E}/\log_2 M$ is the energy required to transmit one binary digit. As a consequence, if B denotes the bandwidth of the modulated signal, the ratio between signal power and noise power is

$$\frac{\mathcal{P}}{N_0 B} = \frac{\mathcal{E}_b R_s}{N_0 B}$$

This shows that the **signal-to-noise ratio** is the product of two quantities, namely, the ratio \mathcal{E}_b/N_0 , the energy per transmitted bit divided by twice the noise spectral density, and the ratio R_s/B , representing the *bandwidth efficiency* of the modulation scheme.

In some instances the *peak energy* \mathcal{E}_p is of importance. This is the energy of the signal with the maximum amplitude level.

Error Probability

The performance of a modulation scheme is measured by its **symbol error probability** $P(e)$, which is the probability that a waveform is detected incorrectly, and by its *bit error probability*, or *bit error rate* (BER) $P_b(e)$, the probability that a bit sent is received incorrectly. A simple relationship between the two quantities can be obtained by observing that, since each symbol carries $\log_2 M$ bits, one symbol error causes at least one and at most $\log_2 M$ bits to be in error,

$$\frac{P(e)}{\log_2 M} \leq P_b(e) \leq P(e)$$

When the transmission takes place over a channel affected by additive white Gaussian noise, and the modulation scheme is memoryless, the symbol error probability is upper bounded as follows:

$$P(e) \leq \frac{1}{2M} \sum_{i=1}^M \sum_{\substack{j=1 \\ j \neq i}}^M \operatorname{erfc}\left(\frac{d_{ij}}{2\sqrt{N_0}}\right)$$

where d_{ij} is the *Euclidean distance* between signals $s_i(t)$ and $s_j(t)$,

$$d_{ij}^2 = \int_0^T [s_i(t) - s_j(t)]^2 dt$$

and $\text{erfc}(\cdot)$ denotes the Gaussian integral function

$$\text{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-z^2} dz.$$

Another function, denoted $Q(x)$, is often used in lieu of $\text{erfc}(\cdot)$. This is defined as

$$Q(x) = \frac{1}{2} \text{erfc}\left(\frac{x}{\sqrt{2}}\right)$$

A simpler upper bound on error probability is given by

$$P(e) \leq \frac{M-1}{2} \text{erfc}\left(\frac{d_{\min}}{2\sqrt{N_0}}\right)$$

where $d_{\min} = \min_{i \neq j} d_{ij}$.

A simple lower bound on symbol error probability is given by

$$P(e) \geq \frac{1}{M} \text{erfc}\left(\frac{d_{\min}}{2\sqrt{N_0}}\right)$$

By comparing the upper and the lower bound we can see that the symbol error probability depends exponentially on the term d_{\min} , the minimum Euclidean distance among signals of the constellation. In fact, upper and lower bounds coalesce asymptotically as the signal-to-noise ratio increases. For intermediate signal-to-noise ratios, a fair comparison among constellations should take into account the *error coefficient* as well as the minimum distance. This is the average number ν of nearest neighbors [i.e., the average number of signals at distance d_{\min} from a signal in the constellation; for example, this is equal to 2 for M -ary **phase-shift keying (PSK)**, $M > 2$]. A good approximation to $P(e)$ is given by

$$P(e) \approx \frac{\nu}{2} \text{erfc}\left(\frac{d_{\min}}{2\sqrt{N_0}}\right)$$

Roughly, at $P(e) = 10^{-6}$, doubling ν accounts for a loss of 0.2 dB in the signal-to-noise ratio.

20.3 One-Dimensional Modulation: Pulse-Amplitude Modulation (PAM)

Pulse-amplitude modulation (PAM) is a linear modulation scheme in which a signal $s(t)$ is modulated by random variables ξ_n taking on values in the set of amplitudes $\{a_i\}_{i=1}^M$, where

$$a_i = (2i - 1 - M) \frac{d_{\min}}{2}, \quad i = 1, 2, \dots, M$$

The transmitter uses the set of waveforms $\{a_i s(t)\}_{i=1}^M$, where $s(t)$ is a unit-energy pulse. The geometric representation of this signal set is shown in [Fig. 20.2](#) for $M = 4$.

FIGURE 20.2 Quaternary PAM constellation.

FIGURE 20.3 Symbol error probability of coherently demodulated PAM.

The symbol-error probability is given by

$$P(e) = \left(1 - \frac{1}{M}\right) \operatorname{erfc} \left(\sqrt{\frac{3 \log_2 M \mathcal{E}_b}{M^2 - 1} \frac{\mathcal{E}_b}{N_0}} \right)$$

The ratio between peak energy and average energy is

$$\frac{\mathcal{E}_p}{\mathcal{E}} = 3 \frac{M-1}{M+1}$$

The bandwidth efficiency of this modulation is

$$\frac{R_s}{B} = \frac{\log_2 M}{T} \cdot 2T = 2 \log_2 M$$

20.4 Two-Dimensional Modulations

Phase-Shift Keying (PSK)

This is a linear modulation scheme generating the signal

$$v(t) = \mathcal{R} \left\{ \sum_{n=-\infty}^{\infty} \xi_n s(t-nT) e^{j2\pi f_0 t} \right\}$$

FIGURE 20.4 An 8-PSK constellation.

FIGURE 20.5 Symbol error probability of coherently demodulated PSK.

where $\xi_n = e^{j\phi_n}$ takes values in the set

$$\left\{ \frac{2\pi}{M}(i-1) + \Phi \right\}_{i=1}^M$$

where Φ is an arbitrary phase. The signal constellation is shown, for $M = 8$, in Fig. 20.4.

The symbol-error probability of M -ary PSK is closely approximated by

$$P(e) \approx \text{erfc} \left(\sqrt{\frac{\mathcal{E}_b}{N_0} \log_2 M \sin \frac{\pi}{M}} \right)$$

for high signal-to-noise ratios (see Fig. 20.5). The bandwidth efficiency of PSK is

$$\frac{R_s}{B} = \frac{\log_2 M}{T} \cdot T = \log_2 M$$

FIGURE 20.6 A 16-QAM constellation.

Quadrature Amplitude Modulation (QAM)

Quadrature amplitude modulation (QAM) is a linear modulation scheme for which the modulated signal takes the form

$$v(t) = \Re \left\{ \sum_{n=-\infty}^{\infty} \xi_n s(t - nT) e^{j2\pi f_0 t} \right\}$$

where

$$\xi_n = \alpha_n + j\beta_n$$

and α_n, β_n take on equally spaced values. Figure 20.6 shows a QAM constellation with 16 points.

When $\log_2 M$ is an even integer, we have

$$P(e) = 1 - (1 - p)^2$$

with

$$p = \left(1 - \frac{1}{\sqrt{M}} \right) \operatorname{erfc} \left(\sqrt{\frac{3 \log_2 M}{2(M-1)}} \frac{\mathcal{E}_b}{N_0} \right)$$

When $\log_2 M$ is odd, the following upper bound holds:

$$P(e) < 2 \operatorname{erfc} \left(\sqrt{\frac{3 \log_2 M}{2(M-1)}} \frac{\mathcal{E}_b}{N_0} \right)$$

(See Fig. 20.7.)

20.5 Multidimensional Modulations: Frequency-Shift Keying (FSK)

In the modulation technique called **frequency-shift keying (FSK)** the transmitter uses the waveforms

$$s_i(t) = A \cos 2\pi f_i t, \quad 0 \leq t < T$$

where $f_i = f_0 + (2i - 1 - M) f_{\Delta}$, for $i = 1, \dots, M$, and f_0 denotes the carrier frequency. The waveforms have

FIGURE 20.7 Symbol error probability of coherently demodulated QAM.

constant energy $\mathcal{E} = A^2 T/2$, and the modulated signal has constant envelope A . The distance properties of these waveforms for a given energy depend on the value of their normalized frequency separation $2f_d T$.

Generation of these waveforms may be accomplished with a set of M separate oscillators, each tuned to the frequency f_i . In this case, the phase discontinuities at frequency-transition times cause large sidelobes in the power density spectrum of the modulated signal. A narrower spectrum can be obtained by using a single oscillator whose frequency is modulated by the source bits. This results in a modulation scheme with memory called continuous-phase FSK (discussed in Section 20.7).

The signals $s_i(t)$ are orthogonal, that is,

$$\int_0^T \cos(2\pi f_i t) \cos(2\pi f_j t) dt = 0 \quad i \neq j$$

if the frequency separation between adjacent signals is such that $2f_d T = m/2$, where m is any nonzero integer. Thus, the minimum frequency separation for orthogonality is $2f_d = 1/2T$.

The symbol error probability for M orthogonal signals with energy \mathcal{E} is upper and lower bounded by

$$\frac{1}{2} \operatorname{erfc} \left(\sqrt{\frac{\mathcal{E}_b \log_2 M}{2N_0}} \right) \leq P(e) \leq \frac{M-1}{2} \operatorname{erfc} \left(\sqrt{\frac{\mathcal{E}_b \log_2 M}{2N_0}} \right).$$

For $M = 2$ the bounds merge into the exact value. The upper bound to $P(e)$ is plotted in Fig. 20.8.

It can be observed from Fig. 20.8 that the error probability for a given value of signal-to-noise ratio decreases as M increases, contrary to what is observed for PAM, PSK, and QAM. On the other hand, the bandwidth efficiency *decreases* as M increases, its value being given by

$$\frac{R_s}{B} = \frac{2 \log_2 M}{M}$$

FIGURE 20.8 Symbol error probability of coherently demodulated orthogonal FSK.

FIGURE 20.9 The lattice Z^2 .

20.6 Multidimensional Modulations: Lattices

The QAM constellations may be considered as carved from an infinite constellation of regularly spaced points in the plane, called the **lattice** Z^2 . This is represented in Fig. 20.9. This concept can be generalized to other lattices, both two-dimensional and multidimensional. In this framework, the design of a signal constellation consists of choosing a lattice, then carving a finite constellation of signal points from the lattice.

In general, a lattice Λ is defined as a set closed under ordinary addition and multiplication by integers. As such, it forms an additive group as well as a vector space. Specifically, an N -dimensional lattice Λ is an infinite set of N vectors.

If d_{\min} is the minimum distance between any two points in the lattice, the number ν of adjacent lattice points located at distance d_{\min} , that is, the number of nearest neighbors of any lattice point, is called its *kissing number*.

Examples of Lattices

The Lattice Z^N

The set Z^N of all N -tuples with integer coordinates is called the *cubic lattice*, or *integer lattice*. The minimum distance is $d_{\min} = 1$, and the kissing number is $\nu = 2N$.

The N -Dimensional Lattices A_N and A_N^*

A_N is the set of all vectors with $(N + 1)$ integer coordinates whose sum is zero. This lattice may be viewed as the intersection of Z^{N+1} and a hyperplane cutting the origin. The minimum distance is $d_{\min} = \sqrt{2}$, and the kissing number is $\nu = N(N + 1)$.

The N -Dimensional Lattice D_N

D_N is the set of all N -dimensional points whose integer coordinates have an even sum. It may be viewed as a punctured version of Z^N , in which the points are colored alternately black and white with a checkerboard coloring, and the white points (those with odd sums) are removed. We have $d_{\min} = \sqrt{2}$, and $\nu = 2N(N - 1)$. D_4 represents the densest lattice packing in R^4 . This means that if unit-radius, four-dimensional spheres with centers in the lattice points are used to pack R^4 , then D_4 is the lattice with the largest number of spheres per unit volume.

The Gosset Lattice E_8

In the *even coordinate system*, E_8 consists of the points

$$\left\{ (x_1, \dots, x_8): \forall x_i \in Z \quad \text{or} \quad \forall x_i \in Z + \frac{1}{2}, \quad \sum_{i=1}^8 x_i \equiv 0 \pmod{2} \right\}$$

In words, E_8 consists of the eight-vectors whose components are all integers, or all halves of odd integers, and whose sum is even.

The *odd coordinate system* is obtained by changing the sign of any coordinate: the points are

$$\left\{ (x_1, \dots, x_8): \forall x_i \in Z \quad \text{or} \quad \forall x_i \in Z + \frac{1}{2}, \quad \sum_{i=1}^8 x_i \equiv 2x_8 \pmod{2} \right\}$$

This lattice has $d_{\min} = \sqrt{2}$ and $\nu = 240$.

Other Lattices

The description and the properties of other important lattices, such as the 16-dimensional Barnes–Wall lattice Λ_{16} and the 24-dimensional Leech lattice Λ_{24} , can be found in [Chapter 4](#) of Conway and Sloane [1988].

The Coding Gain of a Lattice

The *coding gain* $\gamma_c(\Lambda)$ of the lattice Λ is defined as

$$\gamma_c(\Lambda) = \frac{d_{\min}^2(\Lambda)}{V(\Lambda)^{2/N}} \quad (20.2)$$

where $V(\Lambda)$ is the *fundamental lattice volume*, that is, the reciprocal of the number of lattice points per unit volume [for example, $V(Z^N) = 1$]. [Table 20.1](#) lists the coding gains of some of the most popular lattices.

TABLE 20.1 Coding Gains of Lattices

Name	Λ	N	$\gamma_c(\Lambda)$, (dB)
Integer lattice	Z	1	0.00
Hexagonal lattice	A_2	2	0.62
Schläfli	D_4	4	1.51
Gosset	E_8	8	3.01
Barnes-Wall	Λ_{16}	16	4.52
Leech	Λ_{24}	24	6.02

Carving a Signal Constellation out of a Lattice

We denote with $C(\Lambda, \mathcal{R})$ a constellation obtained from Λ (or from its translate $\Lambda + a$) by retaining only the points that fall in the region \mathcal{R} . The resulting constellation has a number of signals approximately equal to the ratio between the volume of \mathcal{R} and the volume of Λ ,

$$M \approx \frac{V(\mathcal{R})}{V(\Lambda)}$$

provided that $V(\mathcal{R}) \gg V(\Lambda)$, that is, that M is large enough.

The *figure of merit* (CFM) of $C = C(\Lambda, \mathcal{R})$ is the ratio between d_{\min}^2 and the average energy of the constellation *per dimension pair*,

$$\text{CFM}(C) = \frac{d_{\min}^2}{\mathcal{E}/(N/2)}$$

To express the figure of merit of the constellation $C(\Lambda, \mathcal{R})$ in terms of parameters related to the lattice Λ and to the region \mathcal{R} , we introduce the definition of the *shape gain* $\gamma_s(\mathcal{R})$ of the region \mathcal{R} [Forney and Wei, 1990]. This is the reduction in average energy (per dimension pair) required by a constellation bounded by \mathcal{R} compared to that which would be required by a constellation bounded by an N -dimensional cube of the same volume $V(\mathcal{R})$. In formulas, the shape gain is the ratio between the *normalized second moment* of any N -dimensional cube (which is equal to $1/12$) and the normalized second moment of \mathcal{R} ,

$$\gamma_s(\mathcal{R}) = \frac{1/12}{G(\mathcal{R})} \quad (20.3)$$

where

$$G(\mathcal{R}) = \frac{\int_{\mathcal{R}} \|\mathbf{r}\|^2 d\mathbf{r}}{NV(\mathcal{R})^{1+2/N}} \quad (20.4)$$

The following result holds [Forney and Wei, 1990]: The figure of merit of the constellation $C(\Lambda, \mathcal{R})$ is given by

$$\text{CFM}(C) \approx \gamma_0 \cdot \gamma_c(\Lambda) \cdot \gamma_s(\mathcal{R}) \quad (20.5)$$

where γ_0 is the figure of merit of the one-dimensional PAM constellation with the same bit rate (chosen as the baseline), $\gamma_c(\Lambda)$ is the coding gain of the lattice Λ [see Eq. (20.2)], and $\gamma_s(\mathcal{R})$ is the shaping gain of the region \mathcal{R} . The approximation holds for large constellations.

This result shows that, at least for large constellations, the gain from shaping by the region \mathcal{R} is almost completely decoupled from the coding gain due to Λ . Thus, for a good design it makes sense to optimize separately $\gamma_c(\Lambda)$ (i.e., the choice of the lattice) and $\gamma_s(\mathcal{R})$ (i.e., the choice of the region).

Spherical Constellations

The maximum shape gain achieved by an N -dimensional region \mathcal{R} is that of a sphere, for which

$$\gamma_s = \frac{\pi(n+1)}{6(n!)^{1/n}}$$

where $n = N/2$ and N is even. As $N \rightarrow \infty$, the γ_s approaches $\pi e/6$, or 1.53 dB. The last figure is the maximum achievable shaping gain. A problem with spherical constellations is that the complexity of the encoding procedure (mapping input symbols to signals) may be too high. The main goal of N -dimensional lattice-constellation design is to obtain a shape gain as close to that of the N sphere as possible, while maintaining a reasonable implementation complexity and other desirable constellation characteristics.

20.7 Modulations with Memory

The modulation schemes considered so far are *memoryless* in the sense that the waveform transmitted in one symbol interval depends only on the symbol emitted by the source in that interval. In contrast, there are modulation schemes with memory.

One example of a modulation scheme with memory is given by *continuous-phase frequency-shift keying* (CPFSK), which in turn is a special case of **continuous-phase modulation (CPM)**. To describe CPFSK, consider standard FSK modulation, whose signals are generated by separate oscillators. As a consequence of this generation technique, at the end of each symbol interval the phase of the carrier changes abruptly whenever the frequency changes, because the oscillators are not phase synchronized. Since spectral occupancy increases by decreasing the smoothness of a signal, these sudden phase changes cause spectrum broadening. To reduce the spectral occupancy of a frequency-modulated signal, one option is CPFSK, in which the frequency is changed continuously.

To describe CPFSK, consider the PAM signal

$$v(t) = \sum_{n=-\infty}^{\infty} \xi_n q(t - nT)$$

where (ξ_n) is the sequence of source symbols, taking on values $\pm 1, \pm 3, \dots, \pm(M-1)$, and $q(t)$ is a rectangular pulse of duration T and area $1/2$. If the signal $v(t)$ is used to modulate the frequency of a sinusoidal carrier, we obtain the signal

$$u(t) = A \cos \left[2\pi f_0 t + 2\pi h \int_{-\infty}^t v(\tau) d\tau + \varphi_0 \right]$$

here f_0 is the unmodulated-carrier frequency, φ_0 is the initial phase, and h is a constant called the *modulation index*. The phase shift induced on the carrier, that is,

$$\theta(t) = 2\pi h \int_{-\infty}^t v(\tau) d\tau$$

turns out to be a continuous function of time t , so that a continuous-phase signal is generated. The trajectories followed by the phase, as reduced mod 2π , form the *phase trellis* of the modulated signal. [Figure 20.10](#) shows a segment (for 7 symbol intervals) of the phase trellis of binary CPFSK with $h = 1/2$ [this is called *minimum-shift keying* or (MSK)].

With MSK, the carrier-phase shift induced by the modulation in the time interval $nT \leq t \leq (n+1)T$ is given by

$$\theta(t) = \theta_n + \frac{\pi}{2} \left(\frac{t - nT}{T} \right) \xi_n \quad nT \leq t \leq (n+1)T$$

FIGURE 20.10 Phase trellis of binary CPFSK with $h = 1/2$ (MSK).

FIGURE 20.11 Power density spectrum of MSK and of quaternary PSK.

where

$$\theta_n = \frac{\pi}{2} \sum_{k=-\infty}^{n-1} \xi_k$$

The corresponding transmitted signal is

$$u(t) = A \cos \left[2\pi \left(f_0 + \frac{1}{4T} a_n \right) t - \frac{n\pi}{2} a_n + \theta_n \right]$$

which shows that MSK is an FSK using the two frequencies

$$f_1 = f_0 - \frac{1}{4T} \quad f_2 = f_0 + \frac{1}{4T}$$

The frequency separation $f_2 - f_1 = 1/2T$ is the minimum separation for orthogonality of two sinusoids, which explains the name given to this modulation scheme.

The spectrum of CPFSK depends of the value of h . For $h < 1$, as the modulation index decreases, so does the spectral occupancy of the modulated signal. For MSK the power density spectrum is shown in [Fig. 20.11](#).

CPM is a generalization of CPFSK. Here the carrier-phase shift in the interval $nT \leq t \leq (n + 1)T$ is given by

$$\theta(t) = 2\pi \sum_{k=-\infty}^n a_k h_k q(t - nT)$$

where the waveform $q(t)$ is the integral of a frequency pulse $g(t)$ of arbitrary shape

$$q(t) = \int_{-\infty}^t g(\tau) d\tau$$

subject to the constraints $g(t) = 0$ for $t < 0$ and

$$\int_0^{\infty} g(\tau) d\tau = \frac{1}{2}$$

When the modulation index h_k varies (usually with a periodic law) from one symbol to another, the modulation is called *multi-h*. If $g(t) \neq 0$ for $t > T$, then the modulated signal is called *partial-response* CPM. Otherwise, it is called *full-response* CPM.

An example of partial-response CPM is given by Gaussian (GMSK), whose frequency pulse is obtained by passing a rectangular waveform into a low-pass filter whose impulse response $h(t)$ has a Gaussian shape,

$$h(t) = \sqrt{\frac{2\pi}{\ln 2}} B \exp\left\{-\frac{2\pi^2 B^2}{\ln 2} t^2\right\}$$

where B denotes the filter bandwidth. By decreasing B , the shape of the frequency pulse becomes smoother and the spectrum occupancy of the modulated signal is reduced. This modulation scheme is employed in the Global System for Mobile Communications (GSM) standard for cellular mobile radio with the choice $BT = 0.3$.

Defining Terms

Bandwidth: The frequency interval in which the density spectrum of a signal is significantly different from zero.

Continuous-phase modulation: A digital modulation scheme derived from phase-shift keying in which the carrier has no phase jumps, that is, the phase transitions occur continuously.

Digital modulation: The mapping of information-source symbols into signals, performed to carry information through the transmission channel.

Error probability: Probability that a symbol emitted by the information source will be received incorrectly by the end user.

Frequency-shift keying: A digital modulation scheme in which the source information is carried by the frequency of a sinusoidal waveform.

Geometric signal representation: Representation of a finite set of signals as a set of vector.

Lattice: An infinite signal constellation of points regularly located in space.

Phase-shift keying: A digital modulation scheme in which the source information is carried by the phase of a sinusoidal waveform, called the carrier.

Pulse-amplitude modulation: A digital modulation scheme in which the source information is carried by the amplitude of a waveform.

Quadrature amplitude modulation: A digital modulation scheme in which the source information is carried by the amplitude and by the phase of a sinusoidal waveform.

Signal constellation: A set of signals geometrically represented in the form of a set of vectors.

Signal-to-noise ratio: The ratio of the signal power and noise power. It is an index of channel quality.

University of Southern California

21.1 Introduction

The acronym POTS stands for plain old telephone service. Over the years, POTS acquired an undeserved reputation for connoting *old-fashioned* and even *obsolete*. The telephone and the switched public network enable us to reach anyone anywhere on this planet at anytime and to speak to them in our natural voices. The minutes of telephone usage, in the number of access lines, and in the revenue of telephone companies, attest to the central importance of telephone service in today's information-age, global economy.

The word *old* in the acronym implies familiarity and ease of use, a major reason for the continued popularity of telephone service. The word *telephone* and the nuances expressed by natural human speech is what it is all about. *Service* used to mean responsiveness to the public, and it is sad that this dimension of the acronym has become so threatened by emphasis on short-term profits, particularly in the new world of competition that characterizes telephone service on all levels. The term *plain* is indeed obsolete, and the provision of today's telephone service utilizes some of the most sophisticated and advanced transmission and switching technology. In fact, telephone service today with all its intelligent and functional new features, advanced technology, and improved quality is truly fantastic. Allowing for a little misspelling, the acronym POTS can still be used, but with the "P" standing for phantastic! So, POTS it was, and POTS is still where the real action is.

Part of the excitement about the telephone network is that it can be used with a wide variety of devices to create exciting and useful services, such as facsimile for graphical communication and modems for access to the Internet. Cellular wireless telephony, pagers, and phones in airplanes extend telephony wherever we travel. Increased functionality in the network brings us voice mail, call forwarding, call waiting, caller ID, and a host of such services. The future of an ever-evolving POTS, indeed, looks bright and exciting.

Bell's Vision

The telegraph is older than the telephone, but special knowledge of Morse code was necessary to use the telegraph, thereby relegating it to use by specialists. The telephone uses normal human speech and, therefore, can be used by anyone and can convey all the nuances of the inflections of human speech.

Dr. Alexander Graham Bell was very prophetic in his vision of a world wired for two-way telecommunication using natural human speech. Bell and his assistant Thomas A. Watson demonstrated the first working model of a telephone on March 10, 1876, but Bell had applied for a patent a month earlier on February 14, 1876. Elisha Grey had submitted a disclosure of invention for a telephone on that same day in February, but ultimately the U.S. Supreme Court upheld Bell’s invention, although in a split decision.

21.2 The Network

The telephone has come to signify a public switched network capable of reaching any other telephone on Earth. This switched network interconnects not only telephones but also facsimile machines, cellular telephones, and personal computers—anything that is connected to the network. As shown in Fig. 21.1, the telephones and other station apparatus in homes are all connected by pairs of copper wire to a single point, called the protector block, which offers simple protection to the network from overvoltages. A twisted pair of copper wires then connects the protector block all the way back to the central office. Many twisted pairs are all carried together in a cable that can be buried underground, placed in conduit, or strung between telephone poles. The twisted pair of copper wires connecting the station apparatus to the central office is called the local loop.

The very first stage of switching occurs at the central office. From there, telephone calls may be connected to other central offices over interoffice trunks. Calls may also be carried over much greater distances by connection to the long-distance networks operated by a number of **interexchange carriers (IXC)** such as AT&T, MCI, and Sprint. The point where the connection is made from the local service provider to the interexchange carrier is known as the **point of presence (POP)**.

The local portion of the telephone network is today known as a **local access and transport area (LATA)**. The local Bell telephone companies (commonly called the Baby Bells) were restricted by the Bell breakup of 1984 solely to the provision of intra-LATA service and were forbidden from providing inter-LATA service. Although the technology of telephony has progressed impressively over the last 100 years, policy and regulation have also had great impact on the telephone industry.

In the past, telephone service in the U.S. was mostly under the control of AT&T and its Bell system and a number of smaller independent telephone companies. Today, a number of competing companies

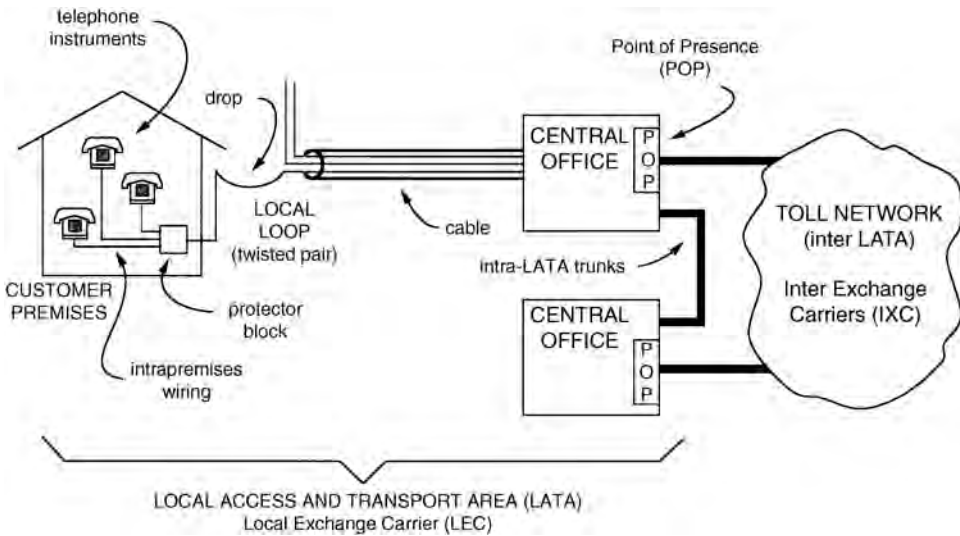

FIGURE 21.1 Network.

own and operate their own long-distance networks, and some futurists believe that local competition will occur soon.

The various long-distance and local networks all interconnect and offer what has been called a *network of networks*. Data communication for the Internet is carried over data networks. With voice being converted to digital bits, a technological convergence of voice and data (which is already encoded as bits) is occurring.

21.3 Station Apparatus

Telephones of the past were black with a rotary dial with limited functionality. Today's telephones come in many colors and sizes and offer push-button dialing along with a variety of intelligent features, such as repertory dialing and display of the dialed number. However, the basic functions of the telephone instrument have not changed and are shown in Fig. 21.2. The telephone needs to signal the central office when service is desired. This is accomplished by lifting the handset, which then closes contacts in the telephone—the switch hook—so that the telephone draws DC over the local loop from the central office. The switching machine at the central office senses this flow of DC and thus knows that the customer desires service. The common battery at the central office has an electromotive force (EMF) of 48 V, and the telephone draws at least about 20 mA of current over the loop. The maximum loop resistance can not exceed about 1300 Ω.

The user needs to specify the telephone number of the called party. This is accomplished by a process called dialing. Older telephones accomplished dialing with a rotary dial that interrupted the flow of DC with short pulses at a rate of about 10 dial pulses per second. Most telephones today use touch-tone dialing and push buttons, as shown in Fig. 21.3. When a specific digit is pushed, a unique combination of two sinusoidal tones is transmitted over the line to the central office. For example, an 8 is indicated by the combination of sine waves at 852 Hz and 1336 Hz. Filters are used at the switching machine at the central office to detect the frequencies of the tones and thus decode the dialed digits. Touch-tone dialing is also known as **dual-tone multifrequency (DTMF)** dialing.

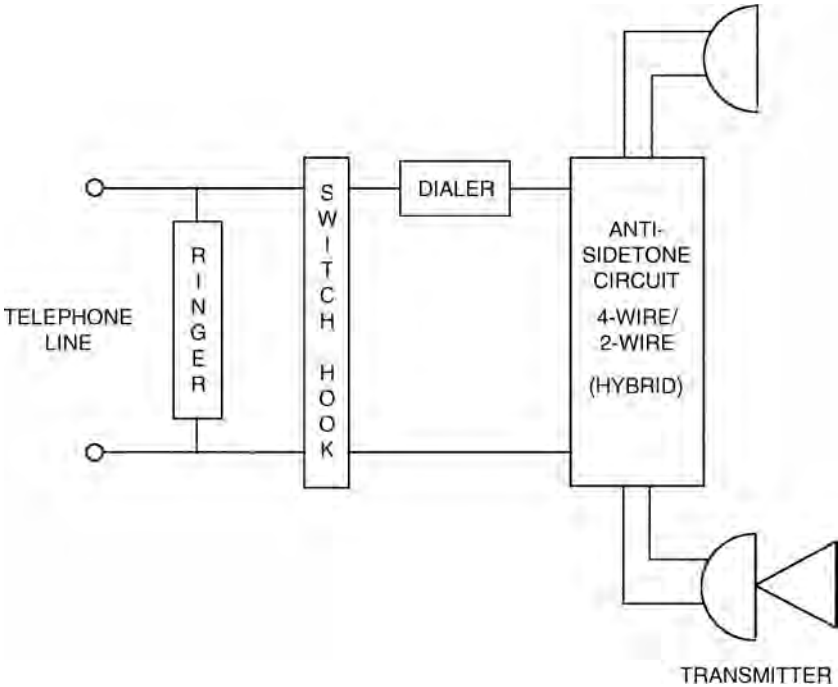

FIGURE 21.2 Telephone.

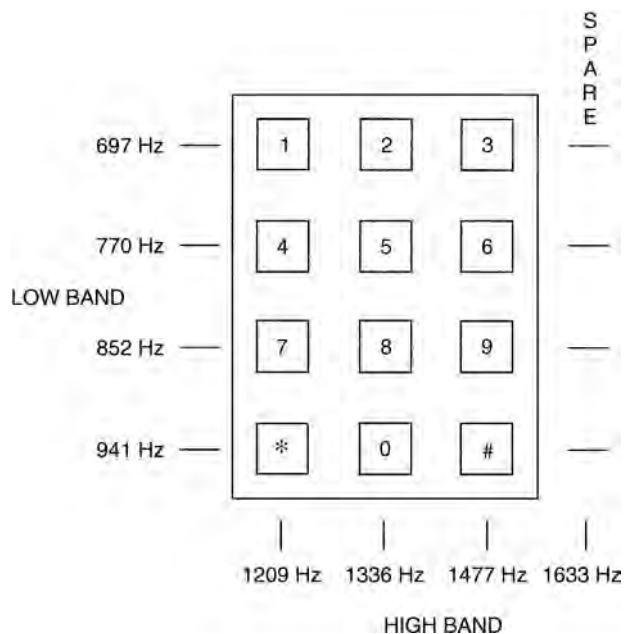

FIGURE 21.3 Touch-tone.

Bell's first telephone microphone, or transmitter, used the principle of variable resistance to create a large varying current. It consisted of a wire that moved in and out of a small cup of acid in response to the acoustic speech signal. Clearly, such a transmitter was not very practical, and it was soon replaced by the use of loosely packed carbon, invented in 1878 by Henry Hummings. In 1886, Thomas Alva Edison improved on the carbon transmitter by using roasted granules of anthracite coal. Today's telephone transmitters use high-quality, small, variable-capacitance, electret microphones. The telephone receiver is a small loudspeaker using a permanent magnet, coil of wire, and metal diaphragm. It was invented in 1876 by Thomas Watson, Bell's assistant, and the basic principles have changed little since then.

The pair of wires going to the telephone transmitter and receiver constitutes a four-wire circuit. The transmitter sends a speech signal down the telephone line, and the receiver receives the signal from the central office. However, a two-wire local loop connects the telephone instrument to the central office, and, hence, two-wire to four-wire conversion is needed within the telephone instrument. A center-tapped transformer, called a **hybrid**, accomplishes this conversion. The leakage current in the secondary receiver circuit depends on how well a balance network exactly matches the impedance of the telephone line. Since this balance network can never match the line perfectly, a small amount of the received transmitted signal leaks into the receiver circuit, and the user hears one's own speech, an effect known as sidetone. Actually, a small amount of sidetone is desirable because it makes the telephone seem live and natural, and, thus, the balance network is designed to allow an optimum amount of sidetone. Too much sidetone results in the user pulling the handset away from the head, which reduces the transmitted speech signal—an undesirable effect. The use of an induction coil to balance the electrical sidetone was patented in 1918 by G.A. Campbell, an AT&T research engineer. The induction coil has been replaced in modern telephones by a speech network that electronically cancels the sidetone leakage and performs the two-wire to four-wire conversion.

The telephone ringer is connected in parallel across the telephone line before the switch hook's contacts. Thomas Watson applied for the first ringer patent in 1878, and today's electromechanical ringers have changed little since then. A hammer attached to an armature with a magnetic field strengthened by a permanent magnet moves in response to the ringer current loudly striking two bells. The high-impedance ringer was invented in 1890 by John J. Carty, a Bell engineer who had invented the two-wire local loop

in 1881. A capacitor is placed in series with the ringer to prevent DC from flowing through it. The ringer signal consists of a short 2-s burst of a 75-V (rms), 20-Hz sine wave followed by 4 s of silence. Piezoelectric transducers and small loudspeakers have replaced electromechanical ringers in today's telephones.

Telephone instruments have progressed greatly in their functionality from the basic-black, rotary-dial phones of the past. Today's phones frequently include repertory dialers, speakerphones, and liquid crystal displays (LCDs). Tomorrow's phones will most likely build up this functionality and extend it to control central office features, to perform e-mail, and to integrate voice and data. Although some people still believe that the telephone of the future will also include a two-way video capability, the videophone, most consumers do not want to be seen while speaking on the phone, and, thus, the videophone will most probably remain an element of science fiction.

The public switched network can be used to transmit and switch any signal that remains within its baseband, namely, about 4 kHz. Thus, devices other than just a telephone can be used on the telephone network. The recent success of facsimile is one example; modems operating at speeds of 56 kb/s are another.

21.4 Transmission

A wide variety of transmission media have been and are used in providing telephone service. At the local level, twisted pairs of copper wire today connect most customers to the central office, although open copper wire was used in the distant past and in rural areas. Many pairs of wire are placed together in a cable, which is then either placed underground or strung between telephone poles. Coaxial cable carried telephone calls across the country. Microwave radio carried telephone calls terrestrially from microwave tower to tower across the country, with each tower located about 26 miles from the next. Microwave radio also carries telephone calls across oceans and continents by communication satellites located in geosynchronous orbits 22,300 miles above the surface of the earth. Today's transmission medium of choice for carrying telephone calls over long distances and between central offices is optical fiber.

Multiplexing is the means by which a number of communication signals are combined together to share a single communication medium. With analog multiplexing, signals are combined by frequency-division multiplexing; with digital multiplexing, signals are combined by time-division multiplexing.

Today analog multiplexing is obsolete in telephony. AT&T replaced all its analog multiplexing with digital multiplexing in the late 1980s; MCI followed suit in the early 1990s. Analog multiplexing was accomplished by A-type channel banks. Each baseband telephone channel was shifted in frequency to its own unique 4-kHz channel. The frequency-division multiplexing was accomplished in hierarchical stages. A hierarchy of multiplexing was created with 12 baseband channels forming a group, 5 groups forming a supergroup, 10 supergroups forming a mastergroup, and 6 mastergroups forming a jumbo group. A jumbo multiplex group contained 10,800 telephone channels and occupied a frequency range from 654 to 17,548 kHz.

With digital multiplexing, each baseband analog voice signal is converted to digital using a sampling rate of 8000 samples/s with 8-b nonlinear quantization for an overall bit rate of 64,000 b/s. A hierarchy of digital multiplexing has evolved with 24 digital telephone signals forming a DS1 signal requiring 1.544 Mb/s, 4 DS1 signals forming a DS2 signal, 7 DS2 signals forming a DS3 signal, 6 DS3 signals forming a DS4 signal. A single digital telephone signal at 64 kb/s is called a DS0 signal. A DS4 signal multiplexes 4032 DS0 signals and requires an overall bit rate of about 274 Mb/s.

The transmission media and systems used for long-distance telephone service have progressed over the decades. The LL-carrier system, first installed in 1946, utilized three working pairs of coax in a buried cable to carry 1800 telephone circuits across the country using analog, frequency-division multiplexing. The L5E-carrier system, installed in 1978, carried 132,000 telephone circuits in 10 coax pairs. Terrestrial microwave radio has been used to carry telephone signals from towers located about every 26 miles across the country. The first system, TD-2, became available in 1950 and carried 2400 voice circuits. The use of polarized radio waves to reduce channel interference, the horn antenna to allow simultaneous operation in both the 6-GHz and 4-GHz bands, solid-state technology, and single-sideband suppressed-carrier amplitude modulation resulted in a total system capacity in 1981 of 61,800 voice circuits.

Communication satellites located in a geosynchronous orbit 22,300 mi above the Earth's equator have been used to carry telephone signals. Here, too, the technology has progressed, offering ever increasing capacities. But geosynchronous communication satellites suffer a serious shortcoming. The time required for the radio signals to travel back and forth between satellite and Earth stations creates a round-trip delay of about 0.5 s, which is quite annoying to most people.

Today's transmission medium of choice is optical fiber utilizing digital, time-division multiplexing of the voice circuits. The basic idea of guiding light through thin glass fibers is quite old and was described by the British physicist Charles Vernon Boys in 1887. Today's optical fiber utilizes ultrapure silica. Optical fiber itself has progressed from multimode stepped index and graded index fibers to today's single-mode fiber. Solid-state lasers have also progressed in their use as light sources, and detector technology is also an area of much technological advancement. Today's fiber strands each carry a few gigabits per second. Technological advances include color multiplexing, in which a number of light signals at different frequencies are carried on the same fiber strand and erbium doped fiber amplifiers that increase the strength of the light signal without the need to convert signals back to an electrical form for regeneration. Usually, a number of fiber strands are placed together in a single cable, but the capacity of each fiber strand is so great that many of the strands are not used and are called *dark fiber*. The theoretical capacity of a single strand is as much as 100 terabits per second. The synchronous optical network (SONET) standard facilitates the interconnection of optical networks operating at rates measured in gigabits per second.

Long-distance transmission systems and local carrier systems all utilize separate paths for each direction of transmission, thereby creating four-wire circuits. These four-wire circuits need to be connected to the two-wire local loop. The hybrids that accomplish this connection and conversion can not perfectly match the transmission characteristics of each and every local loop. The result is that a small portion of the signal leaks through the hybrid and is heard by the speaking party as a very annoying echo. The echo suppressor senses which party is speaking and then introduces loss in the return path to prevent the echo, but this solution also prevents simultaneous talking. Today, echo elimination is accomplished by an **echo canceler**, which uses an adaptive filter to create a synthetic echo, which is then subtracted from the return signal, thereby eliminating the echo entirely but also allowing simultaneous double talking. An echo canceler is required at each end of the transmission circuit.

21.5 Switching

In the old days, one telephone was connected to another telephone at switchboards operated by humans. The human operators used cords with a plug at each end to make the connections. Each plug had a tip and a ring about the tip to create the electric circuit to carry the signals. A sleeve was used for signalling purposes to indicate whether a circuit was in use. Each human operator could reach as many as 10,000 jacks. The automation of the switchboard came early in the history of telephony with Almon B. Strowger's invention in 1892 of an electromechanical automatic switch and the creation of his Automatic Electric Company to manufacture and sell his switching systems, mostly to non-Bell telephone companies. The Strowger switching was ignored by the Bell System until 1919 when it was finally adopted. Now electromechanical switching is totally obsolete in the U.S., and today's telephone system utilizes electronic switching systems. However, the Strowger system, known as step-by-step in the Bell System, was a thing of great mechanical ingenuity that gave an intuitive grasp of switching with turning and stepping switch contacts that is not possible with today's computerized electronic systems. Electromechanical switching was subject to much wear and tear, however, and required considerable space and costly maintenance. Furthermore, electromechanical switching was inflexible and could not be reprogrammed.

In general, a switching system consists of two major functional parts, as shown in Fig. 21.4: (1) the switching network itself, where one telephone call is connected to another and (2) the means of control that determines the specific connections. Calls can be connected by physically connecting wires to create an electrical path, a technique called **space switching**. With space switching, individual telephone circuits

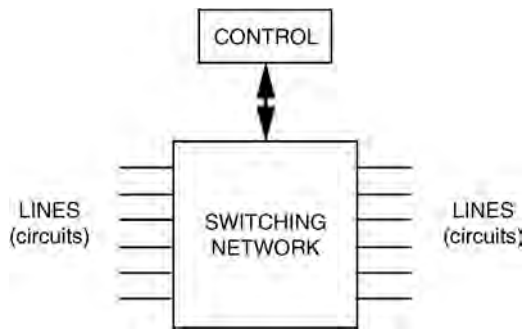

FIGURE 21.4 Switching system.

are connected physically to each other by some form of electromechanical or electronic switch. Calls can also be connected by reordering the time sequence of digitized samples, a technique called **time switching**. Modern digital switching systems frequently utilize both techniques in the switching network.

In the past, the switching network utilized electromechanical technology to accomplish space switching. This technology progressed over time from the automated Strowger switch to the Bell System's crossbar switch. The first crossbar switching system was installed in 1938, and crossbar switching systems were still in use in the U.S. in the early 1990s.

The switching network in today's switching systems is completely digital. Telephone signals either arrive in digital or are converted to digital. The digital signals are then switched, usually using a combination of electronic space switching along with time switching of the sequence of digitized samples. The space switches are shared by a number of digital calls connecting each of them for short durations while a small number of bits in each sample are transferred.

Yesterday's switching systems were controlled by hard-wired electromechanical relays. Today's switching systems are controlled by programmable digital computers, thereby offering great flexibility. The use of a digital computer to control the operation of a switching network is called electronic switching or stored-program control. The intelligence of stored-program control, coupled with the capabilities of modern signalling systems, enables a wide variety of functional services tailored to the needs of individual users.

21.6 Signalling

A variety of signals are sent over the telephone network to control its operation, an aspect of POTS known as signalling. The familiar dial tone, busy signal, and ring-back tone are signals presented to the calling party. Ringing is accomplished by a 20-Hz signal that is on for 2 s and off for 4 s. In addition to these more audible signals that tell us when to dial, whether lines are busy, and when to answer the telephone, other signals are sent over the telephone network itself to control its operation.

In the past, the telephone network needed to know whether a trunk is idle or not, and the presence or absence of DC indicated whether a local trunk was in use or idle. Long-distance trunks used in-band and out-of-band tones to indicate whether a circuit was idle or not. A single-frequency tone of 2600 Hz, which is within the voice band, was placed on an idle circuit to indicate its availability. The telephone number was sent as a sequence of two tones at a rate of 10 combinations per second, a technique known as multifrequency key pulsing (MFKP). Signalling today is accomplished by common channel interoffice signalling (CCIS).

With **common-channel signalling**, a separate dedicated data channel is used solely to carry signalling information in the form of short packets of data. Common-channel signalling is known as signalling system 7 (SS7) in the U.S. It offers advanced 800-service such as time of day routing, identification of the calling party, and various software defined network features. In addition to new features and services,

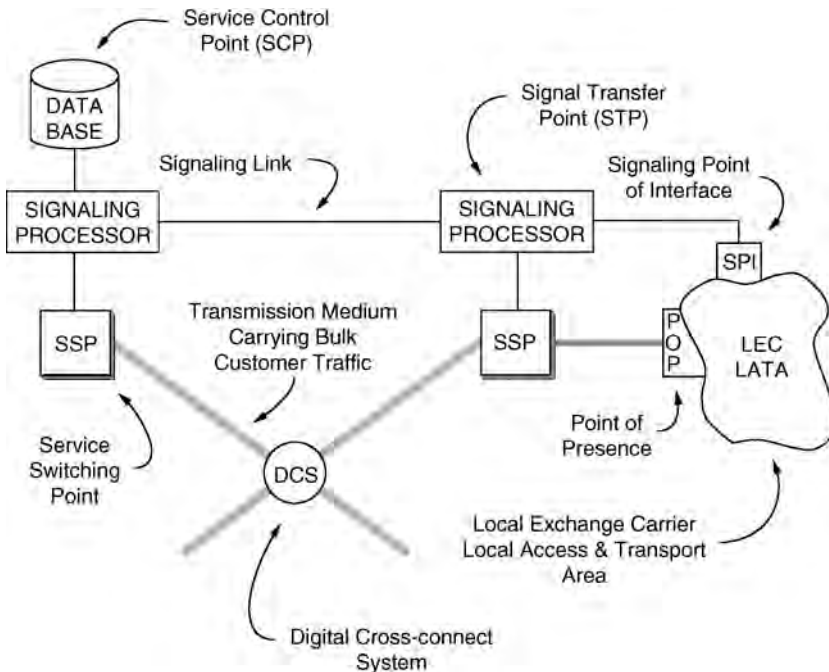

FIGURE 21.5 Intelligent network.

common-channel signalling offers more efficient assignment of telephone circuits and operation of the telephone network. Although first used for long-distance networks, common-channel signalling is also used at the local level.

Signalling has been integrated into a modern telecommunications network, depicted in Fig. 21.5, and when coupled with centralized data-bases, provides many of the features associated with today's intelligent network. The database, known as a service control point (SCP), contains the information needed to translate 800-numbers to the appropriate telephone location, among other items. The signalling information is sent over its own signalling links from one signalling processor to another, located at nodes called signal transfer points (STP). The signalling processors determine the actual switching of the customer circuits, performed by switching systems at service switching points. The bulk traffic carried over transmission media can be switched in times of service failures or to balance loads by digital cross-connect systems (DCS). The signalling links connect to the local network at a signalling point of interface (SPI), and the customer circuits connect at a point of presence. Today's signalling systems add much functionality to the network.

21.7 Functionality

A wide variety of intelligent features was easily available when humans operated the telephone network and its switchboards. The operator could announce the name of the calling party, hold calls if you were busy, transfer calls to other phones and locations, and interrupt a call if another more important one arrived. However, human operators were far too costly and were replaced by automated electromechanical switching systems. This made telephone service more affordable to more people, but lost the functionality of the human intelligence of the operators. Today's telephone switching systems are controlled by programmable computers, and, once again, intelligence has returned to the telephone network so that the functional services of the past can again be offered using today's computer-controlled technology.

Call waiting, call forwarding, and caller-ID are examples of some of these functional services. But not all of these services are wanted by all telephone users.

Caller-ID transmits the telephone number of the calling party over the local loop to the called party where the number is displayed on a small visual display. The number is encoded as digital data and is sent in a short burst, using phase shift keying, during the interval between the first and second ringing signal. Advanced caller-ID systems also transmit the name associated with the directory listing for the calling number. With caller-ID, it is possible to know who is calling before answering the telephone. However, some people consider their telephone number to be very private and personal and do not want it transmitted to others. This privacy issue delayed the availability of caller-ID in some states and is a good example of the importance of understanding the social impacts of the telephone.

21.8 The Future

Based on the false promises of new products and services such as picturephones, videotex, and high-definition television (HDTV), skepticism is warranted toward most new ideas, particularly when so many of them are really reincarnations of past failures. Accepting these words of warning, some last thoughts about the future of POTS will nevertheless be opined.

The telephone system invented by Alexander Graham Bell simply enabled people to convey their speech over distance. Bell's network has evolved to a system that enables people to stay in contact wherever they may be through the use of paging and radio-based cellular telephone services, and even telephones in commercial airplanes. The telephone network carries not only voice signals but also facsimile and data signals.

Bell's vision of a wired world communicating by human speech has been mostly achieved, although there are still many places on this planet for which a simple telephone call is a luxury. A global system of low earth orbit satellites could solve this problem, but it would be far too costly to offer telephone service to the poorer inhabitants of those places without conventional telephone service. Bell was very wise in emphasizing human speech over the Morse code of telegraphy. However, alphanumeric keyboards negate the need for knowledge of Morse code or American Standard Code for Information Interchange (ASCII) bits, and now everyone can communicate by text, or e-mail, as such communication is generally called.

Textual communication can have long-holding times but very low average data transmission. Today's packet-switched networks are most appropriate and efficient for this form of communication. Whether packet-switching will become dominant for voice telecommunication, evolving into a form of an integrated services digital network (ISDN), is promoted by many and yet unclear given today's bandwidth glut in backbone networks.

Much is said about the convergence of telephony and television, of telecommunication and entertainment, and of telephony and community antenna television (CATV). Yet the purpose of passive entertainment seems much different than the interactivity and two-way nature of telephony and most data telecommunication. The entertainment center is quite different than the communication centers in most homes. Yet the myth of convergence continues, although the past would tell us that convergence really is a blurring of boundaries between technologies and industry segments.

A trip to a central office will show that although much progress has been made in substituting electronic switching for electromechanical switching, there are still tens of thousands of physical wires for the provision of service over the local loops. The solution is the use of time-division multiplexing so that thousands of circuits are carried over a few physical optical fibers. However, there are still many engineering and cost challenges that must be solved before copper local loops are eliminated, but someday they clearly will be eliminated, resulting in lower costs and further increases in productivity.

Although the progress of the technology of telephony has been most impressive over the last century of the provision of POTS, many other factors are equally important in shaping the future of telecommunication. Policy, regulatory, and competitive factors caused the breakup of the Bell System in 1984, and this breakup has had tremendous impact on the provision of telecommunication in the U.S. The entry of long-distance companies into local service and the entry of local telephone companies into long

distance will likewise have considerable impact on the balance of power within the industry. Consumer reactions have halted videophones and delayed caller-ID. The financial risks of the provision of CATV and entertainment have had sobering impact on the plans of telephone companies to expand telephone service to these other businesses.

Defining Terms

Common channel signalling: Uses a separate dedicated path to carry signalling information in the form of short packets of data.

Dual tone multifrequency (DTMF) dialing: Touch-tone dialing where pairs of tones denote a dialed number.

Echo canceler: A device that uses an adaptive filter to create synthetic echo to subtract from the return signal to eliminate the echo.

Hybrid: A center tapped transformer that accomplishes two-wire to four-wire conversion.

Interexchange carriers (IXC): Companies that operate long-distance networks, such as AT&T, MCI, and Sprint.

Local access and transport area (LATA): The local portion of the telephone network.

Multiplexing: Method by which a number of communication channels are combined together to share a signal to eliminate the echo.

Point of presence (POP): The point where the connection is made from the local service provider to the interexchange carrier.

Space switching: Physically connecting wires to create an electrical path.

Time switching: Connecting calls by reordering the time sequence of digitized samples.

22.1 Introduction

Circuits linking telephone central offices nationwide carry from dozens to thousands of voice channels, all operating simultaneously. It would be very inefficient and prohibitively expensive to let each pair of copper wires carry a single voice communication. Therefore, very early in the history of the telephone network, telecommunications engineers searched for ways to combine telephone conversations so that several of them could be simultaneously transmitted over one circuit. At the receiver end, the combined channels would be separated back into individual channels.

Such a combining method is called *multiplexing*. There are two main methods of multiplexing:

- Time-division multiplexing (TDM), which can be used only with digital signals and is a more “recent” (1960s) technology.
- Frequency-division multiplexing (FDM), which was first implemented in 1918 by “Ma Bell” (AT&T) between Baltimore and Pittsburgh and could carry four simultaneous conversations per pair¹ of wires.

By the early 1970s, FDM microwave links commonly supported close to 2000 (and sometimes 2700) voice channels on a single radio carrier. In 1981, AT&T introduced its AR6A single sideband (SSB) microwave radio, which carried 6000 channels [Rey, 1987]. Coaxial cable carrier systems, such as the AT&T L5E, could carry in excess of 13,000 channels using frequency-division multiplexing.

This chapter reviews the principle of FDM then describes the details of how FDM channels are combined in a hierarchy sometimes referred to as the *analog hierarchy*.

¹In reality, you need one pair for each direction since, in telephony, it is necessary to have full-duplex communications, i.e., to be able to talk and listen at the same time. These two pairs are usually labelled “GO” and “RETURN” and they create what is called a four-wire (4W) circuit.

22.2 Background Information

Voice-Channel Bandwidth

The voice-spectrum bandwidth in telephone circuits is internationally limited to frequencies in the range from 0.3 to 3.4 kHz. Trunk signaling for that voice channel is generally done *out of band* at 3825 Hz. Furthermore, since bandpass filters are not perfect (the flanks of the filters are not perfectly vertical), it is necessary to provide a guard band between channels. To take all of these factors into account, the overall voice channel is standardized as a 4-kHz channel.

Although most of the time the voice channels will, indeed, be carrying analog voice signals, they can also be used to transmit *analog data signals*, that is, signals generated by data modems. This consideration is important in the calculation of the loading created by FDM **baseband signals**.

22.3 Frequency-Division Multiplexing (FDM)

Frequency-division multiplexing combines the different voice channels by stacking them one above the other in the frequency domain, as shown in Fig. 22.1, before transmitting them. Therefore, each 4-kHz voice channel is shifted up to a frequency 4 kHz above the previous channel.

The FDM concept is not specific to telephony transmission. The TV channels in cable TV (or on-the-air broadcasting for that matter) are also stacked in frequency (channels 1–90, etc.) and are, therefore, frequency-division multiplexed. The TV receiver is the demultiplexer in that case. The difference here is that the TV receiver only needs to receive one channel at a time, whereas the telephone FDM demultiplexer must receive all channels simultaneously.

Implementation Considerations

Practical reasons preclude the assembly (*stacking*) of the different channels, one above the other, continuously from DC on. Problems such as AC power supply hum make the use of low frequencies unwise,

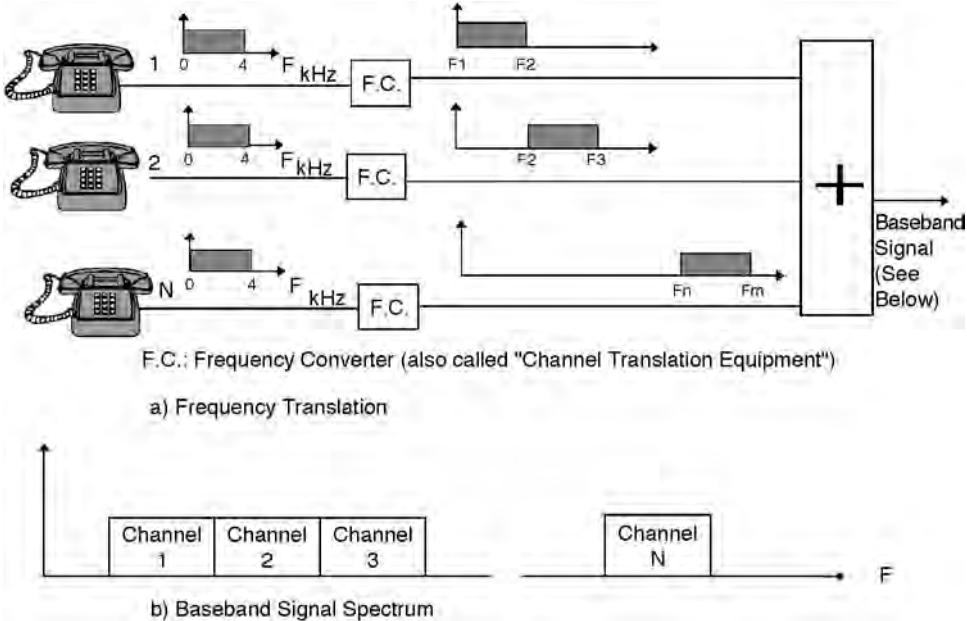

FIGURE 22.1 FDM principle.

thus the first voice channel is usually *transposed* to a frequency of 60 kHz (although for small capacity systems, the first channel can be as low as 12 kHz).

The necessity of having compatible equipment so that FDM links could be established between equipment of different vendors, and even between different countries, dictated the establishment of standards that specified how channels should be grouped for multiplexing. This also allowed the manufacturing of modular equipment, which can be combined to increase the capacity of the links.

All of these considerations led to the development of FDM baseband signals that follow a specific organization and occupy given sets of frequencies, as described in the following sections.

22.4 The Hierarchy

Group

The first step in FDM is to combine 12 voice channels together. This first level of the analog multiplexing hierarchy is called a *group* (also called *basic group* by the International Telecommunications Union and a *primary group* by several countries). The FDM group is, therefore, 48 kHz wide and composed of 12 voice channels stacked from 60 to 108 kHz, as shown in Fig. 22.2. For a *thin route*, that is, a small capacity system, the group can instead be translated to a range of 12–60 kHz so as to reduce the overall baseband bandwidth required.

The equipment performing the frequency translation of each channel uses a combination of mixers and single side band (SSB) modulation with appropriate bandpass filters to create this baseband group. That equipment is called *channel bank* in North America and *channel translation equipment* (CTE) in other English-speaking countries.

The group of 12 channels occupies a bandwidth of 48 kHz from 60 to 108 kHz.

FIGURE 22.2 Basic FDM group.

FIGURE 22.3 FDM supergroup.

Supergroup

If more than 12 channels are needed, the next level in the hierarchy is created by combining 5 groups together, thus providing a capacity of 60 voice channels. This second level is called a *basic supergroup*, usually abbreviated as supergroup, and has a bandwidth of 240 kHz going from 312 to 552 kHz, as shown in Fig. 22.3. Some countries call this 60-channel assembly a *secondary group*.

The related frequency translation equipment is called *group bank* in the U.S. and Canada but *group translation equipment* (GTE) in most other countries.

Mastergroup

The international agreements concerning FDM standards unfortunately stop at the supergroup level. Although both the ITU-T and the U.S./Canadian standards include a third level called *mastergroup*, the number of voice channels differ and the two are, therefore, not compatible! The most common mastergroup in North America was the old Western Electric U600 scheme, which combines 10 supergroups, thus creating a 600-channel system, as shown in Fig. 22.4.

There are several variations of the Western Electric U600 mastergroup such as the AT&T L1 coax-based carrier system, which also carries 600 channels but translated between 60–2788 kHz rather than 564–3084 kHz.

The frequency translation equipment creating mastergroups is called *supergroup bank* or *supergroup translation equipment* (STE). The ITU-T mastergroup on the other hand combines only five supergroups to create a 300-channel baseband, as shown in Fig. 22.5.

Higher Levels

There are many different multiplexing schemes for the higher density FDM systems. They become quite complex and will only be listed here. The reference section of this paper lists several sources where details of these higher level multiplexed signals can be found.

- *IYU-T supermastergroup*. This combines three CCITT mastergroups for a total of 900 channels occupying a 3.9 MHz baseband spectrum from 8.516 to 12.388 MHz.
- *ITU-T 15-Supergroup Assembly*. This also provides 900 channels but bypasses the mastergroup level by directly combining 15 supergroups ($15 \times 60 = 900$) occupying a 3.7-MHz spectrum from 312 to 4028 kHz. This assembly is sometimes called a *hypergroup*. There are variations of the 15-supergroup assembly such as a 16-supergroup assembly (960 channels).

FIGURE 22.4 U.S. (AT&T) basic mastergroup.

FIGURE 22.5 CCITT basic mastergroup.

For the very-high capacity FDM systems, grouping of supermastergroups or of 15-supergroup assemblies are used, with a preference for the latter method.

The AT&T high-level FDM hierarchy is, of course, based on the 600-channel mastergroup. The AT&T *mastergroup multiplex* (MMX) combines these mastergroups to a variety of levels, shown in Table 22.1, by multiplexing from two to eight mastergroups (except for the four-mastergroup level, which is not used).

Two of the 3000-channel intermediate levels are further combined to form the baseband signal for the 6000-channel AR6A microwave radio. At 6000 channels per radio, the AR6A radio system can transmit 42,000 voice channels on a single antenna using seven different RF carriers [Rey, 1987].

TABLE 22.1 AT&T Mastergroup Multiplex Hierarchy

No. of Multiplexed Mastergroups	Resulting No. of Channels	AT&T Application
2	1200	TD microwave radio
3	1800	TH microwave radio
5	3000	Intermediate level
6	3600	Jumbogroup
7	4200	Intermediate level
8	4800	Intermediate level

Two of the 4200-channel intermediate levels are combined with one 4800-channel intermediate level to form the line signal for the L5E, 13,200-channel, coaxial cable system, which occupies a frequency spectrum of 61.592 MHz starting at 3.252 MHz.

Jumbogroup

As was seen in Table 22.1, the basic jumbogroup is composed of six mastergroups (3600 channels). It was the basis for the L4 coaxial-cable system and has a spectrum ranging from 0.564 to 17.548 MHz.

When the L5 coaxial system was implemented in 1974, it used a line signal created by multiplexing three jumbogroups, thus providing a capacity of 10,800 channels occupying frequencies from 3.124 to 60.566 MHz.

22.5 Pilots

In addition to the voice channels (and related signalling tone), special tones called pilots are introduced to provide the receiver end (demultiplexer) with frequency and level references.

Each level of the FDM hierarchy (group, supergroup, mastergroup, etc.) will have its own *reference* pilot tone. Each of the respective demultiplexers monitors the appropriate tone to detect interruptions (faults) in which case it generates an alarm indicating which group, supergroup, etc., is defective. Alarms are also generated if the level of the tone is 4 dB below (or above) its normal value.

Other pilots, called *line regulating*, used to be found in gaps between the FDM building groups (e.g., supergroups). Their name came from the fact that they were used for automatic gain control (AGC) of the miscellaneous amplifiers/repeaters. As FDM equipment became better, the regulation function was transferred to the reference pilots just mentioned and line regulating pilots were no longer implemented. A regulation of 0.5 dB is a typical objective [Freeman, 1989].

Microwave radios use an additional type of pilot tone, the *continuity pilot*, which is generally inserted at the top of the baseband spectrum and controls the receiver AGC and also serves as an overall continuity pilot.

In older FDM equipment, there were also *frequency synchronization pilots* used to ensure that the demultiplexing carriers were within a few hertz of the multiplexing pilots. Otherwise, audio distortion would occur. Newer FDM equipment has sufficiently precise and stable oscillators so that synchronization pilots are no longer needed.

22.6 Direct to Line (DTL)

If interfacing with existing FDM equipment is not needed on a particular link, then a cheaper method of multiplexing can be done with special multiplexing equipment, at least for the low-capacity systems. The direct-to-line (DTL) method of forming the baseband signal moves the voice channels directly to their respective line frequencies, thus bypassing the group and supergroup building blocks. Such equipment is frequently used on thin-route microwave links carrying 60 channels or less but can also be found in multiplexers providing basebands of up to 600 channels.

The DTL method decreases the number of steps in the multiplexing process and, consequently, the number of circuit boards and filters. Therefore, it is cheaper, more reliable, and more flexible. DTL equipment, however, is not compatible with the standard FDM equipment.

22.7 Summary

Multiplexing in the frequency domain (FDM) was the mainstay of carrier systems, on twisted pairs, coaxial cable, and microwave links, until digital carrier systems became prevalent in the early 1980s. FDM is done by stacking voice channels, one above the other, in the frequency domain. In other words, each voice channel is translated from its original 0–4-kHz spectrum to a frequency above the previous channel. This is generally done in building blocks called groups (12 channels), supergroups (5 groups), master-groups (5 or 10 supergroups), etc., which follow international ITU-T standards or AT&T standards. FDM equipment with fewer than 600 channels can also be implemented using a simpler and cheaper technique called direct to line, where the building blocks are bypassed and the voice channels are transposed directly to the appropriate line (baseband) frequency. However, DTL is not a standard, and, therefore, direct interconnection with the public telephone network is not possible.

Defining Term

Baseband signal: Modulating signal at the transmitter (i.e., signal found before modulation of the transmitter). At the receiver, it would be the demodulated signal, that is, the signal found after the demodulator. In the case of FDM, the baseband signal (also called line frequency) is, therefore, the combined signal of all the voice channels being transmitted.

23.1 Telephone Band

A voice channel is considered to require a nominal bandwidth of 4000 Hz. For all practical purposes, however, the usable bandwidth of an end-to-end call in the **public switched telephone network (PSTN)**, including the loop, is considered to fall between approximately 300 and 3400 Hz (this is called the *voice band*), giving a bandwidth of 3100 Hz. This bandwidth is entirely acceptable from a voice transmission point of view, giving subscriber satisfaction levels above 90% [IEEE, 1984].

Although it is not unduly difficult to provide a 3100-Hz bandwidth in the subscriber loop, the loop and the associated terminal equipment have evolved in such a way that this bandwidth is essentially fixed at this value and will continue to be for analog voice and voiceband data transmission. The bandwidth is somewhat restrictive for data transmission when using voiceband modems, and the speeds attained are below approximately 64 kb/s. However, the problem of bandwidth restriction has encouraged a number of innovative solutions in modem design, particularly adaptive equalizers and modulation methods.

Obviously, on a loop derived entirely from copper cable, the frequency response of the loop itself would extend down to DC (zero frequency). The lower response is lost, however, once the loop is switched or connected to other transmission and signaling equipment, all of which are AC coupled. Where DC continuity is not available or not practical, special tone signaling equipment is used to replace the DC signals. When voice signals or other signals with frequency content approaching zero frequency are placed on the loop, the transmission is considered to be in the baseband.

Similarly, the upper voiceband frequency limit is not exactly 3400 Hz. Depending on how it is specified or the type of cable, the limit may be much higher. In practice, the loop does not generally set the upper limit of a voice channel; the upper limit is mostly due to the design of filters in the equipment that interfaces with the loop.

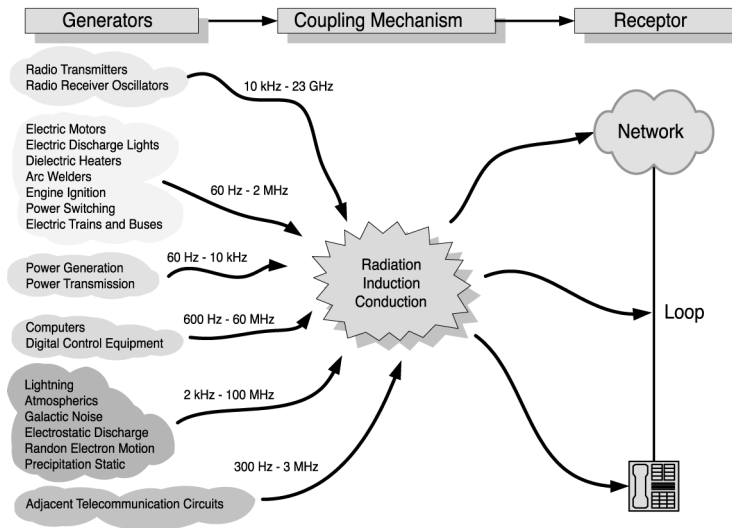

FIGURE 23.1 Noise diagram.

For voice-band transmission, the bandwidth (or frequency response) of a telecommunication channel is defined as the limiting frequencies where loop loss is down by 10 dB from its 1000 Hz value [IEEE, 1984]. The field measurement of bandwidth usually does not proceed with measurement of the 10-dB points. Instead, simple slope tests are made; these provide an indirect but reliable indicator of the transmission channel bandwidth. If the slope, as defined subsequently, is within predetermined limits, the bandwidth of the channel can be assumed to be acceptable.

Slope tests are loss measurements at 404, 1004, and 2804 Hz (this is also called the *three-tone slope*). The loss at the reference frequency of 1004 Hz is subtracted from the loss at 404 Hz to give the low-frequency slope, and from 2804 Hz to give the high-frequency slope.

23.2 Noise

Noise is any interfering signal on the telecommunication channel. There must be a noise source, a coupling mechanism, and a receptor. The relationship among the three is illustrated in Fig. 23.1. Noise sources are either manmade or natural. Practically any piece of electrical or electronic equipment can be a manmade noise source, and power lines are perhaps the most pervasive of all of these. Natural noise comes from lightning and other atmospherics and random thermal motion of electrons and galactic sources, as well as electrostatic discharges.

Noise is coupled by radiation, induction, and conduction. The predominant coupling mode in analog voiceband subscriber loops is by induction from nearby power lines. The other coupling modes exist to some extent, too, depending on the situation. For example, noise can be conducted into the loop through insulation faults or poor or faulty grounding methods.

23.3 Crosstalk

Crosstalk falls in two categories:

1. unintelligible crosstalk (babble)
2. intelligible crosstalk

The latter is most disturbing because it removes any impression of privacy. It can be caused by a single disturbing channel with enough coupling to spill into adjacent circuits. Unintelligible crosstalk is usually

FIGURE 23.2 Crosstalk.

caused by a large number of disturbing channels, none of which is of sufficient magnitude to be understood, or extraneous modulation products in carrier transmission systems.

Crosstalk can be further categorized as near-end and far-end. As these names imply, near-end crosstalk is caused by crosstalk interference at the near end of a circuit with respect to the listener; far-end crosstalk is crosstalk interference at the far end, as shown in Fig. 23.2.

Crosstalk of any kind is caused by insufficient shielding, excessively large disparity between signal levels in adjacent circuits, unbalanced lines, or overloaded analog carrier transmission systems or interfaces. Crosstalk is a statistical quantity because the number of sources and coupling paths is usually too large to quantify.

23.4 Circuit Noise

The noise that appears across the two conductors (tip and ring) of a loop, heard by the subscriber, is called **circuit noise** (also called *message circuit noise*, *noise metallic*, or *differential noise*). The noise can be due to random thermal motion of electrons (known as *white noise* or *Gaussian noise*) or static from lightning storms, but on subscriber loops its most likely source is interference from power line induction. For the purposes of this discussion, then, circuit noise and interference are assumed to be the same.

The total noise power on a loop is related to the noise bandwidth. Since particular frequencies differently affect the various services (for example, voice, data, and radio studio material), filter frequency response curves have been designed to restrict the frequency response of the noise measuring sets with which objective tests are made. This frequency response restriction is called *weighting*.

Noise, in voice applications, is described in terms of decibels above a noise reference when measured with a noise meter containing a special weighting filter. There are four common filters that are used to provide the necessary weighting for analog loop measurements:

- C-message
- 3-kHz flat (3.4 kHz flat and D-filter in newer test equipment)
- 15-kHz flat

The most common filter is called a C-message filter and measurements are based on decibels with respect to reference noise, C-message weighted (dBmC). The noise reference is 1 pW (-90 dBm); noise with reference power of 1 pW will read 0 dBmC on a properly calibrated meter.

C-message weighting is primarily used to measure noise that affects voice transmission when common telephone instruments are used, but it also is used to evaluate the effects of noise on analog voiceband data circuits. It weights the various frequencies according to their perceived annoyance such that frequencies below 600 or 700 Hz and above 3000 Hz have less importance (that is, they are attenuated and do not affect the measurement).

The 3-kHz-flat weighting curve is used on voice circuits, too, but all frequencies within the 3000-Hz bandwidth carry equal importance. This filter rolls off above 3000 Hz and approximates the response of common voiceband modems. It generally is used to investigate problems caused by power induction at

FIGURE 23.3 Weighting curve comparison.

the lower power harmonic frequencies or by higher interfering frequencies. Frequencies in these ranges can affect data transmission as well as voice frequency signaling equipment. The 3-kHz-flat filter has been replaced in modern test equipment with the 3.4-kHz-flat filter. The 3.4-kHz-flat filter better approximates the frequency response of modern high-speed analog voiceband modem loop interface circuits.

The 15-kHz-flat weighting curve is also used to test circuits between radio and television studios and remote transmitter sites. It has a flat response from 20 Hz to 15 kHz.

A comparison of the various weighting curves is shown in Fig. 23.3.

23.5 Impulse Noise

Data circuits are particularly sensitive to **impulse noise**. Impulse noise, heard as clicks, is usually defined as a voltage increase of 12 dB or more above the background [root mean square (rms)] noise lasting 10 ms or less. Its main source is from telephone set rotary dials, switching transients in electromechanical switching systems, maintenance activity on adjacent circuits, or electrical system switching transients. It is less of a problem with modern telecommunication systems because there are fewer rotary dials and very few electromechanical switching systems left in the PSTN.

Impulse noise objectives vary with the type and makeup of the circuit. Usually, a threshold is established and counts are made of any impulse noise that exceeds that threshold in a given time period. When impulse noise tests are made on a single circuit, the usual specification is 15 counts in 15 min. When a group of circuits is being tested, shorter time intervals are used.

On **subscriber loops**, the background noise threshold historically has been 59 dBrnC when measured at the central office [Bellcore, 1986]. However, this threshold is obsolete and no industry standards exist that define current requirements. High-speed analog voiceband modems, such as the 56 kb/s V.90 modems, are very susceptible to impulse noise and use forward error correction and other means to minimize errors.

23.6 Attenuation Distortion

Attenuation distortion is the change in circuit loss with frequency. It is also known as *frequency response*. Ideally, attenuation should be constant throughout the frequency band of interest. Unfortunately, this is not usually the case. Unless it is excessive, however, attenuation distortion is not noticeable to the human ear. Attenuation distortion manifests itself on voice calls by changing the sound of the talker's voice as

it is heard by the listener. The change may be dramatic enough to render the voice unrecognizable. On an analog voiceband data circuit, attenuation distortion can manifest itself in the form of errors through loss of signal energy at critical frequencies.

The inherent attenuation distortion in subscriber loops used in regular switched service is not objectionable except in extreme cases. On voice transmissions, excessive low-frequency slope degrades voice quality, whereas excessive high-frequency slope degrades intelligibility. On data transmissions using *phase-shift keying* (PSK) methods and its derivatives, such as *quadrature amplitude modulation* (QAM), both low- and high-frequency slope affects performance, whereas only high-frequency slope affects low-speed modems that use *frequency-shift keying* (FSK) [CCITT, 1989]. Some slope is considered necessary for stability at band edges.

Attenuation distortion is frequently specified in terms of the three tone slope as discussed previously. The slope objectives for loops used in special switched services [for example, private branch exchange (PBX) trunks and foreign exchange lines] are similar to regular switched loop objectives. It is not an extremely critical parameter on regular switched subscriber loops.

23.7 Envelope Delay Distortion

Envelope delay distortion (EDD), also called group delay distortion, is distortion in the rate of change of phase shift with frequency of a signal. Ideally, the rate of change should be constant with frequency, and it is approximately so in the voice band with nonloaded cables. With loaded cables this is not the case, especially near the cutoff frequency.

Envelope delay distortion is defined as the difference, in time units such as microseconds, between the maximum and minimum envelope delay within the frequency band of interest. If the difference is zero then, by this definition, there is no EDD, but this is hardly ever the case in practical systems.

Voice-band signals (not just voice signals but all signals in the voice band, including analog voiceband data signals) are made up of many frequencies. Each particular frequency propagates at a different velocity (called *phase velocity*) due to the facility's inherent transmission characteristics. This causes phase delay. If the relationship between the resulting phase shift and frequency is nonlinear, the facility will cause delay distortion. EDD at the upper edge of the voice band can cause *near singing* (the "rain-barrel effect") in the conversation. Excessive EDD at the lower edge can cause *speech blurring* [CCITT, 1989].

EDD results from any part of the circuit where a nonlinear relationship exists between phase shift and frequency. Very little EDD results from the loop itself. Usually this occurs at the terminal and intermediate equipment where filters in analog-to-digital and digital-to-analog converters are located. Some data transmission modulation techniques are more susceptible to intersymbol interference caused by EDD than others, which can explain why some modems of a given speed give better performance than others.

23.8 Line Conditioning

When the network consisted primarily of analog transmission facilities, attenuation and envelope delay distortion were major impairments. These were controlled through the use of line conditioning devices such as amplifiers and equalizers, which were installed at the ends of the transmission facilities. When required, equalization was almost always applied to the receiver side of a four-wire circuit. Sometimes, however, predistortion equalization was provided on the transmit side. The loop had little impact on performance unless it was very long.

In modern telecommunication networks, the transmission facilities are based on digital technologies such as optical fibers and digital microwave radios that do not introduce significant distortion. Any analog signal to be transported in today's network requires analog-to-digital (A/D) and digital-to-analog

TABLE 23.1 Analog Voiceband Data Transmission Objectives

Transmission Parameter	Group 1	Group 2		Group 3
		Tier 1	Tier 2	
Loss Deviation (dB)	±1	±1	±1	±1
Attenuation Distortion (dB)				
404–2804 Hz	-2.0/+5.0	-0.8/+1.5	-0.8/+3.5	-1.5/+9.5
304–3004 Hz	-2.0/+6.0	-0.8/+1.5	-0.8/+4.5	-2.5/+11.5
304–3204 Hz	-2.0/+8.0	Not specified	Not specified	Not specified
Envelope Delay Distortion (μs)				
804–2604 Hz	£550	£150	£650	£1700
604–2804 Hz	£800	£200	Not specified	Not specified
504–2804 Hz	Not specified	£550	Not specified	Not specified
504–3004 Hz	£1500	£2950	Not specified	Not specified
Intermodulation Distortion (dB)				
R2	≥49	≥32	≥32	≥26
R3	≥50	≥42	≥42	≥34
Signal-to-C-Notched Noise Ratio (dB)	≥33	≥32	≥32	≥26
Notched Impulse Noise Threshold (dBrnC)	63	65	65	69
Phase Jitter (∞Peak-Peak)				
20–300 Hz	Not applicable	Not applicable	Not applicable	£8
4–300 Hz	Not applicable	Not applicable	Not applicable	£13
Frequency Offset (Hz)	Not applicable	Not applicable	Not applicable	±1

(D/A) conversion at the ends. The analog signals usually are carried to the A/D conversion points by twisted pair loops. If the loops are long, the analog signals may first need to be equalized to offset a loop's high-frequency rolloff characteristic, which affects both attenuation and envelope delay distortion to some extent. Line conditioning is not used on switched voice frequency loops.

The inherent loss of a loop used in most special access (private line) applications can be reduced by adding gain with amplifiers. This has to be done carefully to prevent the loop from singing (oscillating) if two-wire conversion is used at any point in the circuit.

With the divestiture of AT&T in 1984, the specification and provisioning of end-to-end transmission facilities became much more difficult because the public network moved from being mostly one-dimensional to having multi-network operator and multi-dimensional characteristics. Any circuit that crossed exchange boundaries was a concatenation of elements provided by different network operators. A given network operator provided lines with predetermined characteristics according to the facilities owned and operated by them and them only. As a result, Bellcore (now Telcordia) developed standardized *voice grade* (VG) circuit types and transmission performance requirements that applied within the Bell Operating Company's service areas. These requirements recognized the widespread use at that time of analog transmission facilities throughout the Bell System and, thus, were very detailed as to analog transmission parameters. About 10 years later, the T1 Committee of the Alliance for Telecommunications Industry Solutions (ATIS), through the American National Standards Institute (ANSI), published a more general set of specifications that recognized the more widespread use of digital transmission facilities throughout the public network. Table 23.1 shows the characteristics specified by the ANSI standard [ANSI, 1994]. In this table, the attenuation distortion is shown with respect to the attenuation at 1004 Hz. The envelope delay distortion is given in terms of the difference between the maximum and minimum envelope delay (in microseconds) within the frequency band shown. All values are for circuits from network operator demarcation point (network interface) to network operator demarcation point. The ANSI requirements also specify limiting values for other transmission impairments, some of which do not apply to facilities composed entirely of digital transmission systems (Group 1 and 2 in the table).

23.9 Other Impairments to Analog Transmission

Intermodulation distortion (IMD), also known as nonlinear distortion, is an impairment that arises due to the nonlinear characteristics of loop interfaces. IMD is the power generated at extraneous frequencies (intermodulation products) when a multi-tone signal is applied to a circuit. Loop facilities composed entirely of twisted pair cables do not contribute to IMD but the cables always are connected to interfaces. In particular, nonlinearities in the interface electronics lead to generation of undesirable sum and difference signals related to the original desired signals. As with other transmission impairments, IMD manifests itself as analog voiceband modem errors and reduced throughput or connection speed, but IMD does not significantly impair voice quality. Where there is only a single A/D – D/A conversion process in an analog circuit, the ratio of desired signal to undesired signal due to IMD is around 40 to 50 dB.

Signal-to-Noise Ratio (SNR) is also important to modem transmission. In this case, the signal must be high enough above the noise level so the modem receiver can detect and recover the signal with low probability of error. SNR can be specified for both background noise and impulse noise. Typical values for SNR are greater than 30 dB. SNR is not as important on voice circuits as the absolute noise level (high noise during speech is not as disturbing as the same noise level during speech pauses).

Jitter and **Transients** can wreak havoc on high-speed voiceband modem signals and thus must be controlled. They have little effect on voice communications. Jitter is a small but significant periodic movement of the signal in either amplitude (amplitude jitter) or phase (phase jitter) from its desired value. Jitter in analog telephone channels is caused by analog interfaces (A/D and D/A converters) and transmission systems such as analog wireless transmission systems. Digital transmission systems do not introduce jitter on analog channels. Transients are departures of the signal amplitude or phase that exceed a threshold and are followed by quiet intervals. Transients can be caused by fading in wireless transmission systems (both digital and analog) and protection line switching in optical fiber and twisted pair transmission systems.

Defining Terms

Analog telephone channel: A telecommunications channel suitable for transmission of a band-limited, time continuous signal.

Voiceband modem: MOdulator-DEModulator, a device used for transmitting digital data over an analog voiceband channel.

Circuit noise: The noise heard by the subscriber or detected by an analog voiceband modem that appears across the pair of conductors in the loop.

Crosstalk: Interference coupled into the present telephone connection from adjacent channels or connections.

Envelope delay distortion (EDD): Distortion in the rate of change of phase shift as a function of frequency.

Impulse noise: Short voltage increases of 12 dB or more usually caused by electromechanical switching transients, maintenance activity, or electrical system switching transients.

Intermodulation distortion (IMD): The power generated at extraneous frequencies (intermodulation products) when a multi-tone signal is applied to a channel.

Intersymbol interference (ISI): Interference arising in modem signal detection from the edges of neighboring pulses.

Jitter: Relatively small but significant periodic movements of a signal's amplitude or phase from its desired value.

kb/s: Kilobits (1000 bits) per second.

Line conditioning: The use of amplifiers and equalizers or other devices to control the transmission characteristics of metallic twisted cable pairs.

Public switched telephone network (PSTN): Traditionally, the network developed to provide dial-up voice communications but now meant to include all telecommunication facilities available to the public.

Signal-to-noise ratio (SNR): The ratio of signal power to noise power in a channel. Analog voiceband modems require adequate SNR to achieve high throughput and low error rate.

Subscriber loop: The subscriber loop is the transmission and signaling channel between a telephone subscriber's terminal equipment and the network.

Transient: Sudden change in the amplitude or phase of a received signal that lasts at least 4 ms.

Voice band: The usable bandwidth of a telephone voice channel, often taken to be 300–3400 Hz.

Many physical communications channels, such as radio channels, accept a continuous-time waveform as input. Consequently, a sequence of source bits, representing data or a digitized analog signal, must be converted to a continuous-time waveform at the transmitter. In general, each successive group of bits taken from this sequence is mapped to a particular continuous-time pulse. In this chapter we discuss the basic principles involved in selecting such a pulse for channels that can be characterized as linear and time invariant with finite bandwidth.

24.1 Communications System Model

Figure 24.1a shows a simple block diagram of a communications system. The sequence of source bits $\{b_i\}$ are grouped into sequential blocks (vectors) of m bits $\{\mathbf{b}_i\}$, and each binary vector \mathbf{b}_i is mapped to one of 2^m pulses, $p(\mathbf{b}_i; t)$, which is transmitted over the channel. The transmitted signal as a function of time can be written as

$$s(t) = \sum_i p(\mathbf{b}_i; t - iT) \quad (24.1)$$

where $1/T$ is the rate at which each group of m bits, or pulses, is introduced to the channel. The information (bit) rate is therefore m/T .

FIGURE 24.1a Communication system model. The source bits are grouped into binary vectors, which are mapped to a sequence of pulse shapes.

FIGURE 24.1b Channel model consisting of a linear, time-invariant system (transfer function) followed by additive noise.

The channel in Fig. 24.1a can be a radio link, which may distort the input signal $s(t)$ in a variety of ways. For example, it may introduce pulse dispersion (due to finite bandwidth) and multipath, as well as additive background noise. The output of the channel is denoted as $x(t)$, which is processed by the receiver to determine estimates of the source bits. The receiver can be quite complicated; however, for the purpose of this discussion, it is sufficient to assume only that it contains a front-end filter and a sampler, as shown in Fig. 24.1a. This assumption is valid for a wide variety of detection strategies. The purpose of the receiver filter is to remove noise outside of the transmitted frequency band and to compensate for the channel frequency response.

A commonly used channel model is shown in Fig. 24.1b and consists of a linear, time-invariant filter, denoted as $G(f)$, followed by additive noise $n(t)$. The channel output is, therefore,

$$x(t) = [g(t) * s(t)] + n(t) \quad (24.2)$$

where $g(t)$ is the channel impulse response associated with $G(f)$, and the asterisk denotes convolution,

$$g(t) * s(t) = \int_{-\infty}^{\infty} g(t - \tau)s(\tau)d\tau$$

This channel model accounts for all linear, time-invariant channel impairments, such as finite bandwidth and time-invariant multipath. It does not account for time-varying impairments, such as rapid fading due to time-varying multipath. Nevertheless, this model can be considered valid over short time periods during which the multipath parameters remain constant.

In Figs. 24.1a, and 24.1b, it is assumed that all signals are **baseband signals**, which means that the frequency content is centered around $f = 0$ (DC). The channel passband, therefore, partially coincides with the transmitted spectrum. In general, this condition requires that the transmitted signal be modulated by an appropriate carrier frequency and demodulated at the receiver. In that case, the model in Figs. 24.1a, and 24.1b still applies; however, *baseband-equivalent* signals must be derived from their modulated (passband) counterparts. *Baseband signalling* and *pulse shaping* refers to the way in which a group of source bits is mapped to a baseband transmitted pulse.

As a simple example of baseband signalling, we can take $m = 1$ (map each source bit to a pulse), assign a 0 bit to a pulse $p(t)$, and a 1 bit to the pulse $-p(t)$. Perhaps the simplest example of a baseband pulse is the *rectangular* pulse given by $p(t) = 1, 0 < t \leq T$, and $p(t) = 0$ elsewhere. In this case, we can write the transmitted signal as

$$s(t) = \sum_i A_i p(t - iT) \quad (24.3)$$

where each symbol A_i takes on a value of +1 or -1, depending on the value of the i th bit, and $1/T$ is the *symbol rate*, namely, the rate at which the symbols A_i are introduced to the channel.

The preceding example is called *binary pulse amplitude modulation (PAM)*, since the data symbols A_i are binary valued, and they amplitude modulate the transmitted pulse $p(t)$. The information rate (bits per second) in this case is the same as the symbol rate $1/T$. As a simple extension of this signalling technique, we can increase m and choose A_i from one of $M = 2^m$ values to transmit at bit rate m/T . This is known as M -ary PAM. For example, letting $m = 2$, each pair of bits can be mapped to a pulse in the set $\{p(t), -p(t), 3p(t), -3p(t)\}$.

In general, the transmitted symbols $\{A_i\}$, the baseband pulse $p(t)$, and channel impulse response $g(t)$ can be *complex valued*. For example, each successive pair of bits might select a symbol from the set $\{1, -1, j, -j\}$, where $j = \sqrt{-1}$. This is a consequence of considering the baseband equivalent of passband modulation (that is, generating a transmitted spectrum which is centered around a carrier frequency f_c). Here we are not concerned with the relation between the passband and baseband equivalent models and simply point out that the discussion and results in this chapter apply to complex-valued symbols and pulse shapes.

As an example of a signalling technique which is not PAM, let $m = 1$ and

$$\begin{aligned}
 p(0; t) &= \begin{cases} \sqrt{2}\sin(2\pi f_1 t) & 0 < t < T \\ 0 & \text{elsewhere} \end{cases} \\
 p(1; t) &= \begin{cases} \sqrt{2}\sin(2\pi f_2 t) & 0 < t < T \\ 0 & \text{elsewhere} \end{cases}
 \end{aligned}
 \tag{24.4}$$

where f_1 and $f_2 \neq f_1$ are fixed frequencies selected so that $f_1 T$ and $f_2 T$ (number of cycles for each bit) are multiples of $1/2$. These pulses are *orthogonal*, namely,

$$\int_0^T p(1; t)p(0; t) dt = 0$$

This choice of pulse shapes is called *binary frequency-shift keying (FSK)*.

Another example of a set of orthogonal pulse shapes for $m = 2$ bits/ T is shown in Fig. 24.2. Because these pulses may have as many as three transitions within a symbol period, the transmitted spectrum occupies roughly four times the transmitted spectrum of binary PAM with a rectangular pulse shape. The spectrum is, therefore, spread across a much larger band than the smallest required for reliable transmission, assuming a data rate of $2/T$. This type of signalling is referred to as **spread-spectrum**.

FIGURE 24.2 Four orthogonal spread-spectrum pulse shapes.

FIGURE 24.3 Baseband model of a pulse amplitude modulation system.

Spread-spectrum signals are more robust with respect to interference from other transmitted signals than are narrowband signals.¹

24.2 Intersymbol Interference and the Nyquist Criterion

Consider the transmission of a PAM signal illustrated in Fig. 24.3. The source bits $\{b_i\}$ are mapped to a sequence of levels $\{A_i\}$, which modulate the transmitter pulse $p(t)$. The channel input is, therefore, given by Eq. (24.3) where $p(t)$ is the impulse response of the transmitter *pulse-shaping filter* $P(f)$ shown in Fig. 24.3. The input to the transmitter filter $P(f)$ is the modulated sequence of delta functions $\sum_i A_i \delta(t - iT)$. The channel is represented by the transfer function $G(f)$ (plus noise), which has impulse response $g(t)$, and the receiver filter has transfer function $R(f)$ with associated impulse response $r(t)$.

Let $h(t)$ be the overall impulse response of the combined transmitter, channel, and receiver, which has transfer function $H(f) = P(f)G(f)R(f)$. We can write $h(t) = p(t) * g(t) * r(t)$. The output of the receiver filter is then

$$y(t) = \sum_i A_i h(t - iT) + \tilde{n}(t) \quad (24.5)$$

where $\tilde{n}(t) = r(t) * n(t)$ is the output of the filter $R(f)$ with input $n(t)$. Assuming that samples are collected at the output of the filter $R(f)$ at the symbol rate $1/T$, we can write the k th sample of $y(t)$ as

$$\begin{aligned} y(kT) &= \sum_i A_i h(kT - iT) + \tilde{n}(kT) \\ &= A_k h(0) + \sum_{i \neq k} A_i h(kT - iT) + \tilde{n}(kT) \end{aligned} \quad (24.6)$$

The first term on the right-hand side of Eq. (24.6) is the k th transmitted symbol scaled by the system impulse response at $t = 0$. If this were the only term on the right side of Eq. (24.6), we could obtain the source bits without error by scaling the received samples by $1/h(0)$. The second term on the right-hand side of Eq. (24.6) is called **intersymbol interference**, which reflects the view that neighboring symbols interfere with the detection of each desired symbol.

One possible criterion for choosing the transmitter and receiver filters is to minimize intersymbol interference. Specifically, if we choose $p(t)$ and $r(t)$ so that

$$h(kT) = \begin{cases} 1 & k = 0 \\ 0 & k \neq 0 \end{cases} \quad (24.7)$$

¹This example can also be viewed as coded binary PAM. Namely, each pair of two source bits are mapped to 4 coded bits, which are transmitted via binary PAM with a rectangular pulse. The current IS-95 air interface uses an extension of this signalling method in which groups of 6 b are mapped to 64 orthogonal pulse shapes with as many as 63 transitions during a symbol.

then the k th received sample is

$$y(kT) = A_k + \tilde{n}(kT) \quad (24.8)$$

In this case, the intersymbol interference has been eliminated. This choice of $p(t)$ and $r(t)$ is called a **zero-forcing** solution, since it forces the intersymbol interference to zero. Depending on the type of detection scheme used, a zero-forcing solution may not be desirable. This is because the probability of error also depends on the noise intensity, which generally increases when intersymbol interference is suppressed. It is instructive, however, to examine the properties of the zero-forcing solution.

We now view Eq. (24.7) in the frequency domain. Since $h(t)$ has Fourier transform

$$H(f) = P(f)G(f)R(f) \quad (24.9)$$

where $P(f)$ is the Fourier transform of $p(t)$, the bandwidth of $H(f)$ is limited by the bandwidth of the channel $G(f)$. We will assume that $G(f) = 0, |f| > W$. The sampled impulse response $h(kT)$ can, therefore, be written as the inverse Fourier transform

$$h(kT) = \int_{-W}^W H(f)e^{j2\pi f kT} df$$

Through a series of manipulations, this integral can be rewritten as an inverse discrete Fourier transform,

$$h(kT) = T \int_{-1/(2T)}^{1/(2T)} H_{\text{eq}}(e^{j2\pi f T}) e^{j2\pi f kT} df \quad (24.10a)$$

where

$$\begin{aligned} H_{\text{eq}}(e^{j2\pi f T}) &= \frac{1}{T} \sum_k H\left(f + \frac{k}{T}\right) \\ &= \frac{1}{T} \sum_k P\left(f + \frac{k}{T}\right) G\left(f + \frac{k}{T}\right) R\left(f + \frac{k}{T}\right) \end{aligned} \quad (24.10b)$$

This relation states that $H_{\text{eq}}(z), z = e^{j2\pi f T}$, is the discrete Fourier transform of the sequence $\{h_k\}$, where $h_k = h(kT)$. Sampling the impulse response $h(t)$ therefore changes the transfer function $H(f)$ to the *aliased* frequency response $H_{\text{eq}}(e^{j2\pi f T})$. From Eqs. (24.10), and (24.6) we conclude that $H_{\text{eq}}(z)$ is the transfer function that relates the sequence of input data symbols $\{A_i\}$ to the sequence of received samples $\{y_i\}$, where $y_i = y(iT)$, in the absence of noise. This is illustrated in Fig. 24.4. For this reason, $H_{\text{eq}}(z)$ is called the **equivalent discrete-time transfer function** for the overall system transfer function $H(f)$.

Since $H_{\text{eq}}(e^{j2\pi f T})$ is the discrete Fourier transform of the sequence $\{h_k\}$, the time-domain, or sequence condition (24.7) is equivalent to the frequency-domain condition

$$H_{\text{eq}}(e^{j2\pi f T}) = 1 \quad (24.11)$$

This relation is called the **Nyquist criterion**. From Eqs. (24.10b) and (24.11) we make the following observations.

1. To satisfy the Nyquist criterion, the channel bandwidth W must be at least $1/(2T)$. Otherwise, $G(f + n/T) = 0$ for f in some interval of positive length for all n , which implies that $H_{\text{eq}}(e^{j2\pi f T}) = 0$ for f in the same interval.

FIGURE 24.4 Equivalent discrete-time channel for the PAM system shown in Fig. 24.3 [$y_i = y(iT)$, $\tilde{n}_i = \tilde{n}(iT)$].

2. For the minimum bandwidth $W = 1/(2T)$, Eqs. (24.10b) and (24.11) imply that $H(f) = T$ for $|f| < 1/(2T)$ and $H(f) = 0$ elsewhere. This implies that the system impulse response is given by

$$h(t) = \frac{\sin(\pi t/T)}{\pi t/T} \quad (24.12)$$

(Since $\int_{-\infty}^{\infty} h^2(t) dt = T$, the transmitted signal $s(t) = \sum_i A_i h(t - iT)$ has power equal to the symbol variance $E[|A_i|^2]$.) The impulse response in Eq. (24.12) is called a *minimum bandwidth* or Nyquist pulse. The frequency band $[-1/(2T), 1/(2T)]$ [i.e., the passband of $H(f)$] is called the **Nyquist band**.

3. Suppose that the channel is bandlimited to twice the Nyquist bandwidth. That is, $G(f) = 0$ for $|f| > 1/T$. The condition (24.11) then becomes

$$H(f) + H\left(f - \frac{1}{T}\right) + H\left(f + \frac{1}{T}\right) = T \quad (24.13)$$

Assume for the moment that $H(f)$ and $h(t)$ are both real valued, so that $H(f)$ is an even function of f [$H(f) = H(-f)$]. This is the case when the receiver filter is the matched filter (see Section 24.3). We can then rewrite Eq. (24.13) as

$$H(f) + H\left(\frac{1}{T} - f\right) = T, \quad 0 < f < \frac{1}{2T} \quad (24.14)$$

which states that $H(f)$ must have odd symmetry about $f = 1/(2T)$. This is illustrated in Fig. 24.5, which shows two different functions $H(f)$ that satisfy the Nyquist criterion.

4. The pulse shape $p(t)$ enters into Eq. (24.11) only through the product $P(f)R(f)$. Consequently, either $P(f)$ or $R(f)$ can be fixed, and the other filter can be adjusted or adapted to the particular channel. Typically, the pulse shape $p(t)$ is fixed, and the receiver filter is adapted to the (possibly time-varying) channel.

Raised Cosine Pulse

Suppose that the channel is ideal with transfer function

$$G(f) = \begin{cases} 1, & |f| < W \\ 0, & |f| > W \end{cases} \quad (24.15)$$

To maximize bandwidth efficiency, Nyquist pulses given by Eq. (24.12) should be used where $W = 1/(2T)$. This type of signalling, however, has two major drawbacks. First, Nyquist pulses are noncausal and of infinite duration. They can be approximated in practice by introducing an appropriate delay and truncating the pulse. The pulse, however, decays very slowly, namely, as $1/t$, so that the truncation window must be wide.

FIGURE 24.5 Two examples of frequency responses that satisfy the Nyquist criterion.

This is equivalent to observing that the ideal bandlimited frequency response given by Eq. (24.15) is difficult to approximate closely. The second drawback, which is more important, is the fact that this type of signalling is not robust with respect to sampling jitter. Namely, a small sampling offset ε produces the output sample

$$y(kT + \varepsilon) = \sum_i A_i \frac{\sin[\pi(k - i + \varepsilon/T)]}{\pi(k - i + \varepsilon/T)} \quad (24.16)$$

Since the Nyquist pulse decays as $1/t$, this sum is not guaranteed to converge. A particular choice of symbols $\{A_i\}$ can, therefore, lead to very large intersymbol interference, no matter how small the offset. Minimum bandwidth signalling is therefore impractical.

The preceding problem is generally solved in one of two ways in practice:

1. The pulse bandwidth is increased to provide a faster pulse decay than $1/t$.
2. A *controlled* amount of intersymbol interference is introduced at the transmitter, which can be subtracted out at the receiver.

The former approach sacrifices bandwidth efficiency, whereas the latter approach sacrifices power efficiency. We will examine the latter approach in [Section 24.5](#). The most common example of a pulse, which illustrates the first technique, is the **raised cosine pulse**, given by

$$h(t) = \left[\frac{\sin(\pi t/T)}{\pi t/T} \right] \left[\frac{\cos(\alpha \pi t/T)}{1 - (2\alpha t/T)^2} \right] \quad (24.17)$$

which has Fourier transform

$$H(f) = \begin{cases} T & 0 \leq |f| \leq \frac{1-\alpha}{2T} \\ \frac{T}{2} \left\{ 1 + \cos \left[\frac{\pi T}{\alpha} \left(|f| - \frac{1-\alpha}{2T} \right) \right] \right\} & \frac{1-\alpha}{2T} \leq |f| \leq \frac{1+\alpha}{2T} \\ 0 & |f| > \frac{1+\alpha}{2T} \end{cases} \quad (24.18)$$

where $0 \leq \alpha \leq 1$.

Plots of $p(t)$ and $P(f)$ are shown in [Figs. 24.6a](#), and [24.6b](#) for different values of α . It is easily verified that $h(t)$ satisfies the Nyquist criterion (24.7) and, consequently, $H(f)$ satisfies Eq. (24.11). When $\alpha = 0$, $H(f)$ is the Nyquist pulse with minimum bandwidth $1/(2T)$, and when $\alpha > 0$, $H(f)$ has bandwidth $(1 + \alpha)/(2T)$ with a raised cosine rolloff. The parameter α , therefore, represents the additional or **excess bandwidth** as a fraction of the minimum bandwidth $1/(2T)$. For example, when $\alpha = 1$, we say that the pulse is a raised cosine pulse with 100% excess bandwidth. This is because the pulse bandwidth $1/T$ is twice the minimum bandwidth. Because the raised cosine pulse decays as $1/t^3$, performance is robust with respect to sampling offsets.

The raised cosine frequency response (24.18) applies to the combination of transmitter, channel, and receiver. If the transmitted pulse shape $p(t)$ is a raised cosine pulse, then $h(t)$ is a raised cosine pulse only if the combined receiver and channel frequency response is constant. Even with an ideal (transparent) channel, however, the optimum (matched) receiver filter response is generally not constant in the presence of additive Gaussian noise. An alternative is to transmit the *square-root raised cosine* pulse shape, which has frequency response $P(f)$ given by the square-root of the raised cosine frequency response in Eq. (24.18). Assuming an ideal channel, setting the receiver frequency response $R(f) = P(f)$ then results in an overall raised cosine system response $H(f)$.

FIGURE 24.6a Raised cosine pulse.

FIGURE 24.6b Raised cosine spectrum.

24.3 Nyquist Criterion with Matched Filtering

Consider the transmission of an isolated pulse $A_0\delta(t)$. In this case the input to the receiver in Fig. 24.3 is

$$x(t) = A_0\tilde{g}(t) + n(t) \tag{24.19}$$

where $\tilde{g}(t)$ is the inverse Fourier transform of the combined transmitter-channel transfer function $\tilde{G}(f) = P(f)G(f)$. We will assume that the noise $n(t)$ is white with spectrum $N_0/2$. The output of the receiver

filter is then

$$y(t) = r(t) * x(t) = A_0[r(t) * \tilde{g}(t)] + [r(t) * n(t)] \quad (24.20)$$

The first term on the right-hand side is the desired signal, and the second term is noise. Assuming that $y(t)$ is sampled at $t = 0$, the ratio of signal energy to noise energy, or signal-to-noise ratio (SNR) at the sampling instant, is

$$SNR = \frac{E[|A_0|^2] \left| \int_{-\infty}^{\infty} r(-t) \tilde{g}(t) dt \right|^2}{\frac{N_0}{2} \int_{-\infty}^{\infty} |r(t)|^2 dt} \quad (24.21)$$

The receiver impulse response that maximizes this expression is $r(t) = \tilde{g}^*(-t)$ [complex conjugate of $\tilde{g}(-t)$], which is known as the **matched filter** impulse response. The associated transfer function is $R(f) = \tilde{G}^*(-f)$.

Choosing the receiver filter to be the matched filter is optimal in more general situations, such as when detecting a sequence of channel symbols with intersymbol interference (assuming the additive noise is Gaussian). We, therefore, reconsider the Nyquist criterion when the receiver filter is the matched filter. In this case, the baseband model is shown in Fig. 24.7, and the output of the receiver filter is given by

$$y(t) = \sum_i A_i h(t - iT) + \tilde{n}(t) \quad (24.22)$$

where the baseband pulse $h(t)$ is now the impulse response of the filter with transfer function $|\tilde{G}(f)|^2 = |P(f)G(f)|^2$. This impulse response is the *autocorrelation* of the impulse response of the combined transmitter-channel filter $\tilde{G}(f)$,

$$h(t) = \int_{-\infty}^{\infty} \tilde{g}^*(s) \tilde{g}(s+t) ds \quad (24.23)$$

With a matched filter at the receiver, the equivalent discrete-time transfer function is

$$\begin{aligned} H_{\text{eq}}(e^{j2\pi f T}) &= \frac{1}{T} \sum_k \left| \tilde{G}\left(f - \frac{k}{T}\right) \right|^2 \\ &= \frac{1}{T} \sum_k \left| P\left(f - \frac{k}{T}\right) G\left(f - \frac{k}{T}\right) \right|^2 \end{aligned} \quad (24.24)$$

which relates the sequence of transmitted symbols $\{A_k\}$ to the sequence of received samples $\{y_k\}$ in the absence of noise. Note that $H_{\text{eq}}(e^{j2\pi f T})$ is positive, real valued, and an even function of f . If the channel is bandlimited to twice the Nyquist bandwidth, then $H(f) = 0$ for $|f| > 1/2T$, and the Nyquist condition is given by Eq. (24.14) where $H(f) = |G(f)P(f)|^2$. The aliasing sum in Eq. (24.10b) can therefore be described as a folding operation in which the channel response $|H(f)|^2$ is folded around the Nyquist frequency $1/(2T)$. For this reason, $H_{\text{eq}}(e^{j2\pi f T})$ with a matched receiver filter is often referred to as the folded channel spectrum.

FIGURE 24.7 Baseband PAM model with a matched filter at the receiver.

24.4 Eye Diagrams

One way to assess the severity of distortion due to intersymbol interference in a digital communications system is to examine the **eye diagram**. The eye diagram is illustrated in Figs. 24.8a and 24.8b for a raised cosine pulse shape with 25% excess bandwidth and an ideal bandlimited channel. Figure 24.8a shows the data signal at the receiver,

$$y(t) = \sum_i A_i h(t - iT) + \tilde{n}(t) \quad (24.25)$$

FIGURE 24.8a Received signal $y(t)$.

FIGURE 24.8b Eye diagram for received signal shown in Fig. 24.8a.

where $h(t)$ is given by Eq. (24.17), $\alpha = 1/4$, each symbol A_i is independently chosen from the set $\{\pm 1, \pm 3\}$, where each symbol is equally likely, and $\tilde{n}(t)$ is bandlimited white Gaussian noise. (The received SNR is 30 dB.) The eye diagram is constructed from the time-domain data signal $y(t)$ as follows (assuming nominal sampling times at kT , $k = 0, 1, 2, \dots$):

1. Partition the waveform $y(t)$ into successive segments of length T starting from $t = T/2$.
2. Translate each of these waveform segments $[y(t), (k + 1/2)T \leq t \leq (k + 3/2)T, k = 0, 1, 2, \dots]$ to the interval $[-T/2, T/2]$, and superimpose.

The resulting picture is shown in Fig. 24.8(b) for the $y(t)$ shown in Fig. 24.8(a). (Partitioning $y(t)$ into successive segments of length iT , $i > 1$, is also possible. This would result in i successive eye diagrams.) The number of eye openings is one less than the number of transmitted signal levels. In practice, the eye diagram is easily viewed on an oscilloscope by applying the received waveform $y(t)$ to the vertical deflection plates of the oscilloscope and applying a sawtooth waveform at the symbol rate $1/T$ to the horizontal deflection plates. This causes successive symbol intervals to be translated into one interval on the oscilloscope display.

Each waveform segment $y(t)$, $(k + 1/2)T \leq t \leq (k + 3/2)T$, depends on the particular sequence of channel symbols surrounding A_k . The number of channel symbols that affects a particular waveform segment depends on the extent of the intersymbol interference, shown in Eq. (24.6). This, in turn, depends on the duration of the impulse response $h(t)$. For example, if $h(t)$ has most of its energy in the interval $0 < t < mT$, then each waveform segment depends on approximately m symbols. Assuming binary transmission, this implies that there are a total of 2^m waveform segments that can be superimposed in the eye diagram. (It is possible that only one sequence of channel symbols causes significant intersymbol interference, and this sequence occurs with very low probability.) In current digital wireless applications the impulse response typically spans only a few symbols.

The eye diagram has the following important features which measure the performance of a digital communications system.

Vertical Eye Opening

The vertical openings at any time t_0 , $-T/2 \leq t_0 \leq T/2$, represent the separation between signal levels with worst-case intersymbol interference, assuming that $y(t)$ is sampled at times $t = kT + t_0$, $k = 0, 1, 2, \dots$. It is possible for the intersymbol interference to be large enough so that this vertical opening between some, or all, signal levels disappears altogether. In that case, the eye is said to be closed. Otherwise, the eye is said to be open. A closed eye implies that if the estimated bits are obtained by thresholding the samples $y(kT)$, then the decisions will depend primarily on the intersymbol interference rather than on the desired symbol. The probability of error will, therefore, be close to $1/2$. Conversely, wide vertical spacings between signal levels imply a large degree of immunity to additive noise. In general, $y(t)$ should be sampled at the times $kT + t_0$, $k = 0, 1, 2, \dots$, where t_0 is chosen to maximize the vertical eye opening.

Horizontal Eye Opening

The width of each opening indicates the sensitivity to timing offset. Specifically, a very narrow eye opening indicates that a small timing offset will result in sampling where the eye is closed. Conversely, a wide horizontal opening indicates that a large timing offset can be tolerated, although the error probability will depend on the vertical opening.

Slope of the Inner Eye

The slope of the inner eye indicates sensitivity to timing jitter or variance in the timing offset. Specifically, a very steep slope means that the eye closes rapidly as the timing offset increases. In this case, a significant amount of jitter in the sampling times significantly increases the probability of error.

The shape of the eye diagram is determined by the pulse shape. In general, the faster the baseband pulse decays, the wider the eye opening. For example, a rectangular pulse produces a box-shaped eye diagram (assuming binary signalling). The minimum bandwidth pulse shape Eq. (24.12) produces an eye diagram which is closed for all t except for $t = 0$. This is because, as shown earlier, an arbitrarily small timing offset can lead to an intersymbol interference term that is arbitrarily large, depending on the data sequence.

24.5 Partial-Response Signalling

To avoid the problems associated with Nyquist signalling over an ideal bandlimited channel, bandwidth and/or power efficiency must be compromised. Raised cosine pulses compromise bandwidth efficiency to gain robustness with respect to timing errors. Another possibility is to introduce a controlled amount of intersymbol interference at the transmitter, which can be removed at the receiver. This approach is called **partial-response (PR) signalling**. The terminology reflects the fact that the sampled system impulse response does not have the full response given by the Nyquist condition Eq. (24.7).

To illustrate PR signalling, suppose that the Nyquist condition Eq. (24.7) is replaced by the condition

$$h_k = \begin{cases} 1 & k = 0, 1 \\ 0 & \text{all other } k \end{cases} \quad (24.26)$$

The k th received sample is then

$$y_k = A_k + A_{k-1} + \tilde{n}_k \quad (24.27)$$

so that there is intersymbol interference from one neighboring transmitted symbol. For now we focus on the spectral characteristics of PR signalling and defer discussion of how to detect the transmitted sequence $\{A_k\}$ in the presence of intersymbol interference. The equivalent discrete-time transfer function in this case is the discrete Fourier transform of the sequence in Eq. (24.26),

$$\begin{aligned} H_{\text{eq}}(e^{j2\pi fT}) &= \frac{1}{T} \sum_k H\left(f + \frac{k}{T}\right) \\ &= 1 + e^{-j2\pi fT} = 2e^{-j\pi fT} \cos(\pi fT) \end{aligned} \quad (24.28)$$

As in the full-response case, for Eq. (24.28) to be satisfied, the *minimum* bandwidth of the channel $G(f)$ and transmitter filter $P(f)$ is $W = 1/(2T)$. Assuming $P(f)$ has this minimum bandwidth implies

$$H(f) = \begin{cases} 2Te^{-j\pi fT} \cos(\pi fT) & |f| < 1/(2T) \\ 0 & |f| > 1/(2T) \end{cases} \quad (24.29a)$$

and

$$h(t) = T\{\text{sinc}(t/T) + \text{sinc}[(t-T)/T]\} \quad (24.29b)$$

where $\text{sinc } x = (\sin \pi x)/(\pi x)$. This pulse is called a *duobinary* pulse and is shown along with the associated $H(f)$ in Fig. 24.9. [Notice that $h(t)$ satisfies Eq. (24.26).] Unlike the ideal bandlimited frequency response, the transfer function $H(f)$ in Eq. (24.29a) is continuous and is, therefore, easily approximated by a physically realizable filter. Duobinary PR was first proposed by Lender [7] and later generalized by Kretzmer [6].

The main advantage of the duobinary pulse Eq. (24.29b), relative to the minimum bandwidth pulse Eq. (24.12), is that signalling at the Nyquist symbol rate is feasible with zero excess bandwidth. Because the pulse decays much more rapidly than a Nyquist pulse, it is robust with respect to timing errors.

FIGURE 24.9 Duobinary frequency response and minimum bandwidth pulse.

Selecting the transmitter and receiver filters so that the overall system response is duobinary is appropriate in situations where the channel frequency response $G(f)$ is near zero or has a rapid rolloff at the Nyquist band edge $f = 1/(2T)$.

As another example of PR signalling, consider the *modified* duobinary partial response

$$h_k = \begin{cases} 1 & k = -1 \\ -1 & k = 1 \\ 0 & \text{all other } k \end{cases} \quad (24.30)$$

which has equivalent discrete-time transfer function

$$\begin{aligned} H_{\text{eq}}(e^{j2\pi fT}) &= e^{j2\pi fT} - e^{-j2\pi fT} \\ &= j2 \sin(2\pi fT) \end{aligned} \quad (24.31)$$

With zero excess bandwidth, the overall system response is

$$H(f) = \begin{cases} j2T \sin(2\pi fT) & |f| < 1/(2T) \\ 0 & |f| > 1/(2T) \end{cases} \tag{24.32a}$$

and

$$h(t) = T\{\text{sinc} [(t + T)/T] - \text{sinc} [(t - T)/T]\} \tag{24.32b}$$

These functions are plotted in Fig. 24.10. This pulse shape is appropriate when the channel response $G(f)$ is near zero at both DC ($f = 0$) and at the Nyquist band edge. This is often the case for wire (twisted-pair) channels where the transmitted signal is coupled to the channel through a transformer. Like duobinary PR, modified duobinary allows minimum bandwidth signalling at the Nyquist rate.

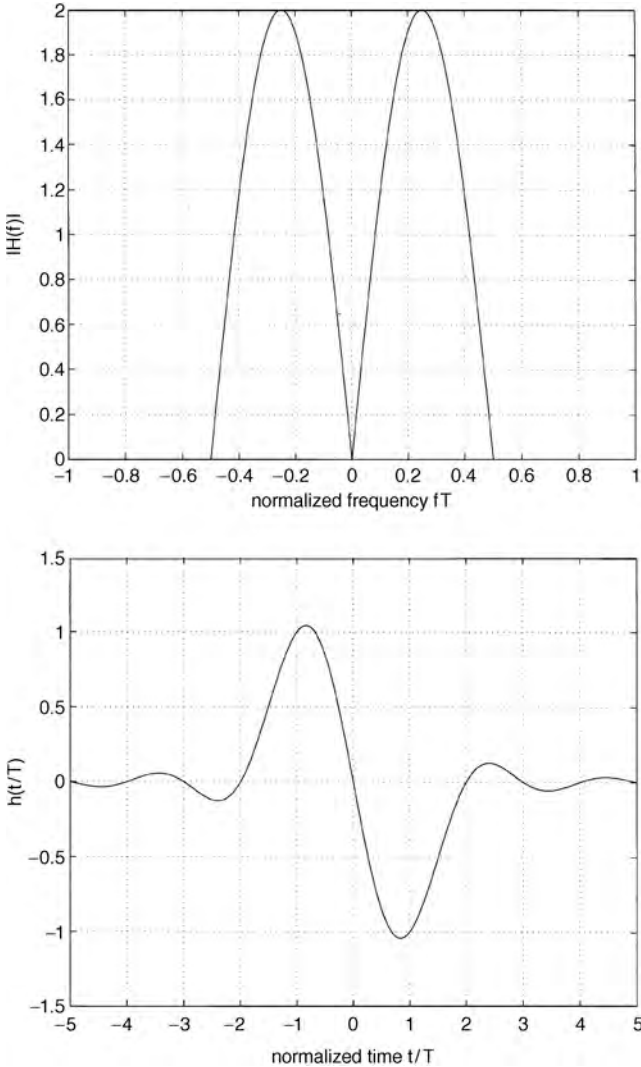

FIGURE 24.10 Modified duobinary frequency response and minimum bandwidth pulse.

FIGURE 24.11 Generation of PR signal.

FIGURE 24.12 Precoding for a PR channel.

A particular partial response is often identified by the polynomial

$$\sum_{k=0}^K h_k D^k$$

where D (for delay) takes the place of the usual z^{-1} in the z transform of the sequence $\{h_k\}$. For example, duobinary is also referred to as $1 + D$ partial response.

In general, more complicated system responses than those shown in Figs. 24.9 and 24.10 can be generated by choosing more nonzero coefficients in the sequence $\{h_k\}$. This complicates detection, however, because of the additional intersymbol interference that is generated.

Rather than modulating a PR pulse $h(t)$, a PR signal can also be generated by filtering the sequence of transmitted levels $\{A_i\}$. This is shown in Fig. 24.11. Namely, the transmitted levels are first passed through a discrete-time (digital) filter with transfer function $P_d(e^{j2\pi fT})$ (where the subscript d indicates discrete). [Note that $P_d(e^{j2\pi fT})$ can be selected to be $H_{eq}(e^{j2\pi fT})$.] The outputs of this filter form the PAM signal, where the pulse shaping filter $P(f) = 1, |f| < 1/(2T)$ and is zero elsewhere. If the transmitted levels $\{A_i\}$ are selected independently and are identically distributed, then the transmitted spectrum is $\sigma_A^2 |P_d(e^{j2\pi fT})|^2$ for $|f| < 1/(2T)$ and is zero for $|f| > 1/(2T)$, where $\sigma_A^2 = E[|A_k|^2]$.

Shaping the transmitted spectrum to have nulls coincident with nulls in the channel response potentially offers significant performance advantages. By introducing intersymbol interference, however, PR signalling increases the number of received signal levels, which increases the complexity of the detector and may reduce immunity to noise. For example, the set of received signal levels for duobinary signalling is $\{0, \pm 2\}$ from which the transmitted levels $\{\pm 1\}$ must be estimated. The performance of a particular PR scheme depends on the channel characteristics as well as the type of detector used at the receiver. We now describe a simple suboptimal detection strategy.

Precoding

Consider the received signal sample Eq. (24.27) with duobinary signalling. If the receiver has correctly de-coded the symbol A_{k-1} , then in the absence of noise A_k can be decoded by subtracting A_{k-1} from the received sample y_k . If an error occurs, however, then subtracting the preceding symbol estimate from the received sample will cause the error to propagate to successive detected symbols. To avoid this problem, the transmitted levels can be **precoded** in such a way as to compensate for the intersymbol interference introduced by the overall partial response.

We first illustrate precoding for duobinary PR. The sequence of operations is illustrated in Fig. 24.12. Let $\{b_k\}$ denote the sequence of source bits where $b_k \in \{0, 1\}$. This sequence is transformed to the sequence $\{b'_k\}$ by the operation

$$b'_k = b_k \oplus b'_{k-1} \tag{24.33}$$

TABLE 24.1 Example of Precoding for Duobinary PR

$\{b_i\}$:	1	0	0	1	1	1	0	0	1	0
$\{b'_i\}$:	0	1	1	1	0	1	0	0	0	1
$\{A_i\}$:	-1	1	1	1	-1	1	-1	-1	-1	1
$\{y_i\}$:	0	2	2	0	0	0	-2	-2	0	2

where \oplus denotes modulo 2 addition (exclusive OR). The sequence $\{b'_k\}$ is mapped to the sequence of binary transmitted signal levels $\{A_k\}$ according to

$$A_k = 2b'_k - 1 \quad (24.34)$$

That is, $b'_k = 0$ ($b'_k = 1$) is mapped to the transmitted level $A_k = -1$ ($A_k = 1$). In the absence of noise, the received symbol is then

$$y_k = A_k + A_{k-1} = 2(b'_k + b'_{k-1} - 1) \quad (24.35)$$

and combining Eqs. (24.33) and (24.35) gives

$$b_k = \left(\frac{1}{2}y_k + 1 \right) \bmod 2 \quad (24.36)$$

That is, if $y_k = \pm 2$, then $b_k = 0$, and if $y_k = 0$, then $b_k = 1$. Precoding, therefore, enables the detector to make *symbol-by-symbol* decisions that do not depend on previous decisions. Table 24.1 shows a sequence of transmitted bits $\{b_i\}$, precoded bits $\{b'_i\}$, transmitted signal levels $\{A_i\}$, and received samples $\{y_i\}$.

The preceding precoding technique can be extended to multilevel PAM and to other PR channels. Suppose that the PR is specified by

$$H_{\text{eq}}(D) = \sum_{k=0}^K h_k D^k$$

where the coefficients are integers and that the source symbols $\{b_k\}$ are selected from the set $\{0, 1, \dots, M-1\}$. These symbols are transformed to the sequence $\{b'_k\}$ via the precoding operation

$$b'_k = \left(b_k - \sum_{i=1}^K h_i b'_{k-i} \right) \bmod M \quad (24.37)$$

Because of the modulo operation, each symbol b'_k is also in the set $\{0, 1, \dots, M-1\}$. The k th transmitted signal level is given by

$$A_k = 2b'_k - (M-1) \quad (24.38)$$

so that the set of transmitted levels is $\{-(M-1), \dots, (M-1)\}$ (i.e., a shifted version of the set of values assumed by b_k). In the absence of noise, the received sample is

$$y_k = \sum_{i=0}^K h_i A_{k-i} \quad (24.39)$$

and it can be shown that the k th source symbol is given by

$$b_k = \frac{1}{2}(y_k + (M-1) \cdot H_{\text{eq}}(1)) \bmod M \quad (24.40)$$

Precoding the symbols $\{b_k\}$ in this manner, therefore, enables symbol-by-symbol decisions at the receiver. In the presence of noise, more sophisticated detection schemes (e.g., maximum likelihood) can be used with PR signalling to obtain improvements in performance.

24.6 Additional Considerations

In many applications, bandwidth and intersymbol interference are not the only important considerations for selecting baseband pulses. Here we give a brief discussion of additional practical constraints that may influence this selection.

Average Transmitted Power and Spectral Constraints

The constraint on average transmitted power varies according to the application. For example, low-average power is highly desirable for mobile wireless applications that use battery-powered transmitters. In many applications (e.g., digital subscriber loops, as well as digital radio), constraints are imposed to limit the amount of interference, or crosstalk, radiated into neighboring receivers and communications systems. Because this type of interference is frequency dependent, the constraint may take the form of a spectral mask that specifies the maximum allowable transmitted power as a function of frequency. For example, crosstalk in wireline channels is generally caused by capacitive coupling and increases as a function of frequency. Consequently, to reduce the amount of crosstalk generated at a particular transmitter, the pulse shaping filter generally attenuates high frequencies more than low frequencies.

In radio applications where signals are assigned different frequency bands, constraints on the transmitted spectrum are imposed to limit *adjacent-channel interference*. This interference is generated by transmitters assigned to adjacent frequency bands. Therefore, a constraint is needed to limit the amount of *out-of-band power* generated by each transmitter, in addition to an overall average power constraint. To meet this constraint, the transmitter filter in Fig. 24.3 must have a sufficiently steep rolloff at the edges of the assigned frequency band. (Conversely, if the transmitted signals are time multiplexed, then the duration of the system impulse response must be contained within the assigned time slot.)

Peak-to-Average Power

In addition to a constraint on average transmitted power, a *peak-power* constraint is often imposed as well. This constraint is important in practice for the following reasons:

1. The dynamic range of the transmitter is limited. In particular, saturation of the output amplifier will “clip” the transmitted waveform.
2. Rapid fades can severely distort signals with high peak-to-average power.
3. The transmitted signal may be subjected to nonlinearities. Saturation of the output amplifier is one example. Another example that pertains to wireline applications is the companding process in the voice telephone network [5]. Namely, the compander used to reduce quantization noise for pulse-code modulated voice signals introduces amplitude-dependent distortion in data signals.

The preceding impairments or constraints indicate that the transmitted waveform should have a low **peak-to-average power ratio (PAR)**. For a transmitted waveform $x(t)$, the PAR is defined as

$$\text{PAR} = \frac{\max |x(t)|^2}{E\{|x(t)|^2\}}$$

where $E(\cdot)$ denotes expectation. Using binary signalling with rectangular pulse shapes minimizes the PAR. However, this compromises bandwidth efficiency. In applications where PAR should be low, binary signalling with rounded pulses are often used. Operating RF power amplifiers with power back-off can also reduce PAR, but leads to inefficient amplification.

For an **orthogonal frequency division multiplexing (OFDM)** system, it is well known that the transmitted signal can exhibit a very high PAR compared to an equivalent single-carrier system. Hence more sophisticated approaches to PAR reduction are required for OFDM. Some proposed approaches are described in [8] and references therein. These include altering the set of transmitted symbols and setting aside certain OFDM tones specifically to minimize PAR.

Channel and Receiver Characteristics

The type of channel impairments encountered and the type of detection scheme used at the receiver can also influence the choice of a transmitted pulse shape. For example, a constant amplitude pulse is appropriate for a fast fading environment with noncoherent detection. The ability to track channel characteristics, such as phase, may allow more bandwidth efficient pulse shapes in addition to multilevel signalling.

High-speed data communications over time-varying channels requires that the transmitter and/or receiver adapt to the changing channel characteristics. Adapting the transmitter to compensate for a time-varying channel requires a feedback channel through which the receiver can notify the transmitter of changes in channel characteristics. Because of this extra complication, adapting the receiver is often preferred to adapting the transmitter pulse shape. However, the following examples are notable exceptions.

1. The current IS-95 air interface for direct-sequence code-division multiple access adapts the transmitter power to control the amount of interference generated and to compensate for channel fades. This can be viewed as a simple form of adaptive transmitter pulse shaping in which a single parameter associated with the pulse shape is varied.
2. Multitone modulation divides the channel bandwidth into small subbands, and the transmitted power and source bits are distributed among these subbands to maximize the information rate. The received signal-to-noise ratio for each subband must be transmitted back to the transmitter to guide the allocation of transmitted bits and power [1].

In addition to multitone modulation, *adaptive precoding* (also known as Tomlinson–Harashima precoding [4,11]) is another way in which the transmitter can adapt to the channel frequency response. Adaptive precoding is an extension of the technique described earlier for partial-response channels. Namely, the equivalent discrete-time channel impulse response is measured at the receiver and sent back to the transmitter, where it is used in a precoder. The precoder compensates for the intersymbol interference introduced by the channel, allowing the receiver to detect the data by a simple threshold operation. Both multitone modulation and precoding have been used with wireline channels (voiceband modems and digital subscriber loops).

Complexity

Generation of a bandwidth-efficient signal requires a filter with a sharp cutoff. In addition, bandwidth-efficient pulse shapes can complicate other system functions, such as timing and carrier recovery. If sufficient bandwidth is available, the cost can be reduced by using a rectangular pulse shape with a simple detection strategy (low-pass filter and threshold).

Tolerance to Interference

Interference is one of the primary channel impairments associated with digital radio. In addition to adjacent-channel interference described earlier, *cochannel interference* may be generated by other transmitters assigned to the same frequency band as the desired signal. Cochannel interference can be controlled through frequency (and perhaps time slot) assignments and by pulse shaping. For example,

assuming fixed average power, increasing the bandwidth occupied by the signal lowers the power spectral density and decreases the amount of interference into a narrowband system that occupies part of the available bandwidth. Sufficient bandwidth spreading, therefore, enables wideband signals to be overlaid on top of narrowband signals without disrupting either service.

Probability of Intercept and Detection

The broadcast nature of wireless channels generally makes eavesdropping easier than for wired channels. A requirement for most commercial as well as military applications is to guarantee the privacy of user conversations (low probability of intercept). An additional requirement, in some applications, is that determining whether or not communications is taking place must be difficult (low probability of detection). Spread-spectrum waveforms are attractive in these applications since spreading the pulse energy over a wide frequency band decreases the power spectral density and, hence, makes the signal less visible. Power-efficient modulation combined with coding enables a further reduction in transmitted power for a target error rate.

24.7 Examples

We conclude this chapter with a brief description of baseband pulse shapes used in existing and emerging standards for digital mobile cellular and Personal Communications Services (PCS).

Global System for Mobile Communications (GSM)

The European GSM standard for digital mobile cellular communications operates in the 900-MHz frequency band and is based on time-division multiple access (TDMA) [9]. The U.S. version operates at 1900 MHz, and is called PCS-1900. A special variant of binary FSK is used called *Gaussian minimum-shift keying (GMSK)*. The GMSK modulator is illustrated in Fig. 24.13. The input to the modulator is a binary PAM signal $s(t)$, given by Eq. (24.3), where the pulse $p(t)$ is a Gaussian function and $|s(t)| < 1$. This waveform frequency modulates the carrier f_c , so that the (passband) transmitted signal is

$$w(t) = K \cos \left[2\pi f_c t + 2\pi f_d \int_{-\infty}^t s(\tau) d\tau \right]$$

The maximum frequency deviation from the carrier is $f_d = 1/(2T)$, which characterizes minimum-shift keying. This technique can be used with a noncoherent receiver that is easy to implement. Because the transmitted signal has a constant envelope, the data can be reliably detected in the presence of rapid fades that are characteristic of mobile radio channels.

U.S. Digital Cellular (IS-136)

The IS-136 air interface (formerly IS-54) operates in the 800 MHz band and is based on TDMA [3]. There is also a 1900 MHz version of IS-136. The baseband signal is given by Eq. (24.3) where the symbols are complex-valued, corresponding to quadrature phase modulation. The pulse has a square-root raised cosine spectrum with 35% excess bandwidth.

FIGURE 24.13 Generation of GMSK signal; LPF is low-pass filter.

Interim Standard-95

The IS-95 air interface for digital mobile cellular uses spread-spectrum signalling (CDMA) in the 800-MHz band [10]. There is also a 1900 MHz version of IS-95. The baseband transmitted pulse shapes are analogous to those shown in Fig. 24.2, where the number of square pulses (chips) per bit is 128. To improve spectral efficiency the (wideband) transmitted signal is filtered by an approximation to an ideal low-pass response with a small amount of excess bandwidth. This shapes the chips so that they resemble minimum bandwidth pulses.

Personal Access Communications System (PACS)

Both PACS and the Japanese personal handy phone (PHP) system are TDMA systems which have been proposed for personal communications systems (PCS), and operate near 2 GHz [2]. The baseband signal is given by Eq. (24.3) with four complex symbols representing four-phase quadrature modulation. The baseband pulse has a square-root raised cosine spectrum with 50% excess bandwidth.

Defining Terms

Baseband signal: A signal with frequency content centered around DC.

Equivalent discrete-time transfer function: A discrete-time transfer function (z transform) that relates the transmitted amplitudes to received samples in the absence of noise.

Excess bandwidth: That part of the baseband transmitted spectrum which is not contained within the Nyquist band.

Eye diagram: Superposition of segments of a received PAM signal that indicates the amount of intersymbol interference present.

Frequency-shift keying: A digital modulation technique in which the transmitted pulse is sinusoidal, where the frequency is determined by the source bits.

Intersymbol interference: The additive contribution (interference) to a received sample from transmitted symbols other than the symbol to be detected.

Matched filter: The receiver filter with impulse response equal to the time-reversed, complex conjugate impulse response of the combined transmitter filter-channel impulse response.

Nyquist band: The narrowest frequency band that can support a PAM signal without intersymbol interference (the interval $[-1/(2T), 1/(2T)]$ where $1/T$ is the symbol rate).

Nyquist criterion: A condition on the overall frequency response of a PAM system that ensures the absence of intersymbol interference.

Orthogonal frequency division multiplexing (OFDM): Modulation technique in which the transmitted signal is the sum of low-bit-rate narrowband digital signals modulated on orthogonal carriers.

Partial-response signalling: A signalling technique in which a controlled amount of intersymbol interference is introduced at the transmitter in order to shape the transmitted spectrum.

Precoding: A transformation of source symbols at the transmitter that compensates for intersymbol interference introduced by the channel.

Pulse amplitude modulation (PAM): A digital modulation technique in which the source bits are mapped to a sequence of amplitudes that modulate a transmitted pulse.

Raised cosine pulse: A pulse shape with Fourier transform that decays to zero according to a raised cosine; see Eq. (24.18). The amount of excess bandwidth is conveniently determined by a single parameter (α).

Spread spectrum: A signalling technique in which the pulse bandwidth is many times wider than the Nyquist bandwidth.

Zero-forcing criterion: A design constraint which specifies that intersymbol interference be eliminated.

25.1 Characterization of Channel Distortion

Many communication channels, including telephone channels and some radio channels, may be generally characterized as band-limited linear filters. Consequently, such channels are described by their frequency response $C(f)$, which may be expressed as

$$C(f) = A(f)e^{j\theta(f)} \quad (25.1)$$

where $A(f)$ is called the *amplitude response* and $\theta(f)$ is called the *phase response*. Another characteristic that is sometimes used in place of the phase response is the *envelope delay* or *group delay*, which is defined as

$$\tau(f) = -\frac{1}{2\pi} \frac{d\theta(f)}{df} \quad (25.2)$$

A channel is said to be nondistorting or ideal if, within the bandwidth W occupied by the transmitted signal, $A(f) = \text{const}$ and $\theta(f)$ is a linear function of frequency [or the envelope delay $\tau(f) = \text{const}$]. On the other hand, if $A(f)$ and $\tau(f)$ are not constant within the bandwidth occupied by the transmitted signal, the channel distorts the signal. If $A(f)$ is not constant, the distortion is called *amplitude distortion* and if $\tau(f)$ is not constant, the distortion on the transmitted signal is called *delay distortion*.

As a result of the amplitude and delay distortion caused by the nonideal channel frequency response characteristic $C(f)$, a succession of pulses transmitted through the channel at rates comparable to the bandwidth W are smeared to the point that they are no longer distinguishable as well-defined pulses at the receiving terminal. Instead, they overlap and, thus, we have **intersymbol interference (ISI)**. As an example of the effect of delay distortion on a transmitted pulse, Fig. 25.1(a) illustrates a band-limited pulse having zeros periodically spaced in time at points labeled $\pm T$, $\pm 2T$, etc. If information is conveyed by the pulse amplitude, as in pulse amplitude modulation (PAM), for example, then one can transmit a sequence of pulses, each of which has a peak at the periodic zeros of the other pulses. Transmission of the pulse through a channel modeled as having a linear envelope delay characteristic $\tau(f)$ [quadratic

FIGURE 25.1 Effect of channel distortion: (a) channel input, (b) channel output, (c) equalizer output.

phase $\theta(f)$], however, results in the received pulse shown in Fig. 25.1(b) having zero crossings that are no longer periodically spaced. Consequently, a sequence of successive pulses would be smeared into one another, and the peaks of the pulses would no longer be distinguishable. Thus, the channel delay distortion results in intersymbol interference. As will be discussed in this chapter, it is possible to compensate for the nonideal frequency response characteristic of the channel by use of a filter or equalizer at the demodulator. Figure 25.1(c) illustrates the output of a linear equalizer that compensates for the linear distortion in the channel.

The extent of the intersymbol interference on a telephone channel can be appreciated by observing a frequency response characteristic of the channel. Figure 25.2 illustrates the measured average amplitude and delay as a function of frequency for a medium-range (180–725 mile) telephone channel of the switched telecommunications network as given by Duffy and Tratcher [17]. We observe that the usable band of the channel extends from about 300 Hz to about 3000 Hz. The corresponding impulse response of the average channel is shown in Fig. 25.3. Its duration is about 10 ms. In comparison, the transmitted symbol rates on such a channel may be of the order of 2500 pulses or symbols per second. Hence, intersymbol interference might extend over 20–30 symbols.

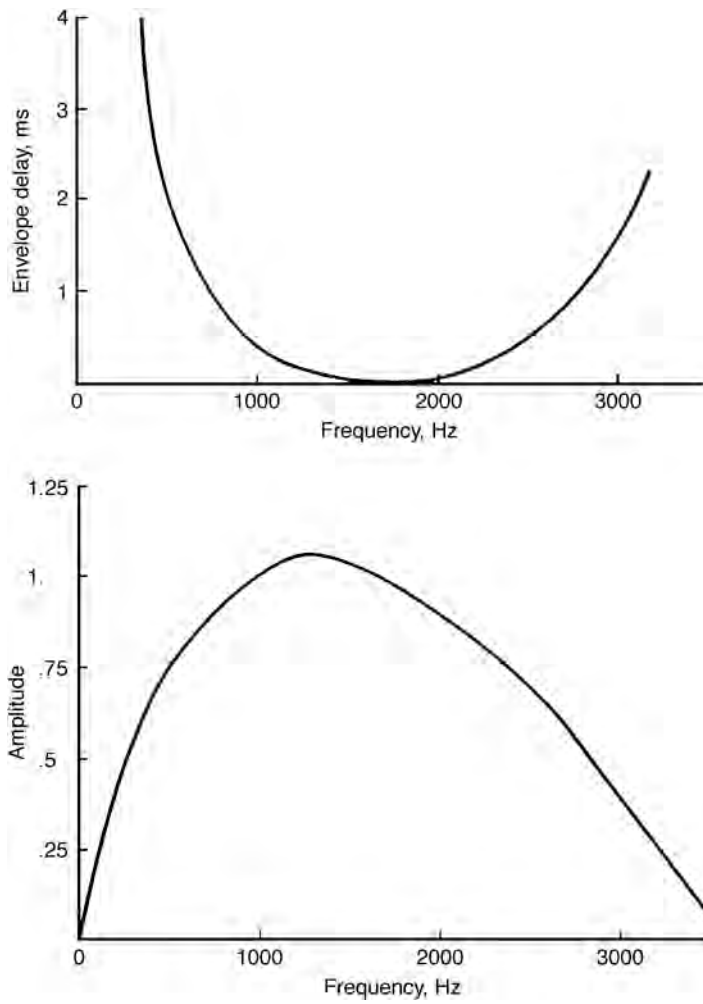

FIGURE 25.2 Average amplitude and delay characteristics of medium-range telephone channel.

FIGURE 25.3 Impulse response of average channel with amplitude and delay shown in Fig. 25.2.

FIGURE 25.4 Scattering function of a medium-range tropospheric scatter channel.

Besides telephone channels, there are other physical channels that exhibit some form of time dispersion and, thus, introduce intersymbol interference. Radio channels, such as short-wave ionospheric propagation (HF), tropospheric scatter, and mobile cellular radio are three examples of time-dispersive wireless channels. In these channels, time dispersion and, hence, intersymbol interference is the result of multiple propagation paths with different path delays. The number of paths and the relative time delays among the paths vary with time and, for this reason, these radio channels are usually called time-variant multipath channels. The time-variant multipath conditions give rise to a wide variety of frequency response characteristics. Consequently, the frequency response characterization that is used for telephone channels is inappropriate for time-variant multipath channels. Instead, these radio channels are characterized statistically in terms of the scattering function, which, in brief, is a two-dimensional representation of the average received signal power as a function of relative time delay and Doppler frequency (see Proakis, 2001).

For illustrative purposes, a scattering function measured on a medium-range (150 mile) tropospheric scatter channel is shown in Fig. 25.4. The total time duration (multipath spread) of the channel response is approximately $0.7 \mu\text{s}$ on the average, and the spread between half-power points in Doppler frequency is a little less than 1 Hz on the strongest path and somewhat larger on the other paths. Typically, if one is transmitting at a rate of 10^7 symbols/s over such a channel, the multipath spread of $0.7 \mu\text{s}$ will result in intersymbol interference that spans about seven symbols.

25.2 Characterization of Intersymbol Interference

In a digital communication system, channel distortion causes intersymbol interference, as illustrated in the preceding section. In this section, we shall present a model that characterizes the ISI. The digital modulation methods to which this treatment applies are PAM, phase-shift keying (PSK), and quadrature amplitude modulation (QAM). The transmitted signal for these three types of modulation may be expressed as

$$\begin{aligned}
 s(t) &= u_c(t) \cos 2\pi f_c t - u_s(t) \sin 2\pi f_c t \\
 &= \text{Re}[u(t)e^{j2\pi f_c t}]
 \end{aligned}
 \tag{25.3}$$

where $v(t) = v_c(t) + jv_s(t)$ is called the *equivalent low-pass signal*, f_c is the carrier frequency, and $\text{Re}[\]$ denotes the real part of the quantity in brackets.

In general, the equivalent low-pass signal is expressed as

$$u(t) = \sum_{n=0} I_n g_T(t - nT) \tag{25.4}$$

where $g_T(t)$ is the basic pulse shape that is selected to control the spectral characteristics of the transmitted signal, $\{I_n\}$ is the sequence of transmitted information symbols selected from a signal constellation consisting of M points, and T is the signal interval ($1/T$ is the symbol rate). For PAM, PSK, and QAM, the values of I_n are points from M -ary signal constellations. Figure 25.5 illustrates the signal constellations for the case of $M = 8$ signal points. Note that for PAM, the signal constellation is one-dimensional. Hence, the equivalent low-pass signal $v(t)$ is real valued, i.e., $v_s(t) = 0$ and $v_c(t) = v(t)$. For M -ary ($M > 2$) PSK and QAM, the signal constellations are two-dimensional and, hence, $v(t)$ is complex valued.

(a) PAM

(b) PSK

(c) QAM

FIGURE 25.5 $M = 8$ signal constellations for PAM, PSK, and QAM.

The signal $s(t)$ is transmitted over a bandpass channel that may be characterized by an equivalent low-pass frequency response $C(f)$. Consequently, the equivalent low-pass received signal can be represented as

$$r(t) = \sum_{n=0}^{\infty} I_n h(t - nT) + w(t) \quad (25.5)$$

where $h(t) = g_r(t) * c(t)$, $c(t)$ is the impulse response of the equivalent low-pass channel, the asterisk denotes convolution, and $w(t)$ represents the additive noise in the channel.

To characterize the ISI, suppose that the received signal is passed through a receiving filter and then sampled at the rate $1/T$ samples/s. In general, the optimum filter at the receiver is matched to the received signal pulse $h(t)$. Hence, the frequency response of this filter is $H^*(f)$. We denote its output as

$$y(t) = \sum_{n=0}^{\infty} I_n x(t - nT) + v(t) \quad (25.6)$$

where $x(t)$ is the signal pulse response of the receiving filter, i.e., $X(f) = H(f)H^*(f) = |H(f)|^2$, and $v(t)$ is the response of the receiving filter to the noise $w(t)$. Now, if $y(t)$ is sampled at times $t = kT$, $k = 0, 1, 2, \dots$, we have

$$\begin{aligned} y(kT) \equiv y_k &= \sum_{n=0}^{\infty} I_n x(kT - nT) + v(kT) \\ &= \sum_{n=0}^{\infty} I_n x_{k-n} + v_k, \quad k = 0, 1, \dots \end{aligned} \quad (25.7)$$

The sample values $\{y_k\}$ can be expressed as

$$y_k = x_0 \left(I_k + \frac{1}{x_0} \sum_{\substack{n=0 \\ n \neq k}}^{\infty} I_n x_{k-n} \right) + v_k, \quad k = 0, 1, \dots \quad (25.8)$$

The term x_0 is an arbitrary scale factor, which we arbitrarily set equal to unity for convenience. Then

$$y_k = I_k + \sum_{\substack{n=0 \\ n \neq k}}^{\infty} I_n x_{k-n} + v_k \quad (25.9)$$

The term I_k represents the desired information symbol at the k th sampling instant, the term

$$\sum_{\substack{n=0 \\ n \neq k}}^{\infty} I_n x_{k-n} \quad (25.10)$$

represents the ISI, and v_k is the additive noise variable at the k th sampling instant.

The amount of ISI and noise in a digital communications system can be viewed on an oscilloscope. For PAM signals, we can display the received signal $y(t)$ on the vertical input with the horizontal sweep

FIGURE 25.6 Examples of eye patterns for binary and quaternary amplitude shift keying (or PAM).

FIGURE 25.7 Effect of intersymbol interference on eye opening.

rate set at $1/T$. The resulting oscilloscope display is called an *eye pattern* because of its resemblance to the human eye. For example, Fig. 25.6 illustrates the eye patterns for binary and four-level PAM modulation. The effect of ISI is to cause the eye to close, thereby reducing the margin for additive noise to cause errors. Figure 25.7 graphically illustrates the effect of ISI in reducing the opening of a binary eye. Note that intersymbol interference distorts the position of the *zero* crossings and causes a reduction in the eye opening. Thus, it causes the system to be more sensitive to a synchronization error.

For PSK and QAM it is customary to display the eye pattern as a two-dimensional scatter diagram illustrating the sampled values $\{y_k\}$ that represent the decision variables at the sampling instants. Figure 25.8 illustrates such an eye pattern for an 8-PSK signal. In the absence of intersymbol interference and noise, the superimposed signals at the sampling instants would result in eight distinct points corresponding to the eight transmitted signal phases. Intersymbol interference and noise result in a deviation of the received samples $\{y_k\}$ from the desired 8-PSK signal. The larger the intersymbol interference and noise, the larger the scattering of the received signal samples relative to the transmitted signal points.

In practice, the transmitter and receiver filters are designed for zero ISI at the desired sampling times $t = kT$. Thus, if $G_T(f)$ is the frequency response of the transmitter filter and $G_R(f)$ is the frequency

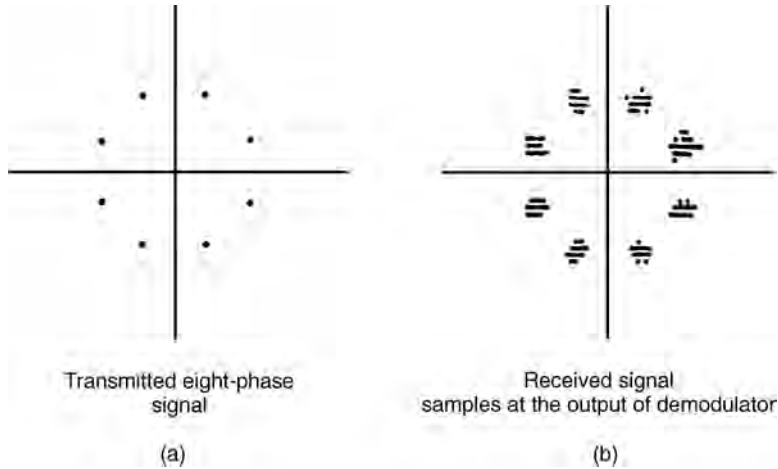

FIGURE 25.8 Two-dimensional digital eye patterns.

response of the receiver filter, then the product $G_T(f)G_R(f)$ is designed to yield zero ISI. For example, the product $G_T(f)G_R(f)$ may be selected as

$$G_T(f)G_R(f) = X_{rc}(f) \quad (25.11)$$

where $X_{rc}(f)$ is the raised-cosine frequency response characteristic, defined as

$$X_{rc}(f) = \begin{cases} T, & 0 \leq |f| \leq (1 - \alpha)/2T \\ \frac{T}{2} \left[1 + \cos \frac{\pi T}{\alpha} \left(|f| - \frac{1 - \alpha}{2T} \right) \right], & \frac{1 - \alpha}{2T} \leq |f| \leq \frac{1 + \alpha}{2T} \\ 0, & |f| > \frac{1 + \alpha}{2T} \end{cases} \quad (25.12)$$

where α is called the *rolloff factor*, which takes values in the range $0 \leq \alpha \leq 1$, and $1/T$ is the symbol rate. The frequency response $X_{rc}(f)$ is illustrated in Fig. 25.9(a) for $\alpha = 0, 1/2$, and 1 . Note that when $\alpha = 0$, $X_{rc}(f)$ reduces to an ideal brick wall physically nonrealizable frequency response with bandwidth occupancy $1/2T$. The frequency $1/2T$ is called the *Nyquist frequency*. For $\alpha > 0$, the bandwidth occupied by the desired signal $X_{rc}(f)$ beyond the Nyquist frequency $1/2T$ is called the *excess bandwidth* and is usually expressed as a percentage of the Nyquist frequency. For example, when $\alpha = 1/2$, the excess bandwidth is 50%, and when $\alpha = 1$, the excess bandwidth is 100%. The signal pulse $x_{rc}(t)$ having the raised-cosine spectrum is

$$x_{rc}(t) = \frac{\sin \pi t/T}{\pi t/T} \frac{\cos(\pi \alpha t/T)}{1 - 4\alpha^2 t^2/T^2} \quad (25.13)$$

Figure 25.9(b) illustrates $x_{rc}(t)$ for $\alpha = 0, 1/2$, and 1 . Note that $x_{rc}(t) = 1$ at $t = 0$ and $x_{rc}(t) = 0$ at $t = kT$, $k = \pm 1, \pm 2, \dots$. Consequently, at the sampling instants $t = kT$, $k \neq 0$, there is no ISI from adjacent symbols when there is no channel distortion. In the presence of channel distortion, however, the ISI given by Eq. (25.10) is no longer zero, and a channel equalizer is needed to minimize its effect on system performance.

FIGURE 25.9 Pulses having a raised-cosine spectrum.

25.3 Linear Equalizers

The most common type of channel equalizer used in practice to reduce ISI is a linear transversal filter with adjustable coefficients $\{c_i\}$, as shown in Fig. 25.10.

On channels whose frequency response characteristics are unknown but are time invariant, we may measure the channel characteristics and adjust the parameters of the equalizer; once adjusted, the parameters remain fixed during the transmission of data. Such equalizers are called **preset equalizers**. On the other hand, **adaptive equalizers** update their parameters on a periodic basis during the transmission of data and, thus, they are capable of tracking a slowly time-varying channel response.

First, let us consider the design characteristics for a linear equalizer from a frequency domain viewpoint. Figure 25.11 shows a block diagram of a system that employs a linear filter as a **channel equalizer**.

The demodulator consists of a receiver filter with frequency response $G_R(f)$ in cascade with a channel equalizing filter that has a frequency response $G_E(f)$. As indicated in the preceding section, the receiver filter response $G_R(f)$ is matched to the transmitter response, i.e., $G_R(f) = G_T^*(f)$, and the product $G_R(f)G_T(f) = X_{rc}(f)$ is usually designed so that there is zero ISI at the sampling instants as, for example, when $G_R(f)G_T(f) = X_{rc}(f)$.

For the system shown in Fig. 25.11, in which the channel frequency response is not ideal, the desired condition for zero ISI is

$$G_T(f)C(f)G_R(f)G_E(f) = X_{rc}(f) \quad (25.14)$$

where $X_{rc}(f)$ is the desired raised-cosine spectral characteristic. Since $G_T(f)G_R(f) = X_{rc}(f)$ by design, the frequency response of the equalizer that compensates for the channel distortion is

$$G_E(f) = \frac{1}{C(f)} = \frac{1}{|C(f)|} e^{-j\theta_c(f)} \quad (25.15)$$

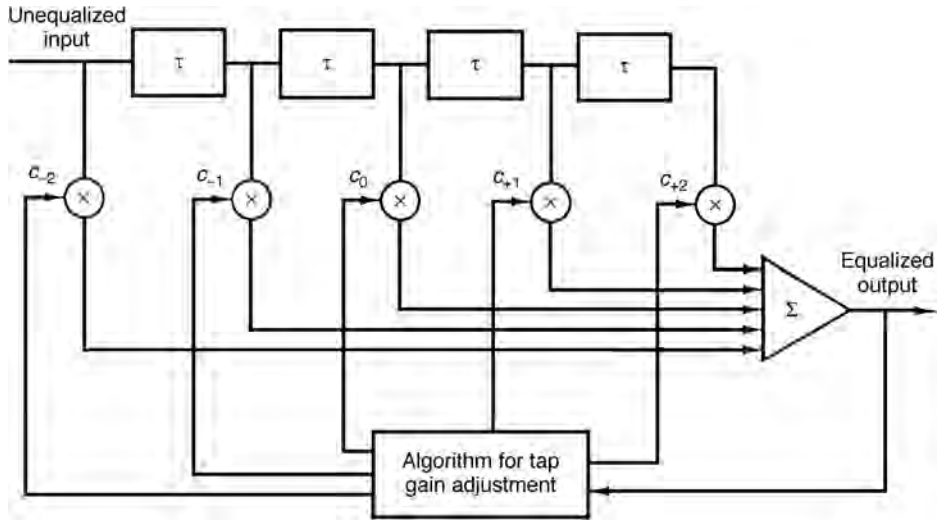

FIGURE 25.10 Linear transversal filter.

FIGURE 25.11 Block diagram of a system with an equalizer.

Thus, the amplitude response of the equalizer is $|G_E(f)| = 1/|C(f)|$ and its phase response is $\theta_E(f) = -\theta_C(f)$. In this case, the equalizer is said to be the *inverse channel filter* to the channel response.

We note that the inverse channel filter completely eliminates ISI caused by the channel. Since it forces the ISI to be zero at the sampling instants $t = kT, k = 0, 1, \dots$, the equalizer is called a **zero-forcing equalizer**. Hence, the input to the detector is simply

$$z_k = I_k + \eta_k, \quad k = 0, 1, \dots \quad (25.16)$$

where η_k represents the additive noise and I_k is the desired symbol.

In practice, the ISI caused by channel distortion is usually limited to a finite number of symbols on either side of the desired symbol. Hence, the number of terms that constitute the ISI in the summation given by Eq. (25.10) is finite. As a consequence, in practice, the channel equalizer is implemented as a finite duration impulse response (FIR) filter, or transversal filter, with adjustable tap coefficients $\{c_n\}$, as illustrated in Fig. 25.10. The time delay τ between adjacent taps may be selected as large as T , the symbol interval, in which case the FIR equalizer is called a **symbol-spaced equalizer**. In this case, the input to the equalizer is the sampled sequence given by Eq. (25.7). We note that when the symbol rate $1/T < 2W$, however, frequencies in the received signal above the folding frequency $1/T$ are aliased into frequencies below $1/T$. In this case, the equalizer compensates for the aliased channel-distorted signal.

On the other hand, when the time delay τ between adjacent taps is selected such that $1/\tau \geq 2W > 1/T$, no aliasing occurs, and, hence, the inverse channel equalizer compensates for the true channel distortion. Since $\tau < T$, the channel equalizer is said to have *fractionally spaced taps* and it is called a **fractionally spaced equalizer**. In practice, τ is often selected as $\tau = T/2$. Notice that, in this case, the sampling rate at the output of the filter $G_R(f)$ is $2/T$.

The impulse response of the FIR equalizer is

$$g_E(t) = \sum_{n=-N}^N c_n \delta(t - n\tau) \quad (25.17)$$

and the corresponding frequency response is

$$G_E(f) = \sum_{n=-N}^N c_n e^{-j2\pi f n \tau} \quad (25.18)$$

where $\{c_n\}$ are the $(2N + 1)$ equalizer coefficients and N is chosen sufficiently large so that the equalizer spans the length of the ISI, i.e., $2N + 1 \geq L$, where L is the number of signal samples spanned by the ISI. Since $X(f) = G_T(f)C(f)G_R(f)$ and $x(t)$ is the signal pulse corresponding to $X(f)$, then the equalized output signal pulse is

$$q(t) = \sum_{n=-N}^N c_n x(t - n\tau) \quad (25.19)$$

The zero-forcing condition can now be applied to the samples of $q(t)$ taken at times $t = mT$. These samples are

$$q(mT) = \sum_{n=-N}^N c_n x(mT - n\tau), \quad m = 0, \pm 1, \dots, \pm N \quad (25.20)$$

Since there are $2N + 1$ equalizer coefficients, we can control only $2N + 1$ sampled values of $q(t)$. Specifically, we may force the conditions

$$q(mT) = \sum_{n=-N}^N c_n x(mT - n\tau) = \begin{cases} 1, & m = 0 \\ 0, & m = \pm 1, \pm 2, \dots, \pm N \end{cases} \quad (25.21)$$

which may be expressed in matrix form as $\mathbf{X}\mathbf{c} = \mathbf{q}$, where \mathbf{X} is a $(2N + 1) \times (2N + 1)$ matrix with elements $\{x(mT - n\tau)\}$, \mathbf{c} is the $(2N + 1)$ coefficient vector, and \mathbf{q} is the $(2N + 1)$ column vector with one nonzero element. Thus, we obtain a set of $2N + 1$ linear equations for the coefficients of the zero-forcing equalizer.

We should emphasize that the FIR zero-forcing equalizer does not completely eliminate ISI because it has a finite length. As N is increased, however, the residual ISI can be reduced, and in the limit as $N \rightarrow \infty$, the ISI is completely eliminated.

Example 25.1

Consider a channel distorted pulse $x(t)$, at the input to the equalizer, given by the expression

$$x(t) = \frac{1}{1 + \left(\frac{2t}{T}\right)^2}$$

where $1/T$ is the symbol rate. The pulse is sampled at the rate $2/T$ and equalized by a zero-forcing equalizer. Determine the coefficients of a five-tap zero-forcing equalizer.

Solution 25.1

According to Eq. (25.21), the zero-forcing equalizer must satisfy the equations

$$q(mT) = \sum_{n=-2}^2 c_n x(mT - nT/2) = \begin{cases} 1, & m = 0 \\ 0, & m = \pm 1, \pm 2 \end{cases}$$

The matrix \mathbf{X} with elements $x(mT - nT/2)$ is given as

$$\mathbf{X} = \begin{bmatrix} \frac{1}{5} & \frac{1}{10} & \frac{1}{17} & \frac{1}{26} & \frac{1}{37} \\ 1 & \frac{1}{2} & \frac{1}{5} & \frac{1}{10} & \frac{1}{17} \\ \frac{1}{5} & \frac{1}{2} & 1 & \frac{1}{2} & \frac{1}{5} \\ \frac{1}{17} & \frac{1}{10} & \frac{1}{5} & \frac{1}{2} & 1 \\ \frac{1}{37} & \frac{1}{26} & \frac{1}{17} & \frac{1}{10} & \frac{1}{5} \end{bmatrix} \quad (25.22)$$

The coefficient vector \mathbf{c} and the vector \mathbf{q} are given as

$$\mathbf{c} = \begin{bmatrix} c_{-2} \\ c_{-1} \\ c_0 \\ c_1 \\ c_2 \end{bmatrix} \quad \mathbf{q} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} \quad (25.23)$$

Then, the linear equations $\mathbf{X}\mathbf{c} = \mathbf{q}$ can be solved by inverting the matrix \mathbf{X} . Thus, we obtain

$$\mathbf{c}_{\text{opt}} = \mathbf{X}^{-1}\mathbf{q} = \begin{bmatrix} -2.2 \\ 4.9 \\ -3 \\ 4.9 \\ -2.2 \end{bmatrix} \quad (25.24)$$

One drawback to the zero-forcing equalizer is that it ignores the presence of additive noise. As a consequence, its use may result in significant noise enhancement. This is easily seen by noting that in a frequency range where $C(f)$ is small, the channel equalizer $G_E(f) = 1/C(f)$ compensates by placing a large gain in that frequency range. Consequently, the noise in that frequency range is greatly enhanced. An alternative is to relax the zero ISI condition and select the channel equalizer characteristic such that the combined power in the residual ISI and the additive noise at the output of the equalizer is minimized. A channel equalizer that is optimized based on the minimum mean square error (MMSE) criterion accomplishes the desired goal.

To elaborate, let us consider the noise corrupted output of the FIR equalizer, which is

$$z(t) = \sum_{n=-N}^N c_n y(t - n\tau) \quad (25.25)$$

where $y(t)$ is the input to the equalizer, given by Eq. (25.6). The equalizer output is sampled at times $t = mT$. Thus, we obtain

$$z(mT) = \sum_{n=-1}^N c_n y(mT - n\tau) \quad (25.26)$$

The desired response at the output of the equalizer at $t = mT$ is the transmitted symbol I_m . The error is defined as the difference between I_m and $z(mT)$. Then, the mean square error (MSE) between the actual output sample $z(mT)$ and the desired values I_m is

$$\begin{aligned} MSE &= E|z(mT) - I_m|^2 \\ &= E \left[\left| \sum_{n=-N}^N c_n y(mT - n\tau) - I_m \right|^2 \right] \\ &= \sum_{n=-N}^N \sum_{k=-N}^N c_n c_k R_y(n-k) - 2 \sum_{k=-N}^N c_k R_{IY}(k) + E(|I_m|^2) \end{aligned} \quad (25.27)$$

where the correlations are defined as

$$\begin{aligned} R_Y(n-k) &= E[y^*(mT - n\tau)y(mT - k\tau)] \\ R_{IY}(k) &= E[y(mT - k\tau)I_m^*] \end{aligned} \quad (25.28)$$

and the expectation is taken with respect to the random information sequence $\{I_m\}$ and the additive noise.

The minimum MSE solution is obtained by differentiating Eq. (25.27) with respect to the equalizer coefficients $\{c_n\}$. Thus, we obtain the necessary conditions for the minimum MSE as

$$\sum_{n=-N}^N c_n R_Y(n-k) = R_{IY}(k), \quad k = 0, \pm 1, 2, \dots, \pm N \quad (25.29)$$

These are the $(2N + 1)$ linear equations for the equalizer coefficients. In contrast to the zero-forcing solution already described, these equations depend on the stastical properties (the autocorrelation) of the noise as well as the ISI through the autocorrelation $R_Y(n)$.

In practice, the autocorrelation matrix $R_Y(n)$ and the crosscorrelation vector $R_{IY}(n)$ are unknown *a priori*. These correlation sequences can be estimated, however, by transmitting a test signal over the channel and using the time-average estimates

$$\begin{aligned} \hat{R}_Y(n) &= \frac{1}{K} \sum_{k=1}^K y^*(kT - n\tau)y(kT) \\ \hat{R}_{IY}(n) &= \frac{1}{K} \sum_{k=1}^K y(kT - n\tau)I_k^* \end{aligned} \quad (25.30)$$

in place of the ensemble averages to solve for the equalizer coefficients given by Eq. (25.29).

Adaptive Linear Equalizers

We have shown that the tap coefficients of a linear equalizer can be determined by solving a set of linear equations. In the zero-forcing optimization criterion, the linear equations are given by Eq. (25.21). On the other hand, if the optimization criterion is based on minimizing the MSE, the optimum equalizer coefficients are determined by solving the set of linear equations given by Eq. (25.29).

In both cases, we may express the set of linear equations in the general matrix form

$$\mathbf{B}\mathbf{c} = \mathbf{d} \tag{25.31}$$

where \mathbf{B} is a $(2N + 1) \times (2N + 1)$ matrix, \mathbf{c} is a column vector representing the $2N + 1$ equalizer coefficients, and \mathbf{d} is a $(2N + 1)$ -dimensional column vector. The solution of Eq. (25.31) yields

$$\mathbf{c}_{\text{opt}} = \mathbf{B}^{-1}\mathbf{d} \tag{25.32}$$

In practical implementations of equalizers, the solution of Eq. (25.31) for the optimum coefficient vector is usually obtained by an iterative procedure that avoids the explicit computation of the inverse of the matrix \mathbf{B} . The simplest iterative procedure is the method of steepest descent, in which one begins by choosing arbitrarily the coefficient vector \mathbf{c} , say \mathbf{c}_0 . This initial choice of coefficients corresponds to a point on the criterion function that is being optimized. For example, in the case of the MSE criterion, the initial guess \mathbf{c}_0 corresponds to a point on the quadratic MSE surface in the $(2N + 1)$ -dimensional space of coefficients. The gradient vector, defined as \mathbf{g}_0 , which is the derivative of the MSE with respect to the $2N + 1$ filter coefficients, is then computed at this point on the criterion surface, and each tap coefficient is changed in the direction opposite to its corresponding gradient component. The change in the j th tap coefficient is proportional to the size of the j th gradient component.

For example, the gradient vector denoted as \mathbf{g}_k , for the MSE criterion, found by taking the derivatives of the MSE with respect to each of the $2N + 1$ coefficients, is

$$\mathbf{g}_k = \mathbf{B}\mathbf{c}_k - \mathbf{d}, \quad k = 0, 1, 2, \dots \tag{25.33}$$

Then the coefficient vector \mathbf{c}_k is updated according to the relation

$$\mathbf{c}_{k+1} = \mathbf{c}_k - \Delta\mathbf{g}_k \tag{25.34}$$

where Δ is the *step-size parameter* for the iterative procedure. To ensure convergence of the iterative procedure, Δ is chosen to be a small positive number. In such a case, the gradient vector \mathbf{g}_k converges toward zero, i.e., $\mathbf{g}_k \rightarrow \mathbf{0}$ as $k \rightarrow \infty$, and the coefficient vector $\mathbf{c}_k \rightarrow \mathbf{c}_{\text{opt}}$ as illustrated in Fig. 25.12 based on two-dimensional optimization. In general, convergence of the equalizer tap coefficients to \mathbf{c}_{opt} cannot

FIGURE 25.12 Example of convergence characteristics of a gradient algorithm.

be attained in a finite number of iterations with the steepest-descent method. The optimum solution \mathbf{c}_{opt} , however, can be approached as closely as desired in a few hundred iterations. In digital communication systems that employ channel equalizers, each iteration corresponds to a time interval for sending one symbol and, hence, a few hundred iterations to achieve convergence to \mathbf{c}_{opt} corresponds to a fraction of a second.

Adaptive channel equalization is required for channels whose characteristics change with time. In such a case, the ISI varies with time. The channel equalizer must track such time variations in the channel response and adapt its coefficients to reduce the ISI. In the context of the preceding discussion, the optimum coefficient vector \mathbf{c}_{opt} varies with time due to time variations in the matrix \mathbf{B} and, for the case of the *MSE* criterion, time variations in the vector \mathbf{d} . Under these conditions, the iterative method described can be modified to use estimates of the gradient components. Thus, the algorithm for adjusting the equalizer tap coefficients may be expressed as

$$\hat{\mathbf{c}}_{k+1} = \hat{\mathbf{c}}_k - \Delta \hat{\mathbf{g}}_k \quad (25.35)$$

where $\hat{\mathbf{g}}_k$ denotes an estimate of the gradient vector \mathbf{g}_k and $\hat{\mathbf{c}}_k$ denotes the estimate of the tap coefficient vector.

In the case of the *MSE* criterion, the gradient vector \mathbf{g}_k given by Eq. (25.33) may also be expressed as

$$\mathbf{g}_k = -E(e_k \mathbf{y}_k^*)$$

An estimate $\hat{\mathbf{g}}_k$ of the gradient vector at the k th iteration is computed as

$$\hat{\mathbf{g}}_k = -e_k \mathbf{y}_k^* \quad (25.36)$$

where e_k denotes the difference between the desired output from the equalizer at the k th time instant and the actual output $z(kT)$, and \mathbf{y}_k denotes the column vector of $2N + 1$ received signal values contained in the equalizer at time instant k . The *error signal* e_k is expressed as

$$e_k = I_k - z_k \quad (25.37)$$

where $z_k = z(kT)$ is the equalizer output given by Eq. (25.26) and I_k is the desired symbol. Hence, by substituting Eq. (25.36) into Eq. (25.35), we obtain the adaptive algorithm for optimizing the tap coefficients (based on the *MSE* criterion) as

$$\hat{\mathbf{c}}_{k+1} = \hat{\mathbf{c}}_k + \Delta e_k \mathbf{y}_k^* \quad (25.38)$$

Since an estimate of the gradient is used in Eq. (25.38), the algorithm is called a stochastic **gradient algorithm**; it is also known as the **LMS algorithm**.

A block diagram of an adaptive equalizer that adapts its tap coefficients according to Eq. (25.38) is illustrated in Fig. 25.13. Note that the difference between the desired output I_k and the actual output z_k from the equalizer is used to form the error signal e_k . This error is scaled by the step-size parameter Δ , and the scaled error signal Δe_k multiplies the received signal values $\{y(kT - n\tau)\}$ at the $2N + 1$ taps. The products $\Delta e_k y^*(kT - n\tau)$ at the $(2N + 1)$ taps are then added to the previous values of the tap coefficients to obtain the updated tap coefficients, according to Eq. (25.38). This computation is repeated as each new symbol is received. Thus, the equalizer coefficients are updated at the symbol rate.

Initially, the adaptive equalizer is trained by the transmission of a known pseudorandom sequence $\{I_m\}$ over the channel. At the demodulator, the equalizer employs the known sequence to adjust its coefficients. Upon initial adjustment, the adaptive equalizer switches from a **training mode** to a **decision-directed mode**,

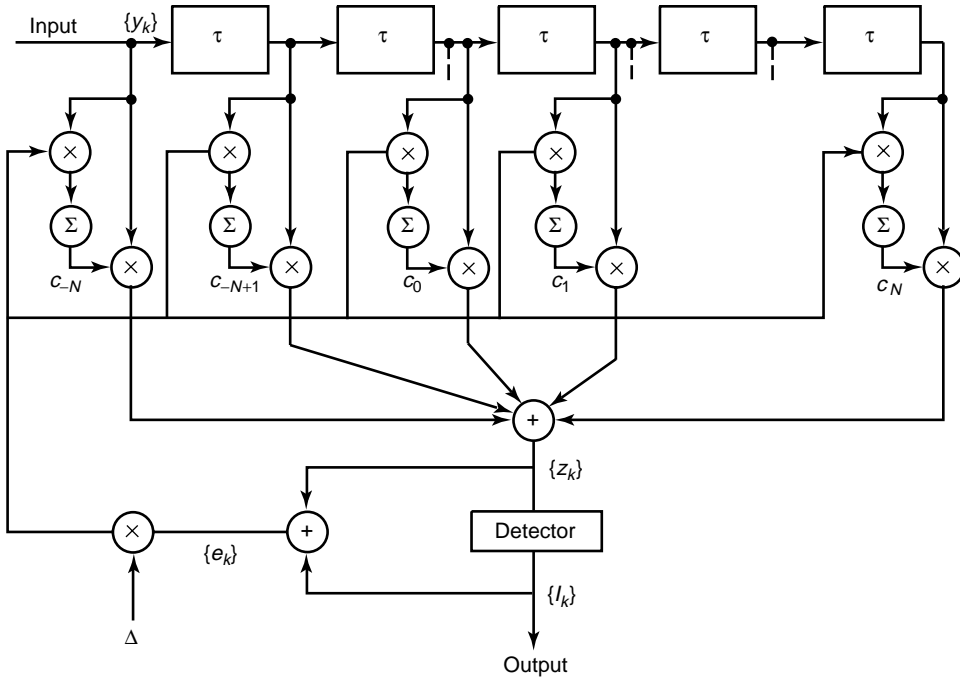

FIGURE 25.13 Linear adaptive equalizer based on the MSE criterion.

in which case the decisions at the output of the detector are sufficiently reliable so that the error signal is formed by computing the difference between the detector output and the equalizer output, i.e.,

$$e_k = \tilde{I}_k - z_k \quad (25.39)$$

where \tilde{I}_k is the output of the detector. In general, decision errors at the output of the detector occur infrequently and, consequently, such errors have little effect on the performance of the tracking algorithm given by Eq. (25.38).

A rule of thumb for selecting the step-size parameter so as to ensure convergence and good tracking capabilities in slowly varying channels is

$$\Delta = \frac{1}{5(2N+1)P_R} \quad (25.40)$$

where P_R denotes the received signal-plus-noise power, which can be estimated from the received signal (see Proakis, 2001).

The convergence characteristic of the stochastic gradient algorithm in Eq. (25.38) is illustrated in Fig. 25.14. These graphs were obtained from a computer simulation of an 11-tap adaptive equalizer operating on a channel with a rather modest amount of ISI. The input signal-plus-noise power P_R was normalized to unity. The rule of thumb given in Eq. (25.40) for selecting the step size gives $\Delta = 0.018$. The effect of making Δ too large is illustrated by the large jumps in MSE as shown for $\Delta = 0.115$. As Δ is decreased, the convergence is slowed somewhat, but a lower MSE is achieved, indicating that the estimated coefficients are closer to \mathbf{c}_{opt} .

FIGURE 25.14 Initial convergence characteristics of the LMS algorithm with different step sizes.

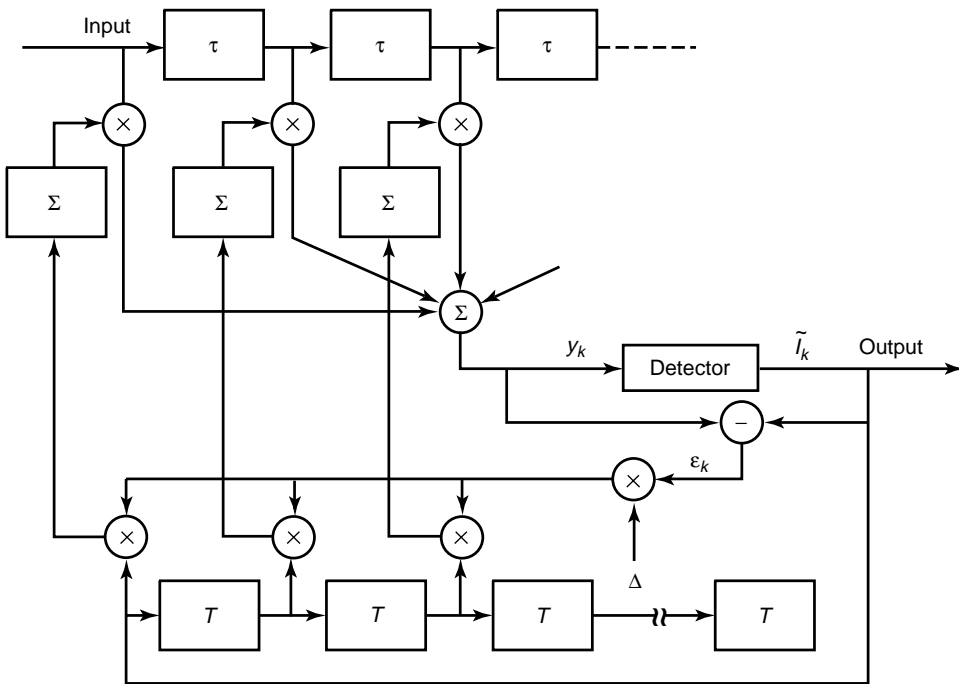

FIGURE 25.15 An adaptive zero-forcing equalizer.

Although we have described in some detail the operation of an adaptive equalizer that is optimized on the basis of the MSE criterion, the operation of an adaptive equalizer based on the zero-forcing method is very similar. The major difference lies in the method for estimating the gradient vectors g_k at each iteration. A block diagram of an adaptive zero-forcing equalizer is shown in Fig. 25.15. For more details on the tap coefficient update method for a zero-forcing equalizer, the reader is referred to the papers by Lucky [2,3] and the text by Proakis [2001].

25.4 Decision-Feedback Equalizer

The linear filter equalizers described in the preceding section are very effective on channels, such as wire line telephone channels, where the ISI is not severe. The severity of the ISI is directly related to the spectral characteristics and not necessarily to the time span of the ISI. For example, consider the ISI resulting from the two channels that are illustrated in Fig. 25.16. The time span for the ISI in channel A is 5 symbol intervals on each side of the desired signal component, which has a value of 0.72. On the other hand, the time span for the ISI in channel B is one symbol interval on each side of the desired signal component, which has a value of 0.815. The energy of the total response is normalized to unity for both channels.

In spite of the shorter ISI span, channel B results in more severe ISI. This is evidenced in the frequency response characteristics of these channels, which are shown in Fig. 25.17. We observe that channel B has a spectral null (the frequency response $C(f) = 0$ for some frequencies in the band $|f| \leq W$) at $f = 1/2T$, whereas this does not occur in the case of channel A. Consequently, a linear equalizer will introduce a large gain in its frequency response to compensate for the channel null. Thus, the noise in channel B will be enhanced much more than in channel A. This implies that the performance of the linear equalizer for channel B will be significantly poorer than that for channel A. This fact is borne out by the computer simulation results for the performance of the two linear equalizers shown in Fig. 25.18. Hence, the basic limitation of a linear equalizer is that it performs poorly on channels having spectral nulls. Such channels are often encountered in radio communications, such as ionospheric transmission at frequencies below 30 MHz, and mobile radio channels, such as those used for cellular radio communications.

A **decision-feedback equalizer (DFE)** is a nonlinear equalizer that employs previous decisions to eliminate the ISI caused by previously detected symbols on the current symbol to be detected. A simple block diagram for a DFE is shown in Fig. 25.19. The DFE consists of two filters. The first filter is called a *feedforward filter* and it is generally a fractionally spaced FIR filter with adjustable tap coefficients. This filter is identical in form to the linear equalizer already described. Its input is the received filtered signal

FIGURE 25.16 Two channels with ISI.

FIGURE 25.17 Amplitude spectra for (a) channel A shown in Fig. 25.16(a) and (b) channel B shown in Fig. 25.16(b).

$y(t)$ sampled at some rate that is a multiple of the symbol rate, e.g., at rate $2/T$. The second filter is a *feedback filter*. It is implemented as an FIR filter with symbol-spaced taps having adjustable coefficients. Its input is the set of previously detected symbols. The output of the feedback filter is subtracted from the output of the feedforward filter to form the input to the detector. Thus, we have

$$z_m = \sum_{n=-N_1}^0 c_n y(mT - n\tau) - \sum_{n=1}^{N_2} b_n \bar{I}_{m-n} \quad (25.41)$$

where $\{c_n\}$ and $\{b_n\}$ are the adjustable coefficients of the feedforward and feedback filters, respectively, \bar{I}_{m-n} , $n = 1, 2, \dots, N_2$ are the previously detected symbols, $N_1 + 1$ is the length of the feedforward filter, and N_2 is the length of the feedback filter. Based on the input z_m , the detector determines which of the possible transmitted symbols is closest in distance to the input signal I_m . Thus, it makes its decision and outputs \tilde{I}_m . What makes the **DFE** nonlinear is the nonlinear characteristic of the detector that provides the input to the feedback filter.

FIGURE 25.18 Error-rate performance of linear MSE equalizer.

FIGURE 25.19 Block diagram of DFE.

The tap coefficients of the feedforward and feedback filters are selected to optimize some desired performance measure. For mathematical simplicity, the MSE criterion is usually applied, and a stochastic gradient algorithm is commonly used to implement an adaptive DFE. Figure 25.20 illustrates the block diagram of an adaptive DFE whose tap coefficients are adjusted by means of the LMS stochastic gradient algorithm. Figure 25.21 illustrates the probability of error performance of the DFE, obtained by computer simulation, for binary PAM transmission over channel B. The gain in performance relative to that of a linear equalizer is clearly evident.

We note that the decision errors from the detector that are fed back to the feedback filter result in a loss in the performance of the DFE, as illustrated in Fig. 25.21. This loss can be avoided by placing the feedback filter of the DFE at the transmitter and the feedforward filter at the receiver. Thus, the problem of error propagation due to incorrect decisions in the feedback filter is completely eliminated.

This approach is especially suitable for wireline channels, where the channel characteristics do not vary significantly with time. The linear fractionally-spaced feedforward filter of the DFE, placed at the receiver, compensates for the ISI that results from any small time variations in the channel response. The synthesis

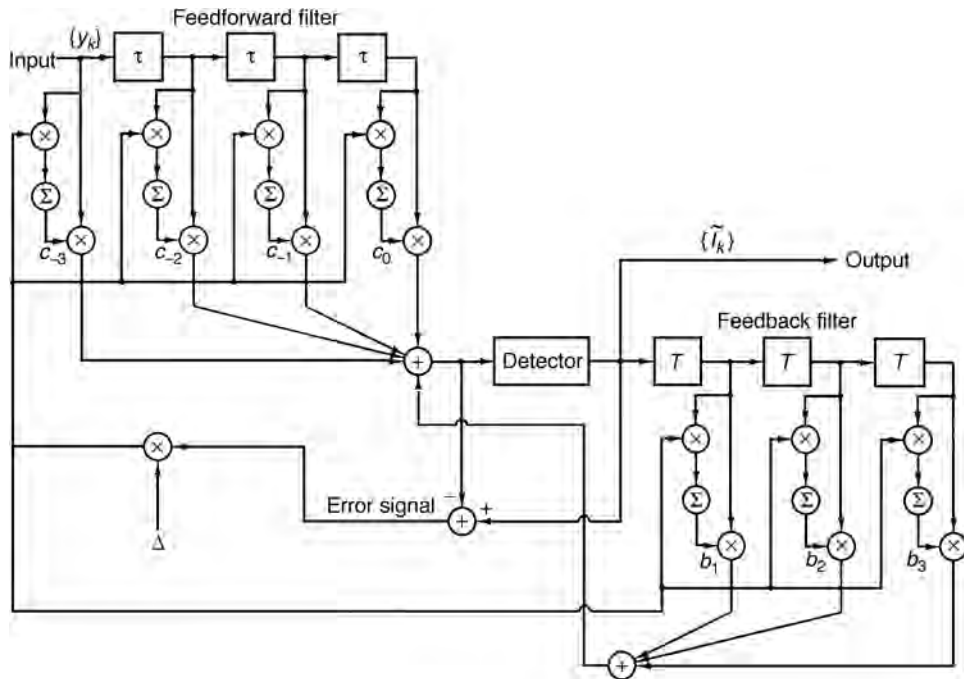

FIGURE 25.20 Adaptive DFE.

FIGURE 25.21 Performance of DFE with and without error propagation.

of the feedback filter of the DFE at the transmitter side is usually performed after the response of the channel is measured at the receiver by the transmission of a channel probe signal and the receiver sends to the transmitter the coefficients of the feedback filter.

One problem with this approach to implementing the DFE is that the signal points at the transmitter, after subtracting the tail (postcursors) of the ISI, generally have a larger dynamic range than the original signal constellation and, consequently, require a larger transmitter power. This problem is solved by precoding the information symbols prior to transmission as described by Tomlinson [5] and Harashima and Miyakawa [6].

25.5 Maximum-Likelihood Sequence Detection

Although the DFE outperforms a linear equalizer, it is not the optimum equalizer from the viewpoint of minimizing the probability of error in the detection of the information sequence $\{I_k\}$ from the received signal samples $\{y_k\}$ given in Eq. (25.5). In a digital communication system that transmits information over a channel that causes ISI, the optimum detector is a maximum-likelihood symbol sequence detector which produces at its output the most probable symbol sequence $\{\tilde{I}_k\}$ for the given received sampled sequence $\{y_k\}$. That is, the detector finds the sequence $\{\tilde{I}_k\}$ that maximizes the *likelihood function*.

$$\Lambda(\{I_k\}) = \ln p(\{y_k\}|\{I_k\}) \quad (25.42)$$

where $p(\{y_k\}|\{I_k\})$ is the joint probability of the received sequence $\{y_k\}$ conditioned on $\{I_k\}$. The sequence of symbols $\{\tilde{I}_k\}$ that maximizes this joint conditional probability is called the **maximum-likelihood sequence detector**.

An algorithm that implements maximum-likelihood sequence detection (MLSD) is the Viterbi algorithm, which was originally devised for decoding convolutional codes. For a description of this algorithm in the context of sequence detection in the presence of ISI, the reader is referred to the paper by Forney [1] and the text by Proakis, 2001.

The major drawback of MLSD for channels with ISI is the exponential behavior in computational complexity as a function of the span of the ISI. Consequently, MLSD is practical only for channels where the ISI spans only a few symbols and the ISI is severe in the sense that it causes a severe degradation in the performance of a linear equalizer or a decision-feedback equalizer. For example, Fig. 25.22 illustrates the error probability performance of the Viterbi algorithm for a binary PAM signal transmitted through channel B (see Fig. 25.16). For purposes of comparison, we also illustrate the probability of error for a DFE. Both results were obtained by computer simulation. We observe that the performance of the maximum likelihood sequence detector is about 4.5 dB better than that of the DFE at an error probability of 10^{-4} . Hence, this is one example where the ML sequence detector provides a significant performance gain on a channel with a relatively short ISI span.

The MLSD implemented efficiently by use of the Viterbi algorithm is widely used in mobile cellular communications systems, such as the GSM system, where the span of the ISI is limited to five or six symbols.

The performance advantage of the MLSD, compared with the linear equalizer and the DFE, in channels with severe ISI, has motivated a significant amount of research on methods for reducing the complexity of MLSD while retaining its superior performance characteristics. One approach to the design of reduced complexity MLSD is focused on methods that reduce the length of the ISI span by pre-processing the received signal prior to the maximum-likelihood detector. Falconer and Magee [7] and Beare [8] used a linear equalizer (LE) to reduce the span of the ISI to some small specified length prior to the Viterbi detector. Lee and Hill [9] employed a DFE in place of the LE. Thus, the large ISI span in the channel is reduced to a sufficiently small length, called the *desired impulse response*, so that the complexity of the Viterbi detector following the LE or DFE is manageable. The choice of the desired impulse response is tailored to the ISI characteristics of the channel. This approach to reducing the complexity of the Viterbi detector has proved very effective in high-density magnetic recording systems, as illustrated in the papers by Siegel and Wolf [10], Tyner and Proakis [11], Moon and Carley [12] and Proakis [13].

FIGURE 25.22 Comparison of performance between MLSE and decision-feedback equalization for channel B of Fig. 25.16.

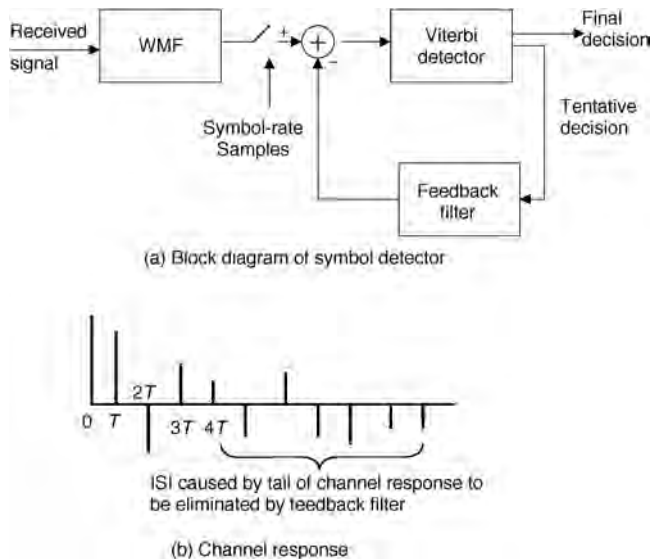

FIGURE 25.23 Reduced complexity MLSD using feedback from the Viterbi detector.

From a performance viewpoint, a more effective approach for reducing the computational complexity of the MLSD is to employ decision feedback within the Viterbi detector to reduce the effective length of the ISI. A prefilter, called a *whitened matched filter (WMF)* precedes the Viterbi detector and reduces the channel to one that has a minimum phase characteristic, as shown in Fig. 25.23. Preliminary decisions from the Viterbi detector are fed back through a filter, as shown in Fig. 25.23, to synthesize the tail in the ISI caused by the channel response and, thus, to cancel the ISI at the input to the Viterbi detector. The preliminary decisions from the Viterbi detector can be obtained by using the most probable surviving sequence in the Viterbi detector. This approach to tail cancellation had been called *global feedback* by

Bergmans et al. [14]. Alternatively, Bergmans et al. [14] propose that one can use preliminary decisions corresponding to each surviving sequence to cancel the ISI in the tail of the corresponding surviving sequence. Thus, the ISI can be perfectly cancelled when the correct sequence is among the surviving sequences in the Viterbi detector, even if it is not the most probable sequence at any instant in time in the detection process. Bergmans et al. [14] named this approach to tail cancellations as using *local feedback*. Simulation results given in the paper by Bergmans et al. [14] indicate that local feedback gives superior performance compared with global feedback.

25.6 Maximum *A Posteriori* Probability Detector and Turbo Equalization

For a channel with ISI, the MLSD minimizes the probability of error in the detection of a sequence of transmitted information symbols. Instead of using the MLSD to recover the information symbols, we may use a detector that makes optimum decisions on a symbol-by-symbol basis based on the computation of the maximum *a posteriori* probability (MAP) for each symbol. Consequently, the MAP detector is optimum in the sense that it minimizes the probability of a symbol error. Basically, the MAP criterion for the information symbol I_k at the k th time interval involves the computation of the *a posteriori* probabilities $P(I_k = S_i / y_{k+D}, y_{k+D-1}, \dots, y_1)$ where $\{y_k\}$ is the observed received sequence, D is a delay parameter that is chosen to be equal to or exceed the span of the ISI, and $\{S_i, 1 \leq i \leq M\}$ is the set of M possible points in the signal constellation. A decision is made of the symbol corresponding to the largest *a posteriori* probability.

A computationally efficient iterative detection algorithm based on the MAP criterion is described in a paper by Bahl et al. [15] and is usually called the BCJR algorithm. In general, the computational complexity of the BCJR algorithm is greater than that of the Viterbi algorithm, so the latter is preferable in implementing an optimum detector for a channel with ISI.

An equalizer based on the MAP criterion is particularly suitable in a receiver that couples the equalizer to a decoder that performs iterative decoding. To elaborate, suppose that the transmitter of a digital communication system employs a binary systematic convolutional encoder followed by a block interleaver and modulator. The channel is a linear time-dispersive channel that introduces ISI having a finite span. In such a case, we view the channel with ISI as an inner encoder in a serially (cascade) concatenated code, as shown in Fig. 25.24. By treating the system as a serially concatenated coded system, we can apply recently developed iterative decoding techniques which provide a significant improvement in performance, compared to a system that performs the equalization and decoding operations separately.

The basic configuration of the iterative equalizer and decoder is shown in Fig. 25.25. The input to the MAP equalizer is the sequence of received signal samples $\{y_k\}$ from the receiver filter, which may be

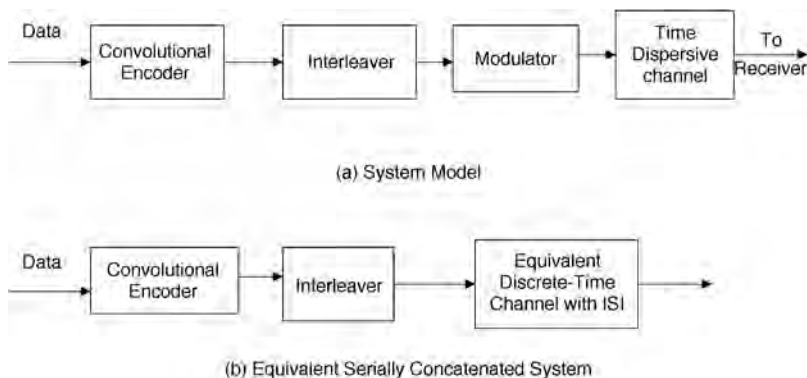

FIGURE 25.24 Channel with ISI viewed as a serially concatenated coded system.

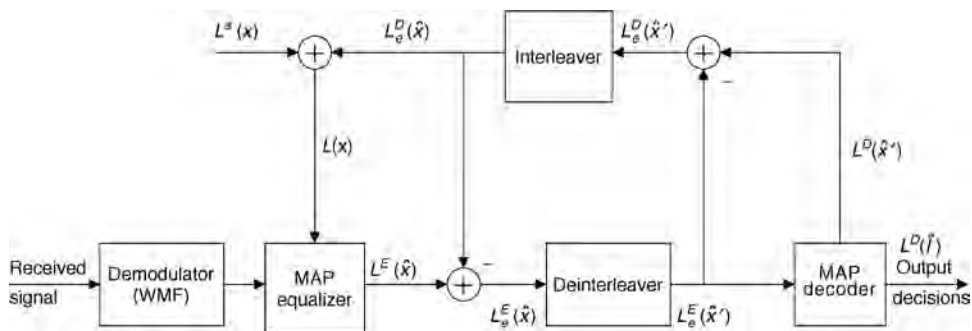

FIGURE 25.25 Iterative MAP equalization and decoding.

implemented as a WMF. The MAP equalizer employs the BCJR algorithm to compute the *a posteriori* probabilities for each of the possible M signal points and feeds to the outer decoder, after deinterleaving, the so-called *extrinsic information*, denoted by $L_e^E(\hat{x}')$. The outer decoder uses this information in computing the corresponding probabilities for each of the coded bits based on the MAP criterion. Thus, the outer decoder for the convolutional code also employs the BCJR algorithm to compute the *a posteriori* probabilities for the information bits. Then, the MAP decoder feeds back to the MAP equalizer, after interleaving, the so-called extrinsic information, denoted as $L_e^D(\hat{x})$. This information is used by the MAP equalizer in making another pass through the data and generally achieves better estimates of the coded bits. This iterative process generally continues for several iterations (usually four to eight) until little additional improvement is achieved with additional iterations.

By using a MAP equalizer in conjunction with an iterative MAP decoder, it is possible to completely eliminate the performance loss due to the ISI. The paper by Bauch et al. [16] provides a description of the computations performed by the MAP equalizer and MAP decoder and illustrates the performance gain that is achieved by joint MAP equalization and iterative decoding. The implementation of a MAP equalizer used in conjunction with an iterative MAP decoder has been called *turbo equalization*. While it yields superior performance compared to the other equalization techniques described above, turbo equalization has the disadvantage of a significantly higher computational complexity. However, we envision that this equalization technique will eventually be implemented in future communication systems that transmit information through time dispersive channels.

25.7 Conclusions

Channel equalizers are widely used in digital communication systems to mitigate the effects of ISI caused by channel distortion. Linear equalizers are widely used for high-speed modems that transmit data over telephone channels. For wireless (radio) transmission, such as in mobile cellular communications and interoffice communications, the multipath propagation of the transmitted signal results in severe ISI. Such channels require more powerful equalizers to combat the severe ISI. The decision-feedback equalizer and the MLSD are two nonlinear channel equalizers that are suitable for radio channels with severe ISI.

Turbo equalization is a newly developed method that couples a MAP equalizer to a MAP decoder to achieve superior performance compared with the conventional equalization methods such as the linear equalizer, the DFE, or MLSD, which operate independently of the decoder.

Defining Terms

Adaptive equalizer: A channel equalizer whose parameters are updated automatically and adaptively during transmission of data.

Channel equalizer: A device that is used to reduce the effects of channel distortion in a received signal.

- Decision-directed mode:** Mode for adjustment of the equalizer coefficient adaptively based on the use of the detected symbols at the output of the detector.
- Decision-feedback equalizer (DFE):** An adaptive equalizer that consists of a feedforward filter and a feedback filter, where the latter is fed with previously detected symbols that are used to eliminate the intersymbol interference due to the tail in the channel impulse response.
- Fractionally spaced equalizer:** A tapped-delay line channel equalizer in which the delay between adjacent taps is less than the duration of a transmitted symbol.
- Intersymbol interference:** Interference in a received symbol from adjacent (nearby) transmitted symbols caused by channel distortion in data transmission.
- LMS algorithm:** See stochastic gradient algorithm.
- Maximum-likelihood sequence detector:** A detector for estimating the most probable sequence of data symbols by maximizing the likelihood function of the received signal.
- Preset equalizer:** A channel equalizer whose parameters are fixed (time-invariant) during transmission of data.
- Stochastic gradient algorithm:** An algorithm for adaptively adjusting the coefficients of an equalizer based on the use of (noise-corrupted) estimates of the gradients.
- Symbol-spaced equalizer:** A tapped-delay line channel equalizer in which the delay between adjacent taps is equal to the duration of a transmitted symbol.
- Training mode:** Mode for adjustment of the equalizer coefficients based on the transmission of a known sequence of transmitted symbols.
- Zero-forcing equalizer:** A channel equalizer whose parameters are adjusted to completely eliminate intersymbol interference in a sequence of transmitted data symbols.

26.1 Introduction and General Description of a Pulse-Code Modulation (PCM) Codec-Filter

This chapter introduces the reader to the pulse-code modulation (PCM) codec-filter function and where it is used in the telephone network. A PCM codec-filter was originally used in the switching offices and network for digitizing and reconstructing the human voice. Over the last five years, linear PCM codec-filters have been used in high-speed modems at the subscriber's premise.

The name codec is an acronym from coder for the analog-to-digital converter (ADC) used to digitize voice, and decoder for the digital-to-analog converter (DAC) used for reconstructing voice. A codec is a single device that does both the ADC and DAC conversions. A PCM codec-filter includes the bandlimiting filter for the ADC and the reconstruction smoothing filter for the output of the DAC, in addition to the ADC and DAC functions. PCM codec-filter is often referred to as a PCM codec, Combo™ (from National Semiconductor), Monocircuit, or Cofidec.

PCM codec-filters were developed to transmit telephone conversations over long distances with improved performance and at lower cost. Digitizing the voice channel is relatively economical compared to expensive low-noise analog transmission equipment.

Multiple digitized voice channels can be multiplexed into one higher data rate digital channel without concern for interference or crosstalk of the analog voice information. Digitized voice data can also be received and retransmitted without attenuation and noise degradation. This digitized data could be transmitted via T1, microwave, satellite, fiber optics, RF carrier, etc. without loss to the digitized voice channel.

26.2 Where PCM Codec-Filters are Used in the Telephone Network

With the advancements in microelectronics, the PCM codec-filter function has evolved from the early 1960s' technology of passive resistor-capacitor-inductor filters with discrete analog-to-digital converter and discrete digital-to-analog converter implementations to the fully integrated devices that were introduced in the late 1970s and early 1980s. As monolithic devices, the PCM codec-filter has experienced performance improvements and cost reductions by taking advantage of the improvements in integrated circuit technology developed within the semiconductor industry. Through this evolutionary progression, the cost reductions of the PCM codec-filter function has increased their applicability to include switching systems for telephone central offices (CO), private branch exchanges (PBX), and key systems. The transmission applications have increased also to include digital loop carriers, pair gain multiplexers, telephone loop extenders, integrated services digital network (ISDN) terminals, digital cellular telephones, and digital cordless telephones. New applications have developed, including voice recognition equipment, voice storage, voice mail, and digital tapeless answering machines.

Figure 26.1 is a simplified diagram showing some of the services that the local telephone service provider has to offer. The telephone network must be able to operate in extreme weather conditions and

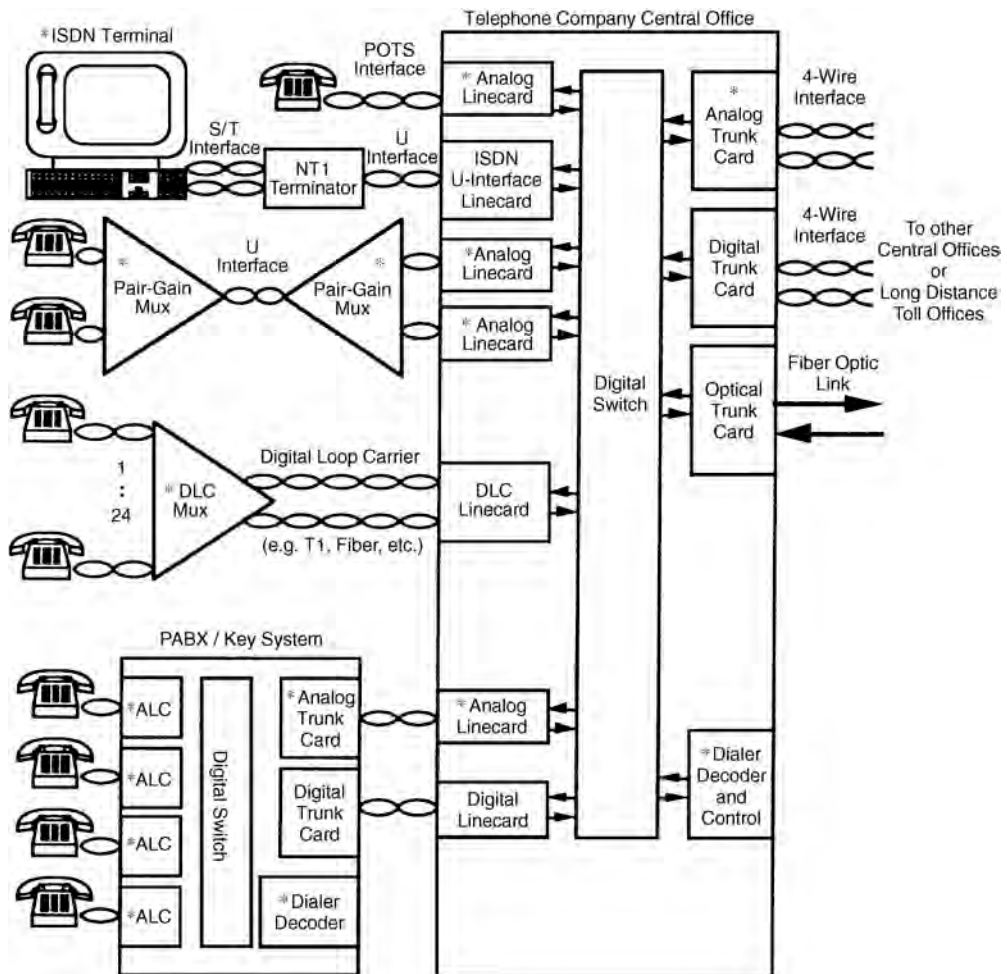

FIGURE 26.1 Public switching telephone network (PSTN).

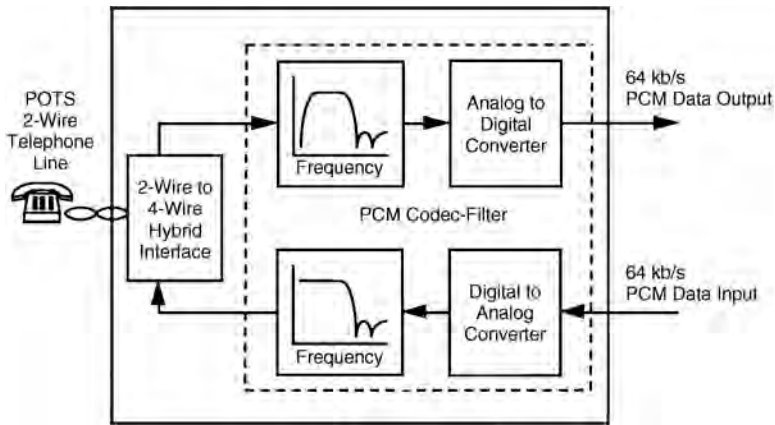

FIGURE 26.2 Analog telephone linecard.

during the loss of AC power by emergency battery backup. This requires low-power dissipation of the PCM codec-filter. Complementary metal-oxide-semiconductor (CMOS) integrated circuit (IC) fabrication technology has proven to be a reliable low-power semiconductor solution for this type of complex analog and digital very large-scale integration (VLSI) circuit. A PCM codec-filter is used in each location with an asterisk (*).

The analog linecard is the interface between the switch and the telephone wires that reach from the central office or service provider to the subscriber's telephone. The analog linecard also provides the digital interface for the switching or transmission equipment. The accepted name for analog telephone service is plain old telephone service (POTS). Figure 26.2 is a simplified block diagram for an analog linecard showing the functions of the PCM codec-filter.

The PCM codec-filter converts voice into 8-b PCM words at a conversion rate of 8 kilosamples per second. This PCM data is serially shifted out of the PCM codec-filter in the form of a serial 8-b word. This results in a 64-kb/s digital bit stream. This 64 kb/s PCM data from an analog linecard is typically multiplexed onto a PCM data bus or highway for transfer to a digital switch, where it will be routed to the appropriate output PCM highway, which routes the data to another linecard, completing the signal path for the conversation (refer to Fig. 26.1).

Transmission equipment will have multiple PCM codec-filters shifting their PCM words onto a single conductor. This is referred to as a serial bus or PCM highway. Figure 26.3 shows the 8-b PCM words

from a PCM codec-filter for one voice channel being multiplexed into a time slot on a PCM highway that can accommodate 32 voice channels. For more information on PCM switching, see the chapters in this handbook on switching systems and common channel signalling. For more information on hybrid interfaces, see the chapters in this handbook on POTS, analog hierarchy, and analog telephone channels and conditioning.

26.3 Design of Voice PCM Codec-Filters: Analog Transmission Performance and Voice Quality for Intelligibility

Filtering

The pass-band frequency response of the voice channel is roughly 300–3000 Hz. The 300–3000 Hz spectrum is where most of the energy in the human voice is located. Voice contains spectral energy below 300 Hz and above 3 kHz, but its absence is not detrimental to intelligibility. The frequency response within the passband of 300 Hz–3 kHz must be tightly controlled, because the public switching telephone network (PSTN) is allowed to have as many as seven ADC/DAC conversions end-to-end. The cumulative effects of the network plus private equipment such as PBX or key systems could audibly distort the frequency response of the voice channel with less stringent requirements. Figure 26.4 shows the typical half-channel pass-band frequency response requirement of ± 0.25 dB.

The 3-kHz bandwidth for voice signals determines the sample rate for the ADC and DAC. In a sampling environment, Nyquist theory states that to properly sample a continuous signal, it must be sampled at a frequency higher than twice the signal's highest frequency component. Minimizing the sample rate for digitizing voice is a priority since it determines the system data rates which are directly proportional to cost. The voice bandwidth of 3 kHz plus the filter transition band sampled at 8 kHz represents the best compromise that meets the Nyquist criterion.

The amount of attenuation required for frequencies of 4 kHz and higher is dictated by the required signal-to-distortion ratio of about 30 dB for acceptable voice communication as determined by the telephone industry. Frequencies in the filter transition band of 3.4–4.6 kHz must be attenuated enough such that their reconstructed alias frequencies will have a combined attenuation of about 30 dB. This permits typical filter transition band attenuation of 15 dB at 4 kHz for both the input filter for the ADC and the output reconstruction filter for the DAC. All frequencies above 4.6 kHz must be satisfactorily attenuated before the ADC conversion to prevent aliasing in-band. The requirement for out-of-band attenuation is specified by the country of interest, but it typically ranges from 25 to 32 dB for frequencies of 4600 Hz and higher.

The requirement for limiting frequencies below 300 Hz is also regionally dependent and application dependent, ranging from flat response to 20 dB or more attenuation at 50 and 60 Hz. The telephone line is susceptible to 50/60-Hz power line coupling, which must be attenuated from the signal by a high-pass filter before the ADC. Attenuation of power line frequencies is desirable to prevent 60 Hz noise during voice applications. Figure 26.4 shows a typical frequency response requirement for North American telephone equipment.

The digital-to-analog conversion process reconstructs a pulse-amplitude modulated (PAM) staircase version of the desired in-band signal, which has spectral images of the in-band signal modulated about the sample frequency and its harmonics. These high-frequency spectral images are called aliasing components which need to be attenuated to meet performance specifications. The low-pass filter used to attenuate these aliasing components is typically called a reconstruction or smoothing filter. The low-pass filter characteristics of the reconstruction filter are similar to the low-pass filter characteristics of the input antialiasing filter for the ADC.

The accuracy of these filters requires op amps with both high gain and low noise on the same monolithic substrate with precision matched capacitors which are used in the switched-capacitor filter structures. For more information on filter requirements and sampling theory, refer to the chapters in this handbook on analog modulation, sampling, and pulse-code modulation.

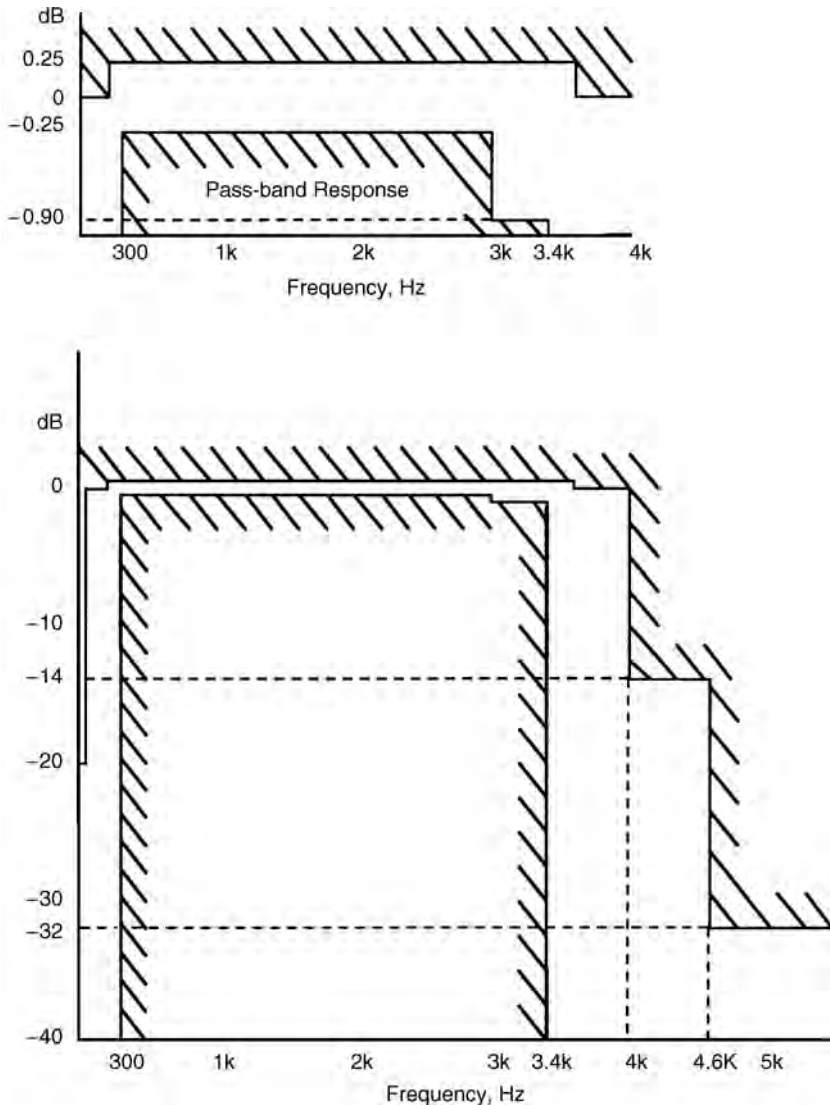

FIGURE 26.4 Typical frequency response requirement for the input filter: pass-band and stop band.

Quantizing Distortion

To digitize voice intelligibly requires a signal-to-distortion ratio of about 30 dB over a dynamic range of about 40 dB. This may be accomplished with a linear 13-b ADC and DAC, but will far exceed the required signal-to-distortion ratio for voice at amplitudes greater than 40 dB below the peak overload amplitude.

This excess performance comes at the expense of increased bits per sample which directly translates into system cost, as stated earlier. Figure 26.5 shows the signal-to-quantization distortion ratio performance of a 13-b linear DAC compared to a companded mu-law DAC. A high-speed modem application is discussed later in this chapter, which requires linear 13 b or better performance.

Two methods of data reduction are implemented, both of which use compressing the 13-b linear codes during the analog-to-digital conversion process and expanding the codes back during the digital-to-analog conversion process. These compression and expansion schemes are referred to as companding. The two companding schemes are: mu-255 law, primarily used in North America and Japan, and A-law, primarily used in Europe. Companding effectively trades the signal to distortion performance at larger

FIGURE 26.5 Signal-to-quantization distortion performance for mu-law and 13-b linear DACs compared to the telephone network requirements.

amplitudes for fewer bits for each sample. These companding schemes map the 13-b linear codes into pseudologarithmic 8-b codes. These companding schemes follow a segmented or piecewise-linear input-output transfer curve formatted as sign bit, three chord bits, and four step bits. For a given chord, all 16 of the steps have the same voltage weighting. As the voltage of the analog input increases, the four step bits increment and carry over to the three chord bits, which increment. When the chord bits increment, the step bits double their voltage weighting. This results in an effective resolution of six bits (1 sign bit + 1 effective chord bit + 4 step bits) with a sinusoidal stimulus across a 42-dB dynamic range (seven chords above zero, by 6 dB per chord, i.e., effectively 1 b). This satisfies the original requirement of 30-dB signal-to-distortion over a 40-dB dynamic range. Figure 26.6 is a graphical explanation of mu-law companding.

Note that to minimize die size area, which further cost reduces the PCM codec-filter, compressing ADC designs and expanding DAC designs are used instead of linear ADC/DAC designs with read-only memory (ROM) conversion lookup tables.

A-law companding is very similar to mu-law with three differences. The first difference is that A-law has equal voltage weighting per step for the two positive or negative chords near zero volts. In mu-law, the step weighting voltage for chord zero is one-half the step weighting voltage for A-law chord zero. This reduces the A-law resolution for small signals near the voltage origin. The second difference is that the smallest voltage of the DAC curve does not include zero volts and instead produces a positive half-step for positive zero and a negative half-step for negative zero. This is in contrast to mu-law companding, which produces a zero voltage output for both positive and negative zero PCM codes. Both mu-law and A-law have symmetric transfer curves about the zero volts origin, but mu-law has redundancy at zero volts and, therefore, effectively an unused code. The third difference between the two companding schemes deals with the data bit format. A-law inverts the least significant bit (LSB) and every other bit, leaving the sign bit unchanged relative to a conventional binary code. For example, applying the A-law data format formula to binary zero, s0000000, results in s1010101, the A-law code for +/- zero. Mu-law

FIGURE 26.6 Mu-law companding showing piecewise-linear approximation of a logarithmic curve.

Level	Mu-Law			A-Law

maintains a positive polarity for the sign bit with all of the magnitude bits inverted. Figure 26.7 shows the zero codes and full-scale codes for both mu-law and A-law companding schemes.

Mu-law and A-law companding schemes are recognized around the world. Many equipment manufacturers build products for distribution worldwide. This distribution versatility is facilitated by the PCM codec-filter being programmable for either mu-law or A-law. With the deployment of ISDN, the PCM codec-filter is located at the subscriber's location. The need to place international telephone calls dictates the need for a PCM codec-filter that is both mu-law and A-law compatible.

Gain Calibration: Transmission Level Point

The test tone amplitude for analog channels is 3 dB down from the sinusoidal clip level. This test level for a POTS line is generally 1 mW, which is 0 dBm. The telephone line historically was referred to as having a 0 dB transmission level point (TLP). (With the improvements in transmission quality and fewer

FIGURE 26.8 PCM codes for digital milliwatt.

losses, telephone lines often have attenuation pads to maintain talker/listener appropriate levels.) Amplitudes that have been TLP calibrated are given unit abbreviations that have a zero added to them, for example, dBm0. The test signal may experience gain or attenuation as it is transmitted through the network. As an example, the absolute magnitude of one electrical node for the voice channel could result in a measured value of +6 dBm when a 0 dBm0 test signal is applied. This node would be gain calibrated as having a +6 dB TLP. This would result in absolute measurements for noise having this same +6 dB of gain. To properly reference the noise, all measurements must be gain calibrated against the 0 dBm0 level, which, in this example, would result in 6 dB being subtracted from all measurements. All signals in this channel, including distortion and noise, would be attenuated by 6 dB by the time they get to the subscriber's telephone.

For PCM channels, the 0 dBm0 calibration level is nominally 3 dB down from maximum sinusoidal clip level; specifically, it is 3.17 dB down for mu-law and 3.14 dB down for A-law. These minor deviations from an ideal 3 dB result from using a simple code series, called the digital milliwatt, for generating the digital calibration signal. The digital milliwatt is a series of eight PCM codes that are repeated to generate the 1 kHz calibration tone. Figure 26.8 shows the eight PCM codes which are repeated to generate a digital milliwatt for both mu-law and A-law in the DAC.

The digital milliwatt is used to calibrate the gains of telephone networks using voice grade PCM codec-filters.

Idle Channel Noise

Idle channel noise is the noise when there is no signal applied to the voice channel, which is different from the quantization distortion caused by the ADC/DAC process. This noise can be from any circuit element in the channel, in addition to the PCM codec-filter. Noise may be coupled in from other circuits including, but not limited to, hybrid transformer interfaces, power supply induced noise, digital circuitry, radio frequency radiation, and resistive noise sources.

The PCM codec-filter itself has many opportunities to contribute to the idle channel noise level. The input high-pass filter often is third order, whereas both the input and the output low-pass filters are typically fifth-order elliptic designs. The potential for noise generation is proportional to the order of the filter. The ADC and DAC arrays have many components that are controlled by sequencing digital circuits. The power supply rejection capability of PCM codec-filters once dominated the noise level of the channel. The power supply rejection ratio of these devices has been improved to a level where the device is virtually immune to power supply noise within the allowable power supply voltage range. This performance was attained by differential analog circuit designs in combination with tightly controlled matching between on-chip components.

Noise measurements require a different decibel unit as they usually involve some bandwidth or filter conditioning. One such unit commonly used (especially in North America) is decibels above reference noise (dBrn). The reference noise level is defined as 1 pW or -90 dBm. Telephone measurements typically refer to dBnC, which is the noise level measured through a C-message weighting filter (a filter that

simulates the frequency response of the human ear's noise sensitivity). European systems use a related term called dBmp, which is the dBm level noise measured through a psophometric filter. Noise measurements made by either dBrnC or dBmp filter weightings have units to show that the noise has been gain referenced to 0 dBm0 by adding a zero, hence dBrnC0 and dBm0p. Two examples are shown to illustrate the use of these units:

1. Mu-law: If 0 dB TLP = +6 dB, then a noise measurement of 20 dBrnC equals 14 dBrnC0.
2. A-law: If 0 dB TLP = +4LPdB, then a noise measurement of -70 dBmp equals -74 dBm0p.

The examples are representative of typical idle channel noise measurements for a full-duplex digital channel. Idle channel noise measuring 14 dBrnC0 at a 0 dB TLP output is about 123- μ V root mean square (rms). This low-noise level is very susceptible to degradation by the noise sources mentioned earlier.

The idle channel noise of the voice channel directly impacts the dynamic range, which is the ratio of maximum power the channel can handle to this noise level. Typical dynamic range for a mu-law PCM codec-filter is about 78 dB. The term dynamic range is similar to signal-to-noise ratio for linear circuits. The signal-to-noise plus distortion ratio for a companded channel is generally limited by the nonlinear companding except at very low-signal amplitudes.

Gain Tracking: Gain Variations as a Function of Level

The quantization curves, as discussed earlier, are not linear and may cause additional nonlinear distortions. The concern is that the gain through the channel may be different if the amplitude of the signal is changed. Gain variations as a function of level or how well the gain tracks with level is also called gain tracking. This is a type of distortion, but could easily be missed by a tone stimulus signal-to-distortion test alone. Gain tracking errors can cause ringing in the 2-wire-4-wire hybrid circuits if the gain at any level gets too large. Gain tracking performance is dominated by the IC fabrication technology, more specifically, the matching consistency of capacitors and resistors on a monolithic substrate. Figure 26.9 shows the half-channel gain tracking performance recommended for a PCM digital interface.

FIGURE 26.9 Variation of gain with input level using a tone stimulus.

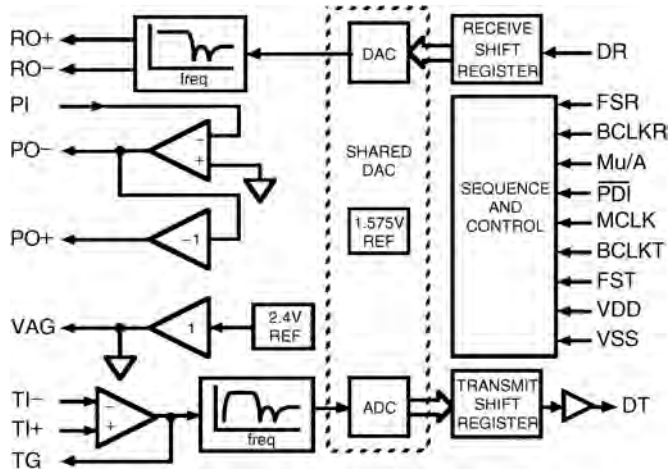

FIGURE 26.10 MC145480 5 V PCM codec-filter.

Figure 26.10 is a block diagram for a monolithic MC145480 5 V PCM codec-filter manufactured by Motorola Inc. The MC145480 uses CMOS for reliable low-power operation. The operating temperature range is from -40° to $+85^{\circ}$ C, with a typical power dissipation of 23 mW. All analog signal processing circuitry is differential utilizing Motorola's six-sigma quality IC fabrication process. This device includes both antialiasing and reconstruction switched capacitor filters, compressing ADC, expanding DAC, a precision voltage reference, shift registers, and additional features to facilitate interfacing to both the analog and digital circuitry on a linecard.

26.4 Linear PCM Codec-Filter for High-Speed Modem Applications

As discussed in previous sections of this chapter, the original PCM codec-filters were developed to facilitate the digital switching of voice signals in the central office of the PSTN. The signal processing in the digital domain consisted of simply moving digitized samples of voice from one time slot to another to accomplish the switching function. As such, the A/D and D/A conversion processes could be nonlinear, and companding was employed.

With the advent of the personal computer, the facsimile machine, and most recently the Internet, the need to transmit data originating at the subscriber over the PSTN at the highest possible rates has grown to the point where the theoretical limits as defined by Shannon's law [Shannon, 1948] are being approached. For data transmission, the signal processing is, in a sense, the inverse of that which spawned the original PCM codecs in that the initial signal is data that must be modulated to look like a voice signal in order to be transmitted over the PSTN. At data rates above 2400 b/s, the modulation is done using sophisticated digital signal processing techniques, which have resulted in the development of a whole new class of linear PCM codec-filters.

Codec-filters for V.32 (9.6 kb/s), V.32bis (14.4 kb/s), and V.34 (28.8 kb/s) modems must be highly linear with a signal to distortion much greater than 30 dB. This linearity and signal to distortion is required to implement the echo cancellation function with sufficient precision to resolve the voltages corresponding to the data points in the dense constellations of high-speed data modems. Please refer to the chapters in this handbook on signal space and echo cancellation for more information. The critical signal-to-noise plus distortion plots for two popular commercially available codec-filters used in V.32bis (T7525) and V.34bis (STLC 7545) modems are shown in Fig. 26.11. Both of these codec-filters are implemented using linear high ratio oversampling sigma-delta (SD) A/D and D/A conversion technology and digital

FIGURE 26.11 Linear codec dynamic range, where f_m is the modulator frequency and f_s is the sample frequency.

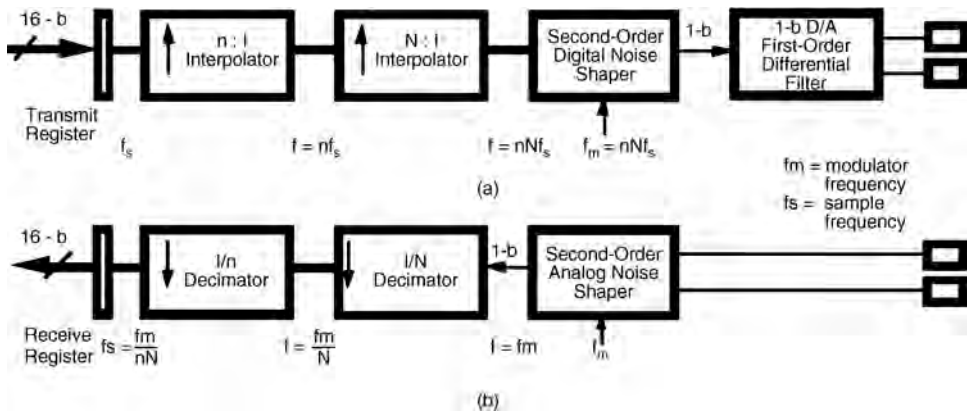

FIGURE 26.12 Generalized SD PCM modem codec-filter: (a) transmit channel and (b) receive channel.

filters. This can be contrasted with the nonlinear companding converters and switched capacitor filters of voice grade PCM codec-filters.

Sigma-delta conversion technology is based on coarsely sampling a signal at a high rate and filtering the resulting noise [Candy and Temes, 1992; Park, 1990]. A generalized block diagram of sigma-delta PCM codec-filters for modem applications is shown in Fig. 26.12. The transmit and receive signal paths are the inverse of each other. The second-order modulators basically consist of two integrators and a comparator with two feedback loops. The action of the modulators is to low-pass filter the signal and high-pass filter the noise so that greater than 12 b of resolution (70 dB) can be achieved in-band. If it is assumed that the input signal is sufficiently active to make the quantization noise random, then it can be shown that [Candy and Oconnell, 1981], for a simple first-order modulator,

$$No^2 = (1/fo)^3$$

where:

- No = net rms noise in band
- fo = oversampling frequency

That is, the in-band noise power decreases in proportion to the cube of the oversampling frequency resulting in improved in-band signal-to-noise performance. The high-frequency quantization noise in the receive channel is removed by the digital decimation filters, whereas the high-frequency alias noise due to the interpolation process in the transmit channel is removed by interpolation filters. The transmit and receive channels are synchronous.

The decimation and interpolation operations are done in two stages: a low-ratio (n) stage and a high-ratio (N) stage. The high-ratio stage is implemented with cascaded comb filters, which are simply moving average filters having the following frequency response:

$$H(z) = 1/N((1 - z^{-N})/(1 - z^{-1}))^i$$

where i is the number of cascaded filters. For modem applications, the order i of the cascade is generally three. Comb filters are essentially linear phase finite impulse response (FIR) filters with unity coefficients and, therefore, they do not require a multiplier to implement, which makes them silicon area efficient. The low-ratio stage is usually implemented with cascaded second-order infinite impulse response (IIR) filters. These filters do require a multiplier to implement. The frequency response of the IIR filters compensate for the $\sin x/x$ droop of the comb filters and shape the pass-band to meet telephone specifications. The total oversampling product, $nN = f_0$, is typically greater than or equal to 128 with $N = 32$ or 64. For V.32bis modems, f_s is fixed at 9.6 kHz, whereas for V.34bis modems, f_s varies from 9.6 to ~14 kHz.

26.5 Concluding Remarks

The PCM voice codec-filter has continuously evolved since the late 1950s. With each improvement in performance and each reduction in cost, the number of applications has increased. The analog IC technology incorporated in today's PCM voice codec-filters represents one of the true bargains in the semiconductor industry.

Sigma-delta-based PCM codec-filters have become the standard for implementing high-speed modems because they can offer sufficient resolution at the lowest cost. Sigma-delta codecs are cost/performance effective because they are 90% digital and digital circuitry scales with integrated circuit (IC) process density improvements and associated speed enhancements. It is interesting to note that although the analog portion of the sigma-delta codec-filter is small and does not require precision or matched components like other converter technologies, it (the D/A output differential filter) limits the ultimate performance of the codec-filter.

27.1 Introduction

Following the introduction of digital encoding and transmission of voice signals in the early 1960s, multiplexing schemes for increasing the number of channels that could be transported were developed by the Consultative Committee on International Telephony and Telegraphy (CCITT) in Europe and by the Bell System in North America. The initial development of such systems was aimed at coaxial cable and millimeter waveguide transmission systems. The advent of low-loss optical fiber and efficient modulation schemes for digital radio greatly increased the need to transport digital channels at rates higher than the primary multiplexing rate.

Separate multiplexing schemes, called digital hierarchies, were developed by CCITT and by the Bell System. During the period in which the two hierarchies were conceived, there was no reliable way to distribute highly accurate clock signals to each central office that might serve as a multiplexing point. Local clock signals were, therefore, provided by relatively inaccurate crystal oscillators, which were the only economical signal sources available. Each hierarchy was, therefore, designed with the expectation that the clocks controlling the various stages of the multiplexing and demultiplexing processes would not be accurate and that means would be required for compensating for the asynchronicities among the various signals.

The mechanism chosen to accomplish synchronization of the multiplexing process was positive bit stuffing, as described elsewhere in this handbook. The CCITT development was termed the plesiochronous digital hierarchy (PDH) and, in North America, the scheme was designated the asynchronous digital hierarchy. The two differ significantly. The North American digital hierarchy will be described in the sections that follow.

The advent of accurate and stable clock sources has made possible the deployment of multiplexing schemes that anticipate that most of the signals involved will be synchronous. The North American synchronous multiplexing scheme is the Synchronous Optical Network (SONET) and is described elsewhere in this handbook. The International Telecommunications Union—Telecommunications Standardization Sector (ITU-T) version is termed the synchronous digital hierarchy (SDH). In spite of the development of these synchronous multiplexing hierarchies, the asynchronous hierarchies remain important because there are substantial numbers of asynchronous legacy systems and routes that must be maintained and that must support further growth.

27.2 North American Asynchronous Digital Hierarchy

Following dissolution of the Bell System in 1984, Committee T1—Telecommunications was formed to take responsibility for maintenance and development of North American telecommunications standards. The Alliance for Telecommunications Industry Solutions (ATIS) serves as the secretariat for Committee T1. Committee T1 maintains standard T1.107 [T1.107, 1995] that describes the North American asynchronous digital hierarchy.

The capacities of the bit streams of the various multiplexing levels in the North American digital hierarchy are divided into overhead and payload. Overhead functions include framing, error checking, and maintenance functions, which will be described separately for each level. Payload capacity is used to carry signals delivered from the next lower level or delivered directly to the multiplexer by a customer.

The various rates in the digital hierarchy are termed digital signal n (DSn), where n is the specified level in the hierarchy. The various rates are summarized in Table 27.1.

In addition, T1.107 provides standards for multiplexing various sub-DS0 digital data signals into a 64 kb/s DS0.

The relationships among the various signals are illustrated in Fig. 27.1. Note that DS1C is a dead-end rate. It is useful for channeling paired cable plant but it cannot be multiplexed into higher level signals. DM in Fig. 27.1 represents digital multiplexer.

Digital Signal Level 0 (DS0)

The DS0 signal is a 64-kb/s signal that is usually organized in 8-b bytes and which may be developed by encoding analog signals as described elsewhere in this handbook. Alternatively, the DS0 may be built from digital signals that are synchronous with the DS1 clock. There is no provision for handling asynchronous signals at the DS0 rate, although lower rate asynchronous signals are sometimes oversampled at 64 kb/s to accommodate them to the rate of the DS0 channel rate or to the rate of a lower rate synchronous channel derived from the DS0.

TABLE 27.1 Rates in the North American Digital Hierarchy

DS0	64-kb/s signal that may contain digital data or $\mu = 255$ encoded analog signals
DS1	1.544 Mb/s signal that byte-interleaves 24 DS0s
DS1C	3.152 Mb/s signal that bit-interleaves 2 DS1s
DS2	6.312 Mb/s signal that bit-interleaves 4 DS1s
DS3	44.736 Mb/s signal that bit-interleaves 7 DS2s

Composite pattern	1	0	0	0	1	1	0	1	1	1	0	0

FIGURE 27.2 DS1 frame structure.

Digital Signal Level 1 (DS1)

The DS1 signal is built by interleaving 1.536 Mb/s of payload capacity with 8 kb/s of overhead. Following each overhead bit, 8-b bytes from each of the 24 DS0 channels to be multiplexed are byte interleaved. The resulting structure appears in Fig. 27.2. The DS0 bytes (channels) are numbered sequentially from 1 to 24 in Fig. 27.2, and that scheme is the standard method for interleaving DS0 channels. Other schemes, which employ a nonsequential ordering of DS0 channels, have been used in the past.

This 193-b pattern is called a frame and is repeated 8000 times per second to coincide with the sampling rate for encoding analog signals. Each 8-b encoded sample of a particular channel may be transmitted in the appropriate channel position of a single frame.

Digital Signal Level 1 Overhead: Superframe Format

In the earliest 1.544 Mb/s systems, the framing pattern was simply used to identify the beginning of each frame so that the channels could be properly demultiplexed by the receiver. With the advent of robbed-bit signaling, it became necessary to identify the particular frames in which robbed-bit signaling occurs. A superframe (SF) of twelve frames was developed in which robbed-bit signaling occurs in the 6th and 12th frames. The overhead capacity in the superframe format is organized into two streams. The pattern carried by the overhead bits (Ft bits—terminal framing) in odd-numbered frames identifies the beginning of the frame structure and serves to locate the overhead stream. The pattern in the even-numbered frames (Fs bits—signaling framing) locates the beginning of each superframe so that the robbed-bit signaling can be properly demultiplexed. The SF framing pattern is shown in Table 27.2.

Note that each frame in which the logical state of the Fs bit changes is a signaling frame that may carry robbed-bit signaling.

There are two bits per superframe devoted to signaling. They are denoted A and B and may be used to carry four-state signaling, although two-state signaling (on- and off-hook indications) is more common.

Digital Signal Level 1: Extended Superframe Format

Improvements in electronics and framing algorithms have made it possible for receivers to frame rapidly and efficiently on patterns with less information than is contained in the 8-kb/s superframe overhead stream. The extended superframe format (ESF) uses a 2-kb/s framing pattern to locate a 24-frame extended superframe. The frame structure remains as for the SF format, and the ESF format therefore provides 6 kb/s of overhead capacity which is not devoted to framing.

A communications channel [data link or (DL)] consumes 4 kb/s of overhead. This channel is used to convey performance monitoring information from one DS1 terminal location to the other (scheduled messages) and to send alarm messages and loopback requests (unscheduled messages). The use of this channel is detailed in T1.403 [ANSI, 1999]. When no message is being sent in the DL, it is usually filled with unconcatenated high-level data link control (HDLC) flags (01111110) although some older

TABLE 27.3 DS1 Extended Superframe Overhead Bit Assignments

Frame Number:	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24
FAS				0				0				1				0			1					1
DL	D	D		D	D		D	D		D		D		D		D		D		D		D		D
CRC		C				C				C				C				C				C		

equipment may fill with an all ones pattern. HDLC frames for carrying performance information from DS1 path terminations, as well as from intermediate points, are defined in T1.403 as the performance report message (PRM), the network performance report message (NPRM), and the supplementary performance report message (SPRM).

The remaining 2 kb/s of overhead in the ESF format carry a cyclic redundancy code with a 6-b remainder (CRC-6) channel to provide error checking. The divisor polynomial is $X^6 + X + 1$. Division is carried out over all 4632 b of an extended superframe with all the overhead bits set to logical ones. The 6-b remainder resulting from the division is written into the CRC-6 bits of the following extended superframe.

Table 27.3 contains a summary of the overhead bit assignments in the ESF format where FAS represents the frame alignment signal. The bits forming the 4 kb/s DL are represented by D and the six individual bit positions for the CRC-6 remainder from the previous extended superframe are shown as C.

Digital Signal Level 1C Format

Although, as mentioned previously, DS1C cannot be multiplexed to higher levels in the hierarchy, it has proved useful for channelizing interoffice cable pairs with more channels than can be carried by a comparable DS1 system. A transmission facility for DS1C, the T1C line, was introduced and deployed during the 1970s. Although lightwave interoffice transmission has significantly diminished the importance of DS1C, a discussion of that rate provides a good starting point for discussing the higher levels in the hierarchy.

The DS1C format multiplexes two 1.544 Mb/s DS1 signals into a single 3.152 Mb/s stream. Unlike the other levels in the digital hierarchy, DS1C signals cannot be multiplexed to higher levels. Two DS1Cs together exceed the capacity of a single DS2, making such multiplexing impossible and making DS1C an orphan rate.

As is the case for all the hierarchical rates above DS1, the DS1C format is organized into M-frames and M-subframes. The length of a single M-frame is 1272 b. Overhead bits occur every 53 b, with 52 payload bits interspersed between adjacent overhead bits. Each M-frame is divided into 4 M-subframes of 318 b each. Overhead assignments are shown in Table 27.4.

Digital Signal Level 1C Frame Alignment

The information in Table 27.4 is reorganized into columns by M-subframe in Table 27.5.

Note that certain of the overhead bits, including the F1 and F2 bits, recur in the same position in every M-subframe. Typical framing practice, therefore, is to frame on the F bits to locate the boundaries of the M-subframes and to then frame on the first bits of the M-subframes to locate the boundaries of the M-frame structure.

Digital Signal Level 1C X Bit

The X bit provides a communications channel between DS1C terminals that runs at just under 2500 b/s. The usual use of the X bit channel is to provide a remote alarm indication (RAI) to the distant terminal. When no alarm condition exists, the X-bit is set to logical one.

TABLE 27.4 DS1C Overhead Bit Assignments

M-frame Bit Number	M-subframe Number	Overhead Bit Assignment	Logical Value of Bit
0	1	M1	0
53	1	C1	first DS1 stuff control

Digital Signal Level 1C Bit Stuffing and Stuffing Control Bits

Of the 1272 b in a DS1C M-frame, 24 are overhead bits. The bandwidth available for transporting payload is therefore:

$$\begin{aligned}
 PC_{max} &= (Mfb\ ts - OHb\ ts) / (Mfb\ ts * rate) \\
 &= (1272 - 24) / (1272 * 3.152\ Mb/s) \\
 &= 3.092\ Mb/s
 \end{aligned}$$

where:

PC_{max} = maximum payload capacity of the DS1C signal

$Mfbits$ = number of bits per M-frame, 1272

$OHbits$ = number of overhead bits per M-frame, 24

$rate$ = DS1C bit rate, 3.152 Mb/s

Note that this is more than the payload required to transport two DS1s running at their nominal rates, which is:

$$\begin{aligned} PC_{req} &= 2 * 1.544 \text{ Mb/s} \\ &= 3.088 \text{ Mb/s} \end{aligned}$$

Each M-subframe, however, contains a payload bit that is designated as a stuff bit. It can be used to carry a payload bit or it may be passed over and left unused. If it is unused in every M-subframe, the bandwidth made available for the payload will be:

$$\begin{aligned} PC_{min} &= (Mfb \text{ ts} - OHb \text{ ts} - Sb \text{ ts}) / (Mfb \text{ ts} * \text{rate}) \\ &= (1272 - 24 - 4) / (1272 * 3.152 \text{ Mb/s}) \\ &= 3.083 \text{ Mb/s} \end{aligned}$$

where:

PC_{min} = minimum payload capacity of the DS1C signal
 Sb = number of stuff bits (opportunities) per M-frame

If all the stuff bits are skipped, the capacity of the DS1C channel is less than the amount required by two DS1s.

Note that, by either using or skipping stuff bits, the actual payload capacity of the DS1C signal may be varied between the extremes represented by PC_{min} and PC_{max} to handle the rate of the DS1 signal to be transported. The range available between PC_{min} and PC_{max} exceeds the range of rates allowed for DS1 signals by T1.102 [ANSI, 1999].

Stuff bits for the first DS1 occur in the first and third M-subframes and for the second DS1 in the second and fourth M-subframes. The stuff bit for a particular M-subframe is always the third time slot allocated to the DS1 involved following overhead bit C3. For DS1 number 1, this is the fifth bit after C3, and for DS1 number 2, it is the sixth bit after C3. For a particular M-subframe, stuffing will be performed if the C bits (C1, C2, and C3) for that M-subframe are all set to logical ones. If the C bits are set to logical zeroes, no stuffing will occur in that M-subframe. The use of three C bits allows for majority voting by the receiver where one of the C bits may have been corrupted by a line error. This makes the process much more robust to such errors.

Digital Level 1C Payload

The two DS1s which are to be multiplexed are bit interleaved together to form the DS1C payload. Prior to bit interleaving, DS1 number 2 is logically inverted. Prior to inserting the interleaved payload into the DS1C overhead structure, the payload is scrambled in a single-stage scrambler. The output of the scrambler is the modulo-2 sum of the current input bit and the previous output bit.

Higher Rate Formats

As does DS1C, the DS2 and DS3 formats use positive bit stuffing to reconcile the rates of the signals being multiplexed. Both use the same M-frame and M-subframe structure with overhead bits assigned to the same tasks as for DS1C. Each of the rates uses bit interleaving to insert subsidiary bit streams into their payload bits. A synopsis of the characteristics of the various rates appears in [Table 27.6](#). Each rate will be discussed in the sections that follow.

The Digital Signal Level 2 Rate

The DS2 rate is summarized in [Table 27.6](#). It operates in a manner very similar to DS1C except that the rate is higher and four DS1s may be carried by a single DS2. A transmission system for carrying DS2 signals over paired copper cable called T2 was once available (1970s) but was never widely deployed.

TABLE 27.6 Characteristics of Levels in the Digital Hierarchy

	DS1C	DS2	DS3
Transmission rate, Mb/s	3.152	6.312	44.736
Subsidiary format	DS1	DS1	DS2
Number of subsidiaries multiplexed	2	4	7
Ratio of payload bits to overhead bits	52:1	48:1	84:1
M-frame length, b	1272	1176	4760
Number of M-subframes per M-Frame	4	4	7
M-subframe length, b	318	294	680
Number of X bits per M-frame	1	1	2
Number of C bits per M-frame	12	12	21
Number of M bits per M-frame	3	3	3
Number of F bits per M-frame	2	2	4
Number of P bits per M-frame	0	0	2
Number of stuff opportunities per tributary channel per M-frame	2	1	1

DS2 serves today primarily as a bridge between DS1 and DS3 and is only rarely found outside the confines of a single unit of equipment.

The Digital Signal Level 3 Rate

DS3 is heavily used as an interface to lightwave and digital radio systems. DS3 operates in much the same way as DS1C and DS2. An additional feature of DS3 is the pair of parity bits carried by each M-frame. They are used to transmit a parity error indication for the preceding M-frame. If the modulo-2 sum of all the information bits in the preceding M-frame is one, then both P bits are set to one. If the modulo-2 sum of the information bits is zero, then the P bits are set to zero. The two P bits of an M-frame are always set to the same value.

The same is true of the two X-bits in an M-frame. They are used as an alarm channel as for DS1C but are always set to the same value.

C-Bit Parity Digital Signal Level 3

A DS3 that operates using positive bit stuffing to multiplex its constituent DS2s is known as an M23 application. Another DS3 application, C-bit parity, is also defined in T1.107 [ANSI, 1995a].

Since the DS2 rate is almost never used except internal to a multiplexer as a stepping stone from DS1 to DS3, it is possible to lock its rate to a particular value which is slaved to the DS3 signal generator in the multiplexer. If the rate chosen for the DS2s provides for either no bit stuffing or for stuffing at every opportunity, the receiver can be made to know that and will be able to demultiplex the DS2s without reading the stuffing information that is normally carried by the C-bits.

The C-bit parity format operates the DS2 with stuffing at every opportunity and so frees up the control bits for other uses. There are 21 C bits per M-frame, which provides a channel running at approximately 197 kb/s. The 21 C bits per M-frame, are assigned as shown in [Table 27.7](#).

The C-bit parity identifier is always set to logical one and is used as a tag to identify the DS3 signal as C-bit parity formatted. Note that the C-bit parity identifier is necessary but not sufficient for this purpose because it may be counterfeited by a DS2 in DS3 timeslot number one running at minimum rate, which, therefore, requires stuffing at every opportunity.

The Far End Alarm and Control Channel (FEAC) carries alarm and status information from one DS3 terminal to another and may be used as a channel to initiate DS1 and DS3 maintenance loopbacks at the distant DS3 terminal.

The path parity (CP) bits are set to the same value as are the P-bits at the terminal that generates them. The CP-bits are not to be changed by intermediate network elements and, therefore, provide a more reliable end-to-end parity indication than do the DS3 P-bits.

TABLE 27.7 Assignment of C Bits in C-bit Parity Application

C bit	Application	C bit	Application
1	C-bit parity identifier	12	FEBE
2	N = 1 (future network use)	13	DL (data link)
3	FEAC	14	DL (data link)
4	application specific	15	DL (data link)
5	application specific	16	application specific
6	application specific	17	application specific
7	CP (path parity)	18	application specific
8	CP (path parity)	19	application specific
9	CP (path parity)	20	application specific
10	FEBE	21	application specific
11	FEBE		

The Far-End Block Error (FEBE) bits are set to all ones (111) only when no framing bit or CP-bit error has been detected in the incoming signal by the terminal generating the outgoing FEBE. When errors are detected, the FEBE-bits are set to any combination of 1s and 0s except 111.

The data link (DL) bits are used as a 28.2 kb/s data channel between the two DS3 terminals. Messages carried by this channel use the LAPD format. When no messages are carried, LAPD idle code (flags), which consists of repetitions of 01111110, is sent. The DL is used to carry messages identifying the DS3 path, the source of a DS3 idle signal, or the source of a DS3 test signal.

A network performance report message (NPRM) for DS3 similar to that defined for DS1 in T1.403 [ANSI, 1999] is under development by Working Group T1E1.2 of Committee T1 at the time of this writing. The NPRM will be transported by the C-bit parity data link.

Unchannelized Digital Signal Level 3

T1.107 also provides for the use of the DS3 payload for direct transport of data at the payload rate of 44.210 Mb/s.

Defining Terms

Alarm Indication Signal (AIS): A signal that is transmitted in the direction of a failure to indicate that a network element has detected the failure. AIS provides a “keep alive” signal to equipment downstream from the failure and prevents multiple network elements from issuing redundant and confusing alarms about the same failure.

Alliance for Telecommunications Industry Solutions (ATIS): The body that serves as the secretariat for Committee T1—Telecommunications.

Committee T1—Telecommunications: An accredited standards development body that develops and maintains standards for telecommunications in North America. Note that the “T1” in the committee name above has no connection with the T1 line that operates at the DS1 rate.

Cyclic redundancy code (CRC) with an n-bit remainder (CRC-n): CRC codes provide highly reliable error checking of blocks of transmitted information.

DL: Data link for transporting messages across a digital path using certain of the overhead bits as a data channel. The DL is sometimes called the FDL, for facility data link.

DSn: DSn stands for digital signal level n and refers to one of the levels (rates) in the North American digital hierarchy that are discussed in this chapter.

Extended superframe (ESF): A DS1 superframe that is 24 frames in length and that makes more efficient use of the overhead bits than the older SF format.

Frame alignment signal (FAS): Serves to allow a receiver to locate significant repetitive points within the received bit stream so that the information may be extracted.

FEAC: Far end alarm and control channel used in C-bit parity DS3. The FEAC uses repeated 16-bit code words to send status messages alarm signals and requests for loopback.

High level data link control (HDLC): A format used to implement layer 2 (the data link layer) of the ISO seven-layer model.

Link access procedure—D channel (LAPD): A subset of HDLC used for transporting messages over the data links (DL) in the North American digital hierarchy.

Network performance report message (NPRM): An HDLC frame that carries DS1 performance information along the extended superframe data link. The NPRM is intended to allow transmission of performance information from points intermediate to the DS1 path terminations in an ESF DL that is already carrying performance information from the path terminations in PRMs.

Overhead: Bits in a digital signal that do not carry the information signals the signal is intended to transport but that perform housekeeping functions such as framing, error detection, and the transport of maintenance data from one digital terminal to the other.

Payload: The aggregate of the information bits the digital signal is intended to transport.

Performance report message (PRM): An HDLC frame that is intended to carry DS1 performance information along the extended superframe data link.

Remote alarm indication (RAI): A Signal that indicates to the terminal at one end of a digital path that the terminal at the other end has detected a failure in the incoming signal.

SF—DS1 superframe format: A format in which the superframe is twelve frames in length and in which all the overhead bits are used for framing.

SPRM: A PRM that has been modified to use spare bits in the HDLC information field to carry performance information from a point intermediate to the DS1 path terminations.

Superframe: The 12-frame superframe format for DS1 known as SF or an aggregation of frames that provides a longer repetitive structure than a frame in any format. The latter definition of the term is more often called a multiframe at rates other than DS1.

28.1 Introduction

The terminology **line coding** originated in telephony with the need to transmit digital information across a copper telephone *line*; more specifically, binary data over a digital repeatered line. The concept of line coding, however, readily applies to any transmission line or channel. In a digital communication system, there exists a known set of symbols to be transmitted. These can be designated as $\{m_i\}$, $i = 1, 2, \dots, N$, with a probability of occurrence $\{p_i\}$, $i = 1, 2, \dots, N$, where the sequentially transmitted symbols are generally assumed to be statistically independent. The conversion or *coding* of these abstract symbols into real, temporal waveforms to be transmitted in baseband is the process of line coding. Since the most common type of line coding is for binary data, such a waveform can be succinctly termed a direct format for serial bits. The concentration in this section will be line coding for binary data.

Different channel characteristics, as well as different applications and performance requirements, have provided the impetus for the development and study of various types of line coding [1,2]. For example, the channel might be AC coupled and, thus, could not support a line code with a DC component or large DC content. Synchronization or timing recovery requirements might necessitate a discrete component at the data rate. The channel bandwidth and **crossstalk** limitations might dictate the type of line coding employed. Even such factors as the complexity of the encoder and the economy of the decoder could determine the line code chosen. Each line code has its own distinct properties. Depending on the application, one property may be more important than the other. In what follows, we describe, in general, the most desirable features that are considered when choosing a line code.

It is commonly accepted [1,2,5,8] that the dominant considerations effecting the choice of a line code are: (1) timing, (2) DC content, (3) power spectrum, (4) performance monitoring, (5) probability of error, and (6) transparency. Each of these are detailed in the following paragraphs.

(1) *Timing*: The waveform produced by a line code should contain enough timing information such that the receiver can synchronize with the transmitter and decode the received signal properly. The timing content should be relatively independent of source statistics, i.e., a long string of **1s** or **0s** should not result in loss of timing or jitter at the receiver.

(2) *DC content*: Since the repeaters used in telephony are AC coupled, it is desirable to have zero DC in the waveform produced by a given line code. If a signal with significant DC content is used in AC coupled lines, it will cause **DC wander** in the received waveform. That is, the received signal baseline will vary with time. Telephone lines do not pass DC due to AC coupling with transformers and capacitors to eliminate DC ground loops. Because of this, the telephone channel causes a droop in constant signals. This causes DC wander. It can be eliminated by DC restoration circuits, feedback systems, or with specially designed line codes.

(3) *Power spectrum*: The power spectrum and bandwidth of the transmitted signal should be matched to the frequency response of the channel to avoid significant distortion. Also, the power spectrum should be such that most of the energy is contained in as small bandwidth as possible. The smaller the bandwidth, the higher the transmission efficiency.

(4) *Performance monitoring*: It is very desirable to detect errors caused by a noisy transmission channel. The error detection capability in turn allows performance monitoring while the channel is in use (i.e., without elaborate testing procedures that require suspending use of the channel).

(5) *Probability of error*: The average error probability should be as small as possible for a given transmitter power. This reflects the reliability of the line code.

(6) *Transparency*: A line code should allow all the possible patterns of **1s** and **0s**. If a certain pattern is undesirable due to other considerations, it should be mapped to a unique alternative pattern.

28.2 Common Line Coding Formats

A line coding format consists of a formal definition of the line code that specifies how a string of binary digits are converted to a line code waveform. There are two major classes of binary line codes: **level codes** and **transition codes**. Level codes carry information in their voltage level, which may be high or low for a full bit period or part of the bit period. Level codes are usually instantaneous since they typically encode a binary digit into a distinct waveform, independent of any past binary data. However, some level codes do exhibit memory. Transition codes carry information in the change in level appearing in the line code waveform. Transition codes may be instantaneous, but they generally have memory, using past binary data to dictate the present waveform. There are two common forms of level line codes: one is called **return to zero (RZ)** and the other is called **nonreturn to zero (NRZ)**. In RZ coding, the level of the pulse returns to zero for a portion of the bit interval. In NRZ coding, the level of the pulse is maintained during the entire bit interval.

Line coding formats are further classified according to the polarity of the voltage levels used to represent the data. If only one polarity of voltage level is used, i.e., positive or negative (in addition to the zero level), then it is called **unipolar** signalling. If both positive and negative voltage levels are being used, with or without a zero voltage level, then it is called **polar** signalling. The term **bipolar** signalling is used by some authors to designate a specific line coding scheme with positive, negative, and zero voltage levels. This will be described in detail later in this section. The formal definition of five common line codes is given in the following along with a representative waveform, the *power spectral density* (PSD), the probability of error, and a discussion of advantages and disadvantages. In some cases specific applications are noted.

Unipolar NRZ (Binary On-Off Keying)

In this line code, a binary **1** is represented by a non-zero voltage level and a binary **0** is represented by a zero voltage level as shown in Fig. 28.1(a). This is an instantaneous level code. The PSD of this code with equally likely 1s and 0s is given by [5,8]

$$S_1(f) = \frac{V^2 T}{4} \left(\frac{\sin \pi f T}{\pi f T} \right)^2 + \frac{V^2}{4} \delta(f) \quad (28.1)$$

where V is the binary **1** voltage level, $T = 1/R$ is the bit duration, and R is the bit rate in bits per second. The spectrum of unipolar NRZ is plotted in Fig. 28.2a. This PSD is a two-sided even spectrum, although only half of the plot is shown for efficiency of presentation. If the probability of a binary **1** is p , and the probability of a binary **0** is $(1 - p)$, then the PSD of this code, in the most general case, is $4p(1 - p)S_1(f)$. Considering the frequency of the first spectral null as the bandwidth of the waveform, the bandwidth of unipolar NRZ is R in hertz. The error rate performance of this code, for equally likely data, with additive white Gaussian noise (AWGN) and optimum, i.e., matched filter, detection is given by [1,5]

$$P_e = \frac{1}{2} \operatorname{erfc} \left(\sqrt{\frac{E_b}{2N_0}} \right) \quad (28.2)$$

where E_b/N_0 is a measure of the signal-to-noise ratio (SNR) of the received signal. In general, E_b is the energy per bit and $N_0/2$ is the two-sided PSD of the AWGN. More specifically, for unipolar NRZ, E_b is the energy in a binary **1**, which is $V^2 T$. The performance of the unipolar NRZ code is plotted in Fig. 28.3.

The principle advantages of unipolar NRZ are ease of generation, since it requires only a single power supply, and a relatively low bandwidth of R Hz. There are quite a few disadvantages of this line code. A loss of synchronization and timing jitter can result with a long sequence of 1s or 0s because no pulse transition is present. The code has no error detection capability and, hence, performance cannot be monitored. There is a significant DC component as well as a DC content. The error rate performance is not as good as that of polar line codes.

Unipolar RZ

In this line code, a binary **1** is represented by a nonzero voltage level during a portion of the bit duration, usually for half of the bit period, and a zero voltage level for rest of the bit duration. A binary **0** is represented by a zero voltage level during the entire bit duration. Thus, this is an instantaneous level code. Figure 28.1(b) illustrates a unipolar RZ waveform in which the **1** is represented by a nonzero voltage level for half the bit period. The PSD of this line code, with equally likely binary digits, is given by [5,6,8]

$$S_2(f) = \frac{V^2 T}{16} \left(\frac{\sin \pi f T/2}{\pi f T/2} \right)^2 + \frac{V^2}{4\pi^2} \left[\frac{\pi^2}{4} \delta(f) + \sum_{n=-\infty}^{\infty} \frac{1}{(2n+1)^2} \delta(f - (2n+1)R) \right] \quad (28.3)$$

where again V is the binary **1** voltage level, and $T = 1/R$ is the bit period. The spectrum of this code is drawn in Fig. 28.2a. In the most general case, when the probability of a **1** is p , the continuous portion of the PSD in Eq. (28.3) is scaled by the factor $4p(1 - p)$ and the discrete portion is scaled by the factor $4p^2$. The first null bandwidth of unipolar RZ is $2R$ Hz. The error rate performance of this line code is the same as that of the unipolar NRZ, provided we increase the voltage level of this code such that the energy in binary **1**, E_b , is the same for both codes. The probability of error is given by Eq. (28.2) and identified in Fig. 28.3. If the voltage level and bit period are the same for unipolar NRZ and unipolar RZ, then the energy in a binary **1** for unipolar RZ will be $V^2 T/2$ and the probability of error is worse by 3 dB.

FIGURE 28.1 Waveforms for different line codes.

FIGURE 28.2a Power spectral density of different line codes, where $R = 1/T$ is the bit rate.

The main advantages of unipolar RZ are, again, ease of generation since it requires a single power supply and the presence of a discrete spectral component at the symbol rate, which allows simple timing recovery. A number of disadvantages exist for this line code. It has a nonzero DC component and nonzero DC content, which can lead to DC wander. A long string of 0s will lack pulse transitions and could lead to loss of synchronization. There is no error detection capability and, hence, performance monitoring is not possible. The bandwidth requirement ($2R$ Hz) is higher than that of NRZ signals. The error rate performance is worse than that of polar line codes.

Unipolar NRZ as well as unipolar RZ are examples of pulse/no-pulse type of signalling. In this type of signalling, the pulse for a binary 0, $g_2(t)$, is zero and the pulse for a binary 1 is specified generically as $g_1(t) = g(t)$. Using $G(f)$ as the Fourier transform of $g(t)$, the PSD of pulse/no-pulse signalling is given as [6,7,10]

$$S_{\text{PNP}}(f) = p(1-p)R|G(f)|^2 + p^2R^2 \sum_{n=-\infty}^{\infty} |G(nR)|^2 \delta(f-nR) \quad (28.4)$$

where p is the probability of a binary 1, and R is the bit rate.

Polar NRZ

In this line code, a binary 1 is represented by a positive voltage $+V$ and a binary 0 is represented by a negative voltage $-V$ over the full bit period. This code is also referred to as NRZ (L), since a bit is represented by maintaining a level (L) during its entire period. A polar NRZ waveform is shown in Fig. 28.1(c). This is again an instantaneous level code. Alternatively, a 1 may be represented by a $-V$

FIGURE 28.2b Power spectral density of different line codes, where $R = 1/T$ is the bit rate.

voltage level and a 0 by a $+V$ voltage level, without changing the spectral characteristics and performance of the line code. The PSD of this line code with equally likely bits is given by [5,8]

$$S_3(f) = V^2 T \left(\frac{\sin \pi f T}{\pi f T} \right)^2 \quad (28.5)$$

This is plotted in Fig. 28.2b. When the probability of a 1 is p , and p is not 0.5 , a DC component exists, and the PSD becomes [10]

$$S_{3p}(f) = 4V^2 T p(1-p) \left(\frac{\sin \pi f T}{\pi f T} \right)^2 + V^2 (1-2p)^2 \delta(f) \quad (28.6)$$

The first null bandwidth for this line code is again R Hz, independent of p . The probability of error of this line code when $p = 0.5$ is given by [1,5]

$$P_e = \frac{1}{2} \operatorname{erfc} \left(\sqrt{\frac{E_b}{N_0}} \right) \quad (28.7)$$

FIGURE 28.3 Bit error probability for different line codes.

The performance of polar NRZ is plotted in Fig. 28.3. This is better than the error performance of the unipolar codes by 3 dB.

The advantages of polar NRZ include a low-bandwidth requirement, R Hz, comparable to unipolar NRZ, very good error probability, and greatly reduced DC because the waveform has a zero DC component when $p = 0.5$ even though the DC content is never zero. A few notable disadvantages are that there is no error detection capability, and that a long string of 1s or 0s could result in loss of synchronization, since there are no transitions during the string duration. Two power supplies are required to generate this code.

Polar RZ [Bipolar, Alternate Mark Inversion (AMI), or Pseudoternary]

In this scheme, a binary 1 is represented by alternating the positive and negative voltage levels, which return to zero for a portion of the bit duration, generally half the bit period. A binary 0 is represented by a zero voltage level during the entire bit duration. This line coding scheme is often called **alternate mark inversion (AMI)** since 1s (marks) are represented by alternating positive and negative pulses. It is

also called *pseudoternary* since three different voltage levels are used to represent binary data. Some authors designate this line code as bipolar RZ (BRZ). An AMI waveform is shown in Fig. 28.1(d). Note that this is a level code with memory. The AMI code is well known for its use in telephony. The PSD of this line code with memory is given by [1,2,7]

$$S_{4p}(f) = 2p(1-p)R|G(f)|^2 \left(\frac{1 - \cos 2\pi f T}{1 + (2p-1)^2 + 2(2p-1)\cos 2\pi f T} \right) \quad (28.8)$$

where $G(f)$ is the Fourier transform of the pulse used to represent a binary 1, and p is the probability of a binary 1. When $p = 0.5$ and square pulses with amplitude $\pm V$ and duration $T/2$ are used to represent binary 1s, the PSD becomes

$$S_4(f) = \frac{V^2 T}{4} \left(\frac{\sin \pi f T/2}{\pi f T/2} \right)^2 \sin^2(\pi f T) \quad (28.9)$$

This PSD is plotted in Fig. 28.2a. The first null bandwidth of this waveform is R Hz. This is true for RZ rectangular pulses, independent of the value of p in Eq. (28.8). The error rate performance of this line code for equally likely binary data is given by [5]

$$P_e \approx \frac{3}{4} \operatorname{erfc} \left(\sqrt{\frac{E_b}{2N_0}} \right), \quad E_b/N_0 > 2 \quad (28.10)$$

This curve is plotted in Fig. 28.3 and is seen to be no more than 0.5 dB worse than the unipolar codes.

The advantages of polar RZ (or AMI, as it is most commonly called) outweigh the disadvantages. This code has no DC component and zero DC content, completely avoiding the DC wander problem. Timing recovery is rather easy since squaring, or full-wave rectifying, this type of signal yields a unipolar RZ waveform with a discrete component at the bit rate, R Hz. Because of the alternating polarity pulses for binary 1s, this code has error detection and, hence, performance monitoring capability. It has a low-bandwidth requirement, R Hz, comparable to unipolar NRZ. The obvious disadvantage is that the error rate performance is worse than that of the unipolar and polar waveforms. A long string of 0s could result in loss of synchronization, and two power supplies are required for this code.

Manchester Coding (Split Phase or Digital Biphase)

In this coding, a binary 1 is represented by a pulse that has positive voltage during the first-half of the bit duration and negative voltage during second-half of the bit duration. A binary 0 is represented by a pulse that is negative during the first-half of the bit duration and positive during the second-half of the bit duration. The negative or positive midbit transition indicates a binary 1 or binary 0, respectively. Thus, a Manchester code is classified as an instantaneous transition code; it has no memory. The code is also called diphase because a square wave with a 0° phase is used to represent a binary 1 and a square wave with a phase of 180° used to represent a binary 0; or vice versa. This line code is used in Ethernet local area networks (LANs). The waveform for Manchester coding is shown in Fig. 28.1(e). The PSD of a Manchester waveform with equally likely bits is given by [5,8]

$$S_5(f) = V^2 T \left(\frac{\sin \pi f T/2}{\pi f T/2} \right)^2 \sin^2(\pi f T/2) \quad (28.11)$$

where $\pm V$ are used as the positive/negative voltage levels for this code. Its spectrum is plotted in Fig. 28.2b. When the probability p of a binary 1 is not equal to one-half, the continuous portion of the PSD is reduced in amplitude and discrete components appear at integer multiples of the bit rate, $R = 1/T$. The resulting

PSD is [6,10]

$$S_{sp}(f) = V^2 T 4p(1-p) \left(\frac{\sin \pi f T/2}{\pi f T/2} \right)^2 \sin^2 \frac{\pi f T}{2} + V^2 (1-2p)^2 \sum_{n=-\infty, n\pi 0}^{\infty} \left(\frac{2}{n\pi} \right)^2 \delta(f-nR) \quad (28.12)$$

The first null bandwidth of the waveform generated by a Manchester code is $2R$ Hz. The error rate performance of this waveform when $p = 0.5$ is the same as that of polar NRZ, given by Eq. (28.9), and plotted in Fig. 28.3.

The advantages of this code include a zero DC content on an individual pulse basis, so no pattern of bits can cause DC buildup; midbit transitions are always present making it is easy to extract timing information; and it has good error rate performance, identical to polar NRZ. The main disadvantage of this code is a larger bandwidth than any of the other common codes. Also, it has no error detection capability and, hence, performance monitoring is not possible.

Polar NRZ and Manchester coding are examples of the use of pure polar signalling where the pulse for a binary $\mathbf{0}$, $g_2(t)$, is the negative of the pulse for a binary $\mathbf{1}$, i.e., $g_2(t) = -g_1(t)$. This is also referred to as an antipodal signal set. For this broad type of polar binary line code, the PSD is given by [10]

$$S_{BP}(f) = 4p(1-p)R|G(f)|^2 + (2p-1)^2 R^2 \sum_{n=-\infty}^{\infty} |G(nR)|^2 \delta(f-nR) \quad (28.13)$$

where $|G(f)|$ is the magnitude of the Fourier transform of either $g_1(t)$ or $g_2(t)$.

A further generalization of the PSD of binary line codes can be given, wherein a continuous spectrum and a discrete spectrum is evident. Let a binary $\mathbf{1}$, with probability p , be represented by $g_1(t)$ over the $T = 1/R$ second bit interval; and let a binary $\mathbf{0}$, with probability $1-p$, be represented by $g_2(t)$ over the same T second bit interval. The two-sided PSD for this general binary line code is [10]

$$S_{GB}(f) = p(1-p)R|G_1(f) - G_2(f)|^2 + R^2 \sum_{n=-\infty}^{\infty} |pG_1(nR) + (1-p)G_2(nR)|^2 \delta(f-nR) \quad (28.14)$$

where the Fourier transform of $g_1(t)$ and $g_2(t)$ are given by $G_1(f)$ and $G_2(f)$, respectively.

28.3 Alternate Line Codes

Most of the line codes discussed thus far were instantaneous level codes. Only AMI had memory, and Manchester was an instantaneous transition code. The alternate line codes presented in this section all have memory. The first four are transition codes, where binary data is represented as the presence or absence of a transition, or by the direction of transition, i.e., positive to negative or vice versa. The last four codes described in this section are level line codes with memory.

Delay Modulation (Miller Code)

In this line code, a binary $\mathbf{1}$ is represented by a transition at the midbit position, and a binary $\mathbf{0}$ is represented by no transition at the midbit position. If a $\mathbf{0}$ is followed by another $\mathbf{0}$, however, the signal transition also occurs at the end of the bit interval, that is, between the two $\mathbf{0}$ s. An example of delay modulation is shown in Fig. 28.1(f). It is clear that delay modulation is a transition code with memory.

This code achieves the goal of providing good timing content without sacrificing bandwidth. The PSD of the Miller code for equally likely data is given by [10]

$$S_6(f) = \frac{V^2 T}{2(\pi f T)^2 (17 + 8 \cos 2\pi f T)} (23 - 2 \cos \pi f T - 22 \cos 2\pi f T - 12 \cos 3\pi f T + 5 \cos 4\pi f T + 12 \cos 5\pi f T + 2 \cos 6\pi f T - 8 \cos 7\pi f T + 2 \cos 8\pi f T) \quad (28.15)$$

This spectrum is plotted in Fig. 28.2b. The advantages of this code are that it requires relatively low bandwidth and most of the energy is contained in less than $0.5R$. However, there is no distinct spectral null within the $2R$ -Hz band. It has low DC content and no DC component. It has very good timing content, and carrier tracking is easier than Manchester coding. Error rate performance is comparable to that of the common line codes. One important disadvantage is that it has no error detection capability and, hence, performance cannot be monitored.

Split Phase (Mark)

This code is similar to Manchester in the sense that there are always midbit transitions. Hence, this code is relatively easy to synchronize and has no DC. Unlike Manchester, however, split phase (mark) encodes a binary digit into a midbit transition dependent on the midbit transition in the previous bit period [12]. Specifically, a binary **1** produces a reversal of midbit transition relative to the previous midbit transition. A binary **0** produces no reversal of the midbit transition. Certainly this is a transition code with memory. An example of a split phase (mark) coded waveform is shown in Fig. 28.1(g), where the waveform in the first bit period is chosen arbitrarily. Since this method encodes bits differentially, there is no 180° -phase ambiguity associated with some line codes. This phase ambiguity may not be an issue in most baseband links but is important if the line code is modulated. Split phase (space) is very similar to split phase (mark), where the role of the binary **1** and binary **0** are interchanged. An example of a split phase (space) coded waveform is given in Fig. 28.1(h); again, the first bit waveform is arbitrary.

Biphase (Mark)

This code, designated as Bi ϕ -M, is similar to a Miller code in that a binary **1** is represented by a midbit transition, and a binary **0** has no midbit transition. However, this code always has a transition at the beginning of a bit period [10]. Thus, the code is easy to synchronize and has no DC. An example of Bi ϕ -M is given in Fig. 28.1 (i), where the direction of the transition at $t = 0$ is arbitrarily chosen. Biphase (space) or Bi ϕ -S is similar to Bi ϕ -M, except the role of the binary data is reversed. Here a binary **0** (space) produces a midbit transition, and a binary **1** does not have a midbit transition. A waveform example of Bi ϕ -S is shown in Fig. 28.1(j). Both Bi ϕ -S and Bi ϕ -M are transition codes with memory.

Code Mark Inversion (CMI)

This line code is used as the interface to a Consultative Committee on International Telegraphy and Telephony (CCITT) multiplexer and is very similar to Bi ϕ -S. A binary **1** is encoded as an NRZ pulse with alternate polarity, $+V$ or $-V$. A binary **0** is encoded with a definitive midbit transition (or square wave phase) [1]. An example of this waveform is shown in Fig. 28.1(k) where a negative to positive transition (or 180° phase) is used for a binary **0**. The voltage level of the first binary **1** in this example is chosen arbitrarily. This example waveform is identical to Bi ϕ -S shown in Fig. 28.1(j), except for the last bit. CMI has good synchronization properties and has no DC.

NRZ (I)

This type of line code uses an inversion (I) to designate binary digits, specifically, a change in level or no change in level. There are two variants of this code, NRZ mark (M) and NRZ space (S) [5,12]. In NRZ (M), a change of level is used to indicate a binary 1, and no change of level is used to indicate a binary 0. In NRZ (S) a change of level is used to indicate a binary 0, and no change of level is used to indicate a binary 1. Waveforms for NRZ (M) and NRZ (S) are depicted in Fig. 28.1(l) and Fig. 28.1(m), respectively, where the voltage level of the first binary 1 in the example is chosen arbitrarily. These codes are level codes with memory. In general, line codes that use differential encoding, like NRZ (I), are insensitive to 180° phase ambiguity. Clock recovery with NRZ (I) is not particularly good, and dc wander is a problem as well. Its bandwidth is comparable to polar NRZ.

Binary N Zero Substitution (BNZS)

The common bipolar code AMI has many desirable properties of a line code. Its major limitation, however, is that a long string of zeros can lead to loss of synchronization and timing jitter because there are no pulses in the waveform for relatively long periods of time. **Binary N zero substitution (BNZS)** attempts to improve AMI by substituting a special code of length N for all strings of N zeros. This special code contains pulses that look like binary 1s but purposely produce violations of the AMI pulse convention. Two consecutive pulses of the same polarity violate the AMI pulse convention, independent of the number of zeros between the two consecutive pulses. These violations can be detected at the receiver and the special code replaced by N zeros. The special code contains pulses facilitating synchronization even when the original data has a long string of zeros. The special code is chosen such that the desirable properties of AMI coding are retained despite the AMI pulse convention violations, i.e., DC balance and error detection capability. The only disadvantage of BNZS compared to AMI is a slight increase in crosstalk due to the increased number of pulses and, hence, an increase in the average energy in the code.

Choosing different values of N yields different BNZS codes. The value of N is chosen to meet the timing requirements of the application. In telephony, there are three commonly used BNZS codes: B6ZS, B3ZS, and B8ZS. All BNZS codes are level codes with memory.

In a B6ZS code, a string of six consecutive zeros is replaced by one of two the special codes according to the rule:

If the last pulse was positive (+), the special code is: 0 + - 0 - +.

If the last pulse was negative (-), the special code is: 0 - + 0 + -.

Here a zero indicates a zero voltage level for the bit period; a plus designates a positive pulse, and a minus indicates a negative pulse.

This special code causes two AMI pulse violations: in its second bit position and in its fifth bit position. These violations are easily detected at the receiver and zeros resubstituted. If the number of consecutive zeros is 12, 18, 24, ..., the substitution is repeated 2, 3, 4, ... times. Since the number of violations is even, the B6ZS waveform is the same as the AMI waveform outside the special code, i.e., between special code sequences.

There are four pulses introduced by the special code that facilitates timing recovery. Also, note that the special code is DC balanced. An example of the B6ZS code is given as follows, where the special code is indicated by the bold characters.

Original data:	0	1	0	0	0	0	0	0	1	1	0	1	0	0	0	0	0	1	1	
B6ZS format:	0	+	0	+	-	0	-	+	-	+	0	-	0	-	+	0	+	-	+	-

The computation of the PSD of a B6ZS code is tedious. Its shape is given in Fig. 28.4, for comparison purposes with AMI, for the case of equally likely data.

TABLE 28.1 B3ZS Substitution Rules

Number of <i>B</i> Pulses Since Last Violation	Polarity of Last <i>B</i> Pulse	Substitution Code	Substitution Code Form
Odd	Negative (-)	00-	00V
Odd	Positive (+)	00+	00V
Even	Negative (-)	+0+	B0V
Even	Positive (+)	-0-	B0V

FIGURE 28.4 Power spectral density of different line codes, where $R = 1/T$ is the bit rate.

In a B3ZS code, a string of three consecutive zeros is replaced by either **B0V** or **00V**, where *B* denotes a pulse obeying the AMI (bipolar) convention and *V* denotes a pulse violating the AMI convention. **B0V** or **00V** is chosen such that the number of bipolar (*B*) pulses between the violations is odd. The B3ZS rules are summarized in Table 28.1.

Observe that the violation always occurs in the third bit position of the substitution code, and so it can be easily detected and zero replacement made at the receiver. Also, the substitution code selection maintains DC balance. There is either one or two pulses in the substitution code, facilitating synchronization. The error detection capability of AMI is retained in B3ZS because a single channel error would make the number of bipolar pulses between violations even instead of being odd. Unlike B6ZS, the B3ZS waveform between violations may not be the same as the AMI waveform. B3ZS is used in the digital signal-3 (DS-3) signal interface in North America and also in the long distance-4 (LD-4) coaxial transmission system in Canada. Next is an example of a B3ZS code, using the same symbol meaning as in the B6ZS code.

Original data:	1	0	0	1	0	0	0	1	1	0	0	0	0	1	0	0	0	1
B3ZS format:																		
Even No. of <i>B</i> pulses:	+	0	0	-	+	0	+	-	+	-	0	-	0	+	0	0	+	-
Odd No. of <i>B</i> pulses:	+	0	0	-	0	0	-	+	-	+	0	+	0	-	0	0	-	+

The last BNZS code considered here uses $N = 8$. A B8ZS code is used to provide transparent channels for the Integrated Services Digital Network (ISDN) on T1 lines and is similar to the B6ZS code. Here a

TABLE 28.2 HDB3 Substitution Rules

Number of <i>B</i> Pulses Since Last Violation	Polarity of Last <i>B</i> Pulse	Substitution Code	Substitution Code Form
Odd	Negative (-)	000-	000V
Odd	Positive (+)	000+	000V
Even	Negative (-)	+00+	B00V
Even	Positive (+)	-00-	B00V

string of eight consecutive zeros is replaced by one of two special codes according to the following rule:

If the last pulse was positive (+), the special code is: 0 0 0 + - 0 - +.

If the last pulse was negative (-), the special code is: 0 0 0 - + 0 + -.

There are two bipolar violations in the special codes, at the fourth and seventh bit positions. The code is DC balanced, and the error detection capability of AMI is retained. The waveform between substitutions is the same as that of AMI. If the number of consecutive zeros is 16, 24, ..., then the substitution is repeated 2, 3, ..., times.

High-Density Bipolar *N* (HDBN)

This coding algorithm is a CCITT standard recommended by the Conference of European Posts and Telecommunications Administrations (CEPT), a European standards body. It is quite similar to BNZS coding. It is thus a level code with memory. Whenever there is a string of $N + 1$ consecutive zeros, they are replaced by a special code of length $N + 1$ containing AMI violations. Specific codes can be constructed for different values of N . A specific **high-density bipolar N (HDBN)** code, HDB3, is implemented as a CEPT primary digital signal. It is very similar to the B3ZS code. In this code, a string of four consecutive zeros is replaced by either **B00V** or **000V**. **B00V** or **000V** is chosen such that the number of bipolar (B) pulses between violations is odd. The HDB3 rules are summarized in [Table 28.2](#).

Here the violation always occurs in the fourth bit position of the substitution code, so that it can be easily detected and zero replacement made at the receiver. Also, the substitution code selection maintains DC balance. There are either one or two pulses in the substitution code facilitating synchronization. The error detection capability of AMI is retained in HDB3 because a single channel error would make the number of bipolar pulses between violations even instead of being odd.

Ternary Coding

Many line coding schemes employ three symbols or levels to represent only one bit of information, like AMI. Theoretically, it should be possible to transmit information more efficiently with three symbols, specifically the maximum efficiency is $\log_2 3 = 1.58$ bits per symbol. Alternatively, the redundancy in the code signal space can be used to provide better error control. Two examples of ternary coding are described next [1,2]: **pair selected ternary (PST)** and **4 binary 3 ternary (4B3T)**. The PST code has many of the desirable properties of line codes, but its transmission efficiency is still 1 bit per symbol. The 4B3T code also has many of the desirable properties of line codes, and it has increased transmission efficiency.

In the PST code, two consecutive bits, termed a binary pair, are grouped together to form a word. These binary pairs are assigned codewords consisting of two ternary symbols, where each ternary symbol can be +, -, or 0, just as in AMI. There are nine possible ternary codewords. Ternary codewords with identical elements, however, are avoided, i.e., ++, --, and 00. The remaining six codewords are transmitted using two modes called + mode and - mode. The modes are switched whenever a codeword with a single pulse is transmitted. The PST code and mode switching rules are summarized in [Table 28.3](#).

PST is designed to maintain DC balance and include a strong timing component. One drawback of this code is that the bits must be framed into pairs. At the receiver, an *out-of-frame* condition is signalled

TABLE 28.3 PST Codeword Assignment and Mode Switching Rules

Binary Pair	Ternary Codewords		Mode Switching
	+Mode	-Mode	
11	+ -	+ -	No
10	+ 0	- 0	Yes
01	0 +	0 -	Yes
00	- +	- +	No

TABLE 28.4 Modified PST Codeword Assignment and Mode Switching Rules

Binary Pair	Ternary Codewords		Mode Switching
	+ Mode	- Mode	
11	+ 0	0 -	Yes
10	0 -	0 -	No
01	- +	- +	No
00	0 +	- 0	Yes

TABLE 28.5 4B3T Codeword Assignment

Binary Words	Ternary Codewords		
	Column 1	Column 2	Column 3
0000	- - -		+ + +
0001	- - 0		+ + 0
0010	- 0 -		+ 0 +
0011	0 - -		0 + +
0100	- - +		+ + -
0101	- + -		+ - +
0110	+ - -		- + +
0111	- 0 0		+ 0 0
1000	0 - 0		0 + 0
1001	0 0 -		0 0 +
1010		0 + -	
1011		0 - +	
1100		+ 0 -	
1101		- 0 +	
1110		+ - 0	
1111		- + 0	

when unused ternary codewords (+ +, - -, and 00) are detected. The mode switching property of PST provides error detection capability. PST can be classified as a level code with memory.

If the original data for PST coding contains only 1s or 0s, an alternating sequence of +- +- ... is transmitted. As a result, an out-of-frame condition cannot be detected. This problem can be minimized by using the modified PST code as shown in [Table 28.4](#).

It is tedious to derive the PSD of a PST coded waveform. Again, [Fig. 28.4](#) shows the PSD of the PST code along with the PSD of AMI and B6ZS for comparison purposes, all for equally likely binary data. Observe that PST has more power than AMI and, thus, a larger amount of energy per bit, which translates into slightly increased crosstalk.

In 4B3T coding, words consisting of four binary digits are mapped into three ternary symbols. Four bits imply $2^4 = 16$ possible binary words, whereas three ternary symbols allow $3^3 = 27$ possible ternary codewords. The binary-to-ternary conversion in 4B3T insures DC balance and a strong timing component. The specific codeword assignment is as shown in [Table 28.5](#).

There are three types of codewords in Table 28.5, organized into three columns. The codewords in the first column have negative DC, codewords in the second column have zero DC, and those in the third column have positive DC. The encoder monitors the integer variable

$$I = N_p - N_n \quad (28.16)$$

where N_p is the number of positive pulses transmitted and N_n are the number of negative pulses transmitted. Codewords are chosen according to following rule:

- If $I < 0$, choose the ternary codeword from columns 1 and 2.
- If $I > 0$, choose the ternary codeword from columns 2 and 3.
- If $I = 0$, choose the ternary word from column 2, and from column 1 if the previous $I > 0$ or from column 3 if the previous $I < 0$.

Note that the ternary codeword 000 is not used, but the remaining 26 codewords are used in a complementary manner. For example, the column 1 codeword for 0001 is --0, whereas the column 3 codeword is ++0. The maximum transmission efficiency for the 4B3T code is 1.33 bits per symbol compared to 1 bit per symbol for the other line codes. The disadvantages of 4B3T are that framing is required and that performance monitoring is complicated. The 4B3T code is used in the T148 span line developed by ITT Telecommunications. This code allows transmission of 48 channels using only 50% more bandwidth than required by T1 lines, instead of 100% more bandwidth.

28.4 Multilevel Signalling, Partial Response Signalling, and Duobinary Coding

Ternary coding, such as 4B3T, is an example of the use of more than two levels to improve the transmission efficiency. To increase the transmission efficiency further, more levels and/or more signal processing is needed. Multilevel signalling allows an improvement in the transmission efficiency at the expense of an increase in the error rate, i.e., more transmitter power will be required to maintain a given probability of error. In partial response signalling, intersymbol interference is deliberately introduced by using pulses that are wider and, hence, require less bandwidth. The controlled amount of interference from each pulse can be removed at the receiver. This improves the transmission efficiency, at the expense of increased complexity. **Duobinary coding**, a special case of partial response signalling, requires only the minimum theoretical bandwidth of $0.5R$ Hz. In what follows, these techniques are discussed in slightly more detail.

Multilevel Signalling

The number of levels that can be used for a line code is not restricted to two or three. Since more levels or symbols allow higher transmission efficiency, multilevel signalling can be considered in bandwidth-limited applications. Specifically, if the signalling rate or baud rate is R_s and the number of levels used is L , the equivalent transmission bit rate R_b is given by

$$R_b = R_s \log_2 [L] \quad (28.17)$$

Alternatively, multilevel signalling can be used to reduce the baud rate, which in turn can reduce crosstalk for the same equivalent bit rate. The penalty, however, is that the SNR must increase to achieve the same error rate. The T1G carrier system of AT&T uses multilevel signalling with $L = 4$ and a baud rate of 3.152 mega-symbols/s to double the capacity of the T1C system from 48 channels to 96 channels. Also, a four

level signalling scheme at 80-kB is used to achieve 160 kb/s as a basic rate in a digital subscriber loop (DSL) for ISDN.

Partial Response Signalling and Duobinary Coding

This class of signalling is also called *correlative* coding because it purposely introduces a controlled or correlated amount of intersymbol interference in each symbol. At the receiver, the known amount of interference is effectively removed from each symbol. The advantage of this signalling is that wider pulses can be used requiring less bandwidth, but the SNR must be increased to realize a given error rate. Also, errors can propagate unless *precoding* is used.

There are many commonly used partial response signalling schemes, often described in terms of the delay operator D , which represents one signalling interval delay. For example, in $(1 + D)$ signalling the current pulse and the previous pulse are added. The T1D system of AT&T uses $(1 + D)$ signalling with precoding, referred to as duobinary signalling, to convert binary (two level) data into ternary (three level) data at the same rate. This requires the minimum theoretical channel bandwidth without the deleterious effects of intersymbol interference and avoids error propagation. Complete details regarding duobinary coding are found in Lender [9] and Schwartz [11]. Some partial response signalling schemes, such as $(1 - D)$, are used to shape the bandwidth rather than control it. Another interesting example of duobinary coding is a $(1 - D^2)$, which can be analyzed as the product $(1 - D)(1 + D)$. It is used by GTE in its modified T carrier system. AT&T also uses $(1 - D^2)$ with four input levels to achieve an equivalent data rate of 1.544 Mb/s in only a 0.5-MHz bandwidth.

28.5 Bandwidth Comparison

We have provided the PSD expressions for most of the commonly used line codes. The actual bandwidth requirement, however, depends on the pulse shape used and the definition of bandwidth itself. There are many ways to define bandwidth, for example, as a percentage of the total power or the sidelobe suppression relative to the main lobe. Using the first null of the PSD of the code as the definition of bandwidth, Table 28.6 provides a useful bandwidth comparison.

The notable omission in Table 28.6 is delay modulation (Miller code). It does not have a first null in the $2R$ -Hz band, but most of its power is contained in less than $0.5R$ Hz.

28.6 Concluding Remarks

An in-depth presentation of line coding, particularly applicable to telephony, has been included in this chapter. The most desirable characteristics of line codes were discussed. We introduced five common line codes and eight alternate line codes. Each line code was illustrated by an example waveform. In most cases expressions for the PSD and the probability of error were given and plotted. Advantages and disadvantages of all codes were included in the discussion, and some specific applications were noted. Line codes for optical fiber channels and networks built around them, such as fiber distributed data interface (FDDI), were not included in this section. A discussion of line codes for optical fiber channels and other new developments in this topic area can be found in [1,3,4].

TABLE 28.6 First Null Bandwidth Comparison

Bandwidth	Codes	
R	Unipolar NRZ	BNZS
	Polar NRZ	HDBN
	Polar RZ (AMI)	PST
$2R$	Unipolar RZ	Split Phase
	Manchester	CMI

Defining Terms

Alternate mark inversion (AMI): A popular name for bipolar line coding using three levels: zero, positive, and negative.

Binary N zero substitution (BNZS): A class of coding schemes that attempts to improve AMI line coding.

Bipolar: A particular line coding scheme using three levels: zero, positive, and negative.

Crosstalk: An unwanted signal from an adjacent channel.

DC wander: The DC level variation in the received signal due to a channel that cannot support DC.

Duobinary coding: A coding scheme with binary input and ternary output requiring the minimum theoretical channel bandwidth.

4 Binary 3 Ternary (4B3T): A line coding scheme that maps four binary digits into three ternary symbols.

High-density bipolar N (HDBN): A class of coding schemes that attempts to improve AMI.

Level codes: Line codes carrying information in their voltage levels.

Line coding: The process of converting abstract symbols into real, temporal waveforms to be transmitted through a baseband channel.

Nonreturn to zero (NRZ): A signal that stays at a nonzero level for the entire bit duration.

Pair selected ternary (PST): A coding scheme based on selecting a pair of three level symbols.

Polar: A line coding scheme using both polarity of voltages, with or without a zero level.

Return to zero (RZ): A signal that returns to zero for a portion of the bit duration.

Transition codes: Line codes carrying information in voltage level transitions.

Unipolar: A line coding scheme using only one polarity of voltage, in addition to a zero level.

29.1 Introduction

Today's telecommunications network comprises customer premises equipment and telephone central offices interconnected by suitable transmission facilities. Although analog technology still exists in the customer loop, digital time-division multiplex (TDM) technology is more prevalent in the central office switching and transmission systems.

A digital switch located within the interoffice network terminates TDM signals originating from many other offices. It performs a combination of time-slot interchange and space switching to accomplish the interconnect function amongst the individual channels of the multiplexed signals. In order to accomplish this function without impairments, the average rates of all of the TDM signals terminating on the switch have to be synchronized to within some achievable bound. Furthermore, the reference clock of the switch itself must also be synchronized to the common rate of the incoming signals. These synchronization requirements are also applicable to a digital cross-connect system since it realizes the channel interconnection function in a similar manner.

Synchronous multiplexers, such as synchronous optical network (SONET) and synchronous digital hierarchy (SDH) terminals, used in fiber optic systems, generate the high-speed output signal by interleaving the time slots of the lower speed input signals. Again, to accomplish this function properly, the rates of the incoming lines and that of the multiplexer clock have to be synchronized. Primary rate multiplexers (known as channel banks) also employ synchronous time interleaving of the 64-kb/s, tributary signals, often generated by other network elements (digital switches and signalling transfer points, for example) within the same office. For unimpaired information transfer in this case, the network elements that terminate these 64-kb/s signals have to be synchronized in both frequency and phase (bit and byte synchronization!).

Network synchronization is the background technology that enables the operating clocks of the various network elements throughout the network to be synchronized. Robust and accurate synchronization networks are essential to the proper functioning of these elements and the reliable transfer of information between them. The growth of data services and the deployment of SONET and SDH transmission equipment has further emphasized the need for such networks.

29.2 Synchronization Distribution Networks

The goal of the synchronization distribution network is to provide reference clocks, traceable to a highly accurate clock called a primary reference source (PRS), to all of the network elements. Since the transport of timing signals over long distances incurs many impairments, the *interoffice* distribution of synchronization references is generally more difficult compared to the task of distributing these reference clocks to the network elements within an office (*intraoffice* distribution).

One method of achieving synchronization in the interoffice network is to designate a single PRS as the master clock for the entire network and transport this clock to every office using a **master–slave** hierarchical discipline. This method is impractical for large networks because of noise accumulation through many levels of cascaded slave clocks, delay variations caused by the rerouting of clock distribution paths under failure conditions, and geopolitical problems. At the other extreme is the **plesiochronous** mode of operation where each office has its own PRS, and no interoffice clock distribution is necessary. This strategy is expensive to implement now, although it can be envisioned in the future because of the projected availability of affordable PRSs. Therefore, a combination of the two techniques is typically employed in practice. As shown in Fig. 29.1, the network is divided into small synchronization regions, each of which has a duplicated set of PRSs as the master clock. Within each region, the timing distribution is accomplished by following a master-slave hierarchy of **stratum clocks**. A stratum 1 clock, normally implemented with cesium beam technology, is required to have a long term accuracy of better than 1×10^{-11} , completely autonomous of other references. The PRS is also required to have the same long-term accuracy as a stratum 1 clock. However, it can be realized either as an autonomous cesium clock or as a nonautonomous clock disciplined by precision global positioning system (GPS) or LORAN-C radio-navigational signals. Stratum 2, 3, and 4 clocks have progressively lower accuracy and performance requirements. Synchronization references are passed from higher performance master clocks to equivalent or lower performance slave clocks. Path redundancy is achieved by providing primary and secondary reference sources at the slave clocks.

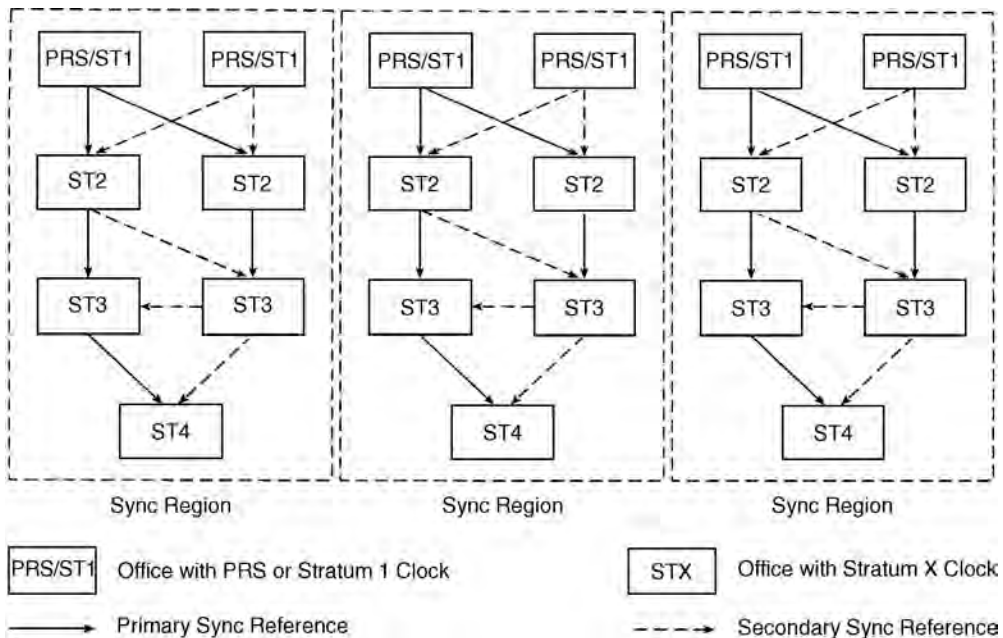

FIGURE 29.1 Network synchronization distribution plan.

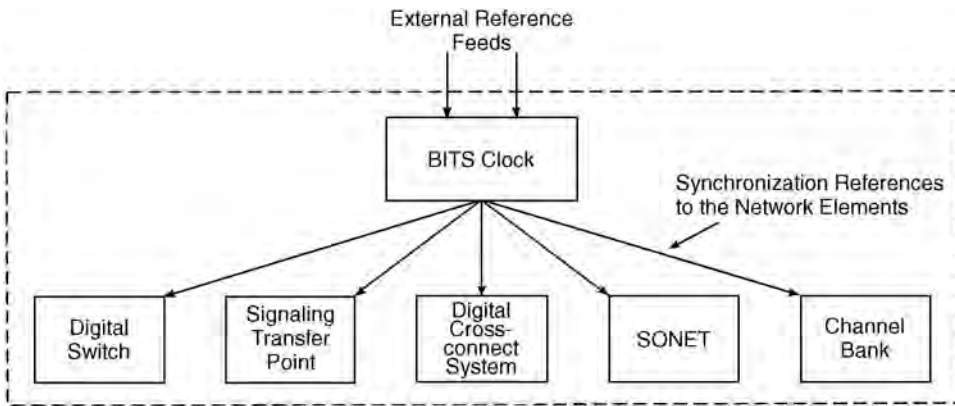

FIGURE 29.2 Intraoffice synchronization distribution plan.

Whereas the interoffice plan for distributing synchronization follows the regionalized master–slave hierarchical strategy previously described, the distribution of reference clocks within an office is realized with a discipline known as the building integrated timing supply (BITS) plan. As shown in Fig. 29.2, this plan calls for the deployment of a properly stratified slave clock called the BITS in each office, which distributes reference timing to all of the network elements. It is the only clock in the office that is directly synchronized to an external reference traceable to a PRS. For robustness, it accepts two external reference feeds and contains duplicated stratum oscillators. If both the external reference feeds are disrupted, the BITS enters the holdover mode of operation where the output reference timing signals are generated using the data acquired during the normal (synchronized) mode.

The master–slave synchronization distribution scheme functions well within a (small) region if the underlying network topology is of the star or tree type. However, self-healing ring topologies are popular with fiber optic networks using the SONET and SDH technology, especially in the loop environment. Feeding multiple synchronization references to slave clocks, or directly to the network elements at the nodes where the BITS plan is not implemented, in such networks can lead to **timing loops** under failure conditions [Bellcore, 1992]. Timing loops are undesirable since they lead to isolation of the clocks within the loop from the PRS and can also cause frequency instabilities due to reference feedback. Providing only a single-synchronization reference source at the nodes is one method of avoiding the possibility of timing loops [Bellcore, 1992]. However, this compromises the path redundancy provided by dual feeds. An alternate procedure is the use of synchronization messages embedded in the overhead channels of the reference signals. Here the nodes indicate the synchronization status (e.g., reference traceable to stratum 1, traceability unknown, etc.) of the transmitted signals to neighboring nodes. The slave clocks (or the network elements) at the other nodes can then avoid the inadvertent creation of timing loops by deciding intelligently, based on the embedded messages, whether or not to switch to the secondary synchronization reference source upon failure of the primary.

29.3 Effect of Synchronization Impairments

The severity of impact on network traffic due to disruptions in the synchronization distribution system or accumulation of phase noise depends on many factors. These include buffering techniques employed to manage the incoming phase variations at the network elements, the type of information transported through the traffic network, and the architecture of the synchronization distribution system itself.

Figure 29.3 shows the situation where the reference clocks of the two interconnected digital switches (or two digital cross-connect systems) are operating at different frequencies due to disruptions in the synchronization distribution network, for example. The receiver at switch 2 has a 125- μ s slip buffer to

TABLE 29.1 Impact of Slips on Network Service

Service	Observed Effect
PCM voice	No noticeable degradation for moderate slip rates
Voice-band data	Serious degradation with some modems needing up to 6 s to recover from a slip
Group III fax	Each slip can wipe out 0.08 in. of vertical space
Encrypted voice	Serious degradation requiring retransmission of the encryption key
Compressed video	Serious degradation resulting in freeze frames or missing lines
Digital data (e.g., SS7)	Loss of messages resulting in requests for retransmission and degraded throughput

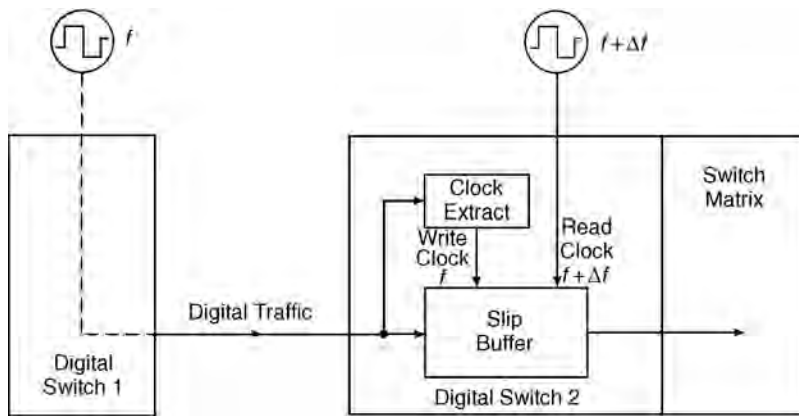

FIGURE 29.3 Slips in the digital network.

absorb the phase variations of the incoming line with respect to its clock. Since the rates of the write and read clocks at the slip buffer are different, however, an eventual overflow or underflow of the buffer is inevitable. This results in a frame of data either being repeated or deleted at the output of the buffer. Such an event is called a controlled slip. The duration between slips is given by $(125/\epsilon) \mu\text{s}$, where ϵ is the fractional frequency deviation $|Df|/f$. As an example, the duration between slips for plesiochronous operation ($\epsilon = \pm 10^{-11}$) is about 72 days. The impact of slips on various network services is delineated in Table 29.1.

Slips occur infrequently when there are no synchronization disruptions since the $125\text{-}\mu\text{s}$ slip buffers can readily absorb the phase noise caused by the existing transmission systems. However, excessive phase noise either in the incoming lines or in the reference clock at a synchronous multiplexer can cause impairments to the transported data. To understand this, consider the operation of a SONET multiplexer, shown in Fig. 29.4, that combines three 51.84-Mb/s synchronous transport system level 1 (STS-1) signals to form a 155.52-Mb/s STS-3 signal. Data is written into the small-capacity (8-16 bytes) receive buffer in the pointer processor at the rate of the incoming line. If the buffer is near its normal half-full capacity, it is read out at the rate of the local reference clock. However, if the buffer shows signs of filling up or emptying (determined by the upper and lower threshold settings), its read clock is modified by either augmenting or deleting eight pulses from the reference clock. This event, known as a *pointer adjustment*, results in a phase jump of eight unit intervals for the data read out of the buffer and multiplexed onto the STS-3 signal. Occasional pointer adjustments occur even in a synchronized network because of short-term phase variations of the incoming signals, and they cause no harm since data is not lost. However, existing asynchronous equipment may not function properly when receiving

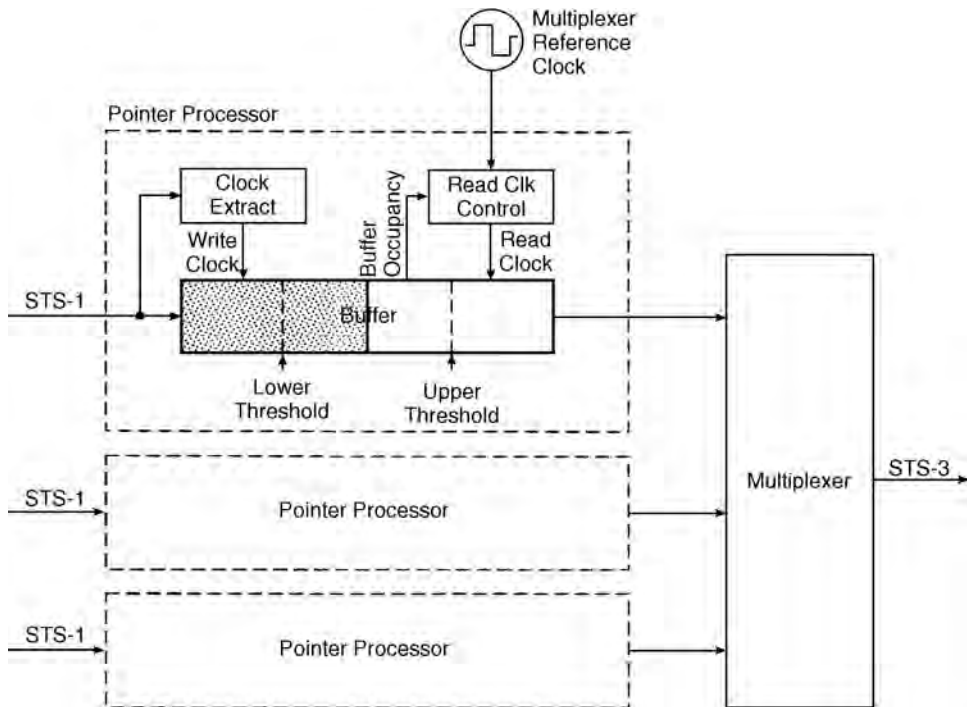

FIGURE 29.4 SONET multiplexer.

severely jittered signals, caused by frequent pointer adjustments, at gateway points between the synchronous and the asynchronous networks. Furthermore, the rate of pointer adjustments is not allowed to exceed certain limits in SONET and SDH networks. Severe phase noise may cause these limits to be exceeded resulting in a buffer overflow or underflow situation, which leads to loss or repetition of data as in the case of a slip.

29.4 Characterization of Synchronization Impairments

The synchronization performance of a telecommunications signal is typically determined from measured values of the deviations in time between when the signal transitions actually occur and when they are ideally expected. The master clock that provides the ideal time positions should be significantly more accurate than the signal under test. The measurement yields the raw phase error signal, also known as the *time delay* or simply *phase*, in units of time as a function of elapsed time. Postprocessing of this raw data is, however, necessary to extract useful parameters that help define the underlying synchronization impairment model.

The current synchronization impairment model used for the telecommunications signal is based mainly on the source of the impairments. It refers to the higher frequency components of the phase (error) oscillations as **jitter** and to the lower frequency components as **wander**, with 10 Hz being the demarcation frequency. Jitter is produced mainly by regenerative repeaters and asynchronous multiplexers, and normal levels of it can readily be buffered and filtered out. However, excessive jitter is a potential source of bit errors in the digital network. Wander, on the other hand, has many causes. These include temperature cycling effects in cables, waiting time effects in asynchronous multiplexers, and the effects of frequency and phase quantization in slave clocks which employ narrowband filters in their servocontrol loops. Since it contains very low-frequency components, wander cannot be completely filtered out and,

hence, is passed on. Excessive wander adversely affects the slip performance of the network and can also lead to an unacceptable rate of pointer adjustments in SONET and SDH multiplexers. Furthermore, wander on an input reference signal compromises the holdover performance of a slave clock during reference interruptions.

Although jitter and wander are adequate descriptors of synchronization impairments in the existing digital network, a more comprehensive model is necessary to characterize the phase variations caused by the newly introduced SONET and SDH equipment and to appropriately specify the limits on timing noise at network interfaces. Recently, there has been renewed interest in adapting the traditional noise model used with precision oscillators and clocks in time and frequency metrology to the telecommunications applications. This model permits the characterization of the complex timing impairments with a handful of parameters classified into systematic components (phase offset, frequency offset, and frequency drift) and stochastic power-law noise components (white PM, flicker PM, white FM, flicker FM, and random walk FM).

Maximum time interval error (MTIE) and time variance (TVAR) are two parameters [ANSI, 1994] for specifying the synchronization performance of telecommunications signals that are defined to capture the essential features of the traditional model. MTIE is effective in characterizing peak-to-peak phase movements, which are primarily due to systematic components, whereas TVAR is useful in characterizing the stochastic power-law noise components of the phase noise.

The algorithm for computing the MTIE from N time delay (phase error) samples x_i , $i = 1, 2, \dots, N$, measured at time intervals τ_0 , is illustrated in Fig. 29.5. For a given observation interval S spanning n samples, the peak-to-peak phase excursion values are noted for all possible positions of the observation window that can be accommodated by the collected data. The maximum of all such values yields MTIE(S). This computation can be expressed as

$$\text{MTIE}(S) = \max_{j=1, \dots, N-n+1} x_{ppj}(S)$$

where

$$x_{ppj}(S) = \max x_i - \min x_i, \quad i = j, \dots, j + n - 1$$

FIGURE 29.5 Computation of the MTIE from measured time delay samples.

The calculation of TVAR for the same set of time delay samples is expressed by the equation:

$$\text{TVAR}(\tau) = \frac{1}{6n^2(N-3n+1)} \sum_{j=1}^{N-3n+1} \left[\sum_{k=0}^{n-1} (x_{j+2n+k} - 2x_{j+n+k} + x_{j+k}) \right]^2$$

where the independent variable $\tau = n\tau_0$ and spanning n samples is known as the *integration time*. This calculation may be viewed as a spectral estimation process with a nonuniform bandpass filter bank. The magnitude response of the bandpass filter corresponding to the integration time τ at frequency f is given by

$$\left| \sqrt{\frac{8}{3}} \frac{\sin^3(\pi\tau f)}{n \sin(\pi\tau_0 f)} \right|$$

A standard variance estimate of the filtered samples then yields $\text{TVAR}(\tau)$. The square root of TVAR is denoted by time deviation (TDEV).

The graphs of MTIE plotted as a function of the observation interval S and TDEV plotted as a function of the integration time τ are primarily used to characterize the synchronization performance of a telecommunications signal.

29.5 Synchronization Standards

Standards for synchronization in telecommunications systems are set by the American National Standards Institute (ANSI) in the U.S. and by the Consultative Committee on International Telephony and Teleg-raphy (CCITT), now known as the International Telecommunications Union (ITU), for international applications. In addition, Bellcore issues technical references and technical advisories that specify the requirements from the viewpoint of the regional Bell operating companies (RBOCs). These documents are listed in the References. Some highlights of these standards are reviewed here.

The various standards deal with two categories of specifications: the characteristics of the clocks used in the synchronization distribution network, and the synchronization performance of the reference signals at network interfaces.

The **free-run accuracy**, the **holdover stability**, and the **pull-in range** requirements of the stratum clocks employed in the synchronized network are delineated in Table 29.2. (The ITU uses a different terminology for the stratum levels. Refer to Annex D of the revised ANSI standard T1.101 for the differences.) In addition to the pull-in range requirements, the slave clocks should be able to tolerate certain amounts of jitter, wander, and **phase transients** at their reference inputs. Moreover, there are other performance constraints, besides accuracy and stability, on the output signal. These include wander generation, wander transfer, jitter generation, and phase transients. These are detailed in the Bellcore [1993b] Technical Reference TR-NWT-00 1244.

As an illustration, Fig. 29.6 shows the MTIE specification mask for a PRS. Also shown are the measured performance curves of typical PRS clocks based on GPS and LORAN-C receiver technology.

TABLE 29.2 Performance Requirements of Stratum Clocks

Stratum	Free-Run Accuracy	Holdover Stability	Pull-In Range
1	$\pm 1 \times 10^{-11}$	—	—
2	$\pm 1.6 \times 10^{-8}$	$\pm 1 \times 10^{-10}/\text{day}$	$\pm 1.6 \times 10^{-8}$
3E	$\pm 4.6 \times 10^{-6}$	$\pm 1 \times 10^{-8}/\text{day}$	$\pm 4.6 \times 10^{-6}$
3	$\pm 4.6 \times 10^{-6}$	$\pm 3.7 \times 10^{-7}/\text{day}$	$\pm 4.6 \times 10^{-6}$
4/4E	$\pm 32 \times 10^{-6}$	—	$\pm 32 \times 10^{-6}$

FIGURE 29.6 MTIE specification mask and measured performance of GPS and LORAN PRSs.

FIGURE 29.7 MTIE specification for synchronization reference signals at network interfaces.

The performance requirements of synchronization references at network interfaces depend on whether optical rate signals [i.e., optical carrier level N (OC-N)] or primary rate electrical signals [e.g., digital signal level 1 (DS1)] are being considered. The specifications for optical interfaces are tighter because SONET and SDH pointer adjustments are sensitive to short-term phase noise. The MTIE and TDEV specification masks for DS1 and OC-N signals are shown in Figs. 29.7 and 29.8.

These reference signals also have to satisfy certain constraints on the magnitude of phase transients. The revised ANSI Standard T1.101-1987 [ANSI, 1994] specifies these details.

FIGURE 29.8 TDEV specification for synchronization reference signals at network interfaces.

29.6 Summary and Conclusions

The deployment of digital switching exchanges and cross-connect equipment in telecommunications systems created the necessity for robust synchronization distribution networks. These networks were originally designed to guarantee satisfactory slip performance for an end-to-end connection. However, recently introduced high-speed synchronous multiplexing and transmission systems based on SONET and SDH technology have emphasized the need for enhancing their accuracy and reliability. A disciplined approach to the design of such networks is delineated in many of the synchronization standards issued so far.

Our current understanding of the sources of synchronization impairments in telecommunications networks has not yet reached a mature point. The adaption of traditional clock noise models, such as those used in time and frequency metrology, to describe these impairments is a step in the right direction. However, much work is necessary to first evaluate reliably the parameters of this model from the phase error measurements, and then to identify the actual sources of impairments from them. As newer transport technologies such as asynchronous transfer mode (ATM) are introduced, the distribution of accurate synchronization references will be more complicated, and the impact of synchronization disruptions on network services will be harder to predict. These and other issues are currently being investigated by the various standards organizations.

Defining Terms

Free-run accuracy: The maximum long-term (20 years) deviation limit of a clock from the nominal frequency with no external frequency reference.

Holdover stability: The maximum rate of change of the clock frequency with respect to time upon loss of all input frequency references.

Jitter: The short-term variations of the significant instants (e.g., zero level crossings) of a digital signal from their ideal positions in time, where short term implies phase variations of frequency greater than or equal to 10 Hz.

Master-slave hierarchy: The hierarchical method where synchronization references are distributed from offices with higher performance master stratum clocks to offices with the same or lower performance slave stratum clocks.

- Phase transient:** Perturbations in phase of limited duration (typically several time constants of the slave clock which produces it) seen at synchronization interfaces.
- Plesiochronous:** Two signals are plesiochronous if their corresponding significant instants (e.g., zero level crossings) occur at nominally the same rate, any variation in rate being constrained within specified limits.
- Pull-in range:** Measure of the maximum reference frequency deviation from the nominal rate that can be overcome by a slave clock to pull itself into synchronization.
- Stratum clocks:** A classification of clocks in the synchronization network based on performance. Stratum 1 is the highest and stratum 4 is the lowest level of performance.
- Timing loop:** The situation where a slaved clock receives input reference timing from itself via a chain of other slaved clocks.
- Wander:** The long-term variations of the significant instants (e.g., zero level crossings) of a digital signal from their ideal positions in time, where long term implies phase variations of low frequency (less than 10 Hz).

30.1 Introduction

Full-duplex data transmission over a single twisted-pair cable permits the simultaneous flow of information in two directions when the same frequency band is used. Examples of applications of this technique are found in digital communications systems that operate over the telephone network. In a digital subscriber loop, at each end of the full-duplex link, a circuit known as a hybrid separates the two directions of transmission. To avoid signal reflections at the near- and far-end hybrid, a precise knowledge of the line impedance would be required. Since the line impedance depends on line parameters that, in general, are not exactly known, an attenuated and distorted replica of the transmit signal leaks to the receiver input as an echo signal. Data-driven adaptive echo cancellation mitigates the effects of impedance mismatch.

A similar problem is caused by crosstalk in transmission systems over voice-grade unshielded twisted-pair cables for local-area network applications, where multipair cables are used to physically separate the two directions of transmission. Crosstalk is a statistical phenomenon due to randomly varying differential capacitive and inductive coupling between adjacent two-wire transmission lines. At the rates of several megabits per second that are usually considered for local-area network applications, near-end crosstalk (NEXT) represents the dominant disturbance; hence, adaptive NEXT cancellation must be performed to ensure reliable communications.

In voiceband data modems, the model for the echo channel is considerably different from the echo model adopted in baseband transmission. The transmitted signal is a passband signal obtained by quadrature amplitude modulation (QAM), and the far-end echo may exhibit significant carrier-phase jitter and carrier-frequency shift, which are caused by signal processing at intermediate points in the telephone network. Therefore, a digital adaptive echo canceller for voiceband modems needs to embody algorithms that account for the presence of such additional impairments.

In this chapter, we describe the echo channel models and adaptive echo canceller structures that are obtained for various digital communications systems, which are classified according to the employed modulation techniques. We also address the tradeoffs between complexity, speed of adaptation, and accuracy of cancellation in adaptive echo cancellers.

30.2 Echo Cancellation for Pulse-Amplitude Modulation (PAM) Systems

The model of a full-duplex baseband data transmission system employing pulse-amplitude modulation (PAM) and adaptive echo cancellation is shown in Fig. 30.1. To describe system operations, we consider one end of the full-duplex link. The configuration of an echo canceller for a PAM transmission system is shown in Fig. 30.2. The transmitted data consist of a sequence $\{a_n\}$ of independent and identically distributed (i.i.d.) real-valued symbols from the M -ary alphabet $\mathcal{A} = \{\pm 1, \pm 3, \dots, \pm(M-1)\}$. The sequence $\{a_n\}$ is converted into an analog signal by a digital-to-analog (D/A) converter. The conversion to a staircase signal by a zero-order hold D/A converter is described by the frequency response $H_{D/A}(f) = T \sin(\pi f T) / (\pi f T)$, where T is the modulation interval. The D/A converter output is filtered by the analog transmit filter and is input to the channel through the hybrid.

The signal $x(t)$ at the output of the low-pass analog receive filter has three components, namely, the signal from the far-end transmitter $r(t)$, the echo $u(t)$, and additive Gaussian noise $w(t)$. The signal $x(t)$ is given by

$$\begin{aligned} x(t) &= r(t) + u(t) + w(t) \\ &= \sum_{n=-\infty}^{\infty} a_n^R h(t - nT) + \sum_{n=-\infty}^{\infty} a_n h_E(t - nT) + w(t) \end{aligned} \quad (30.1)$$

where $\{a_n^R\}$ is the sequence of symbols from the remote transmitter, and $h(t)$ and $h_E(t) = \{h_{D/A} \otimes g_E\}(t)$ are the impulse responses of the overall channel and the echo channel, respectively. In the expression of $h_E(t)$, the function $h_{D/A}(t)$ is the inverse Fourier transform of $H_{D/A}(f)$, and the operator \otimes denotes convolution. The signal obtained after echo cancellation is processed by a detector that outputs the sequence of estimated symbols $\{\hat{a}_n^R\}$. In the case of full-duplex PAM data transmission over multi-pair cables for

FIGURE 30.1 Model of a full-duplex PAM transmission system.

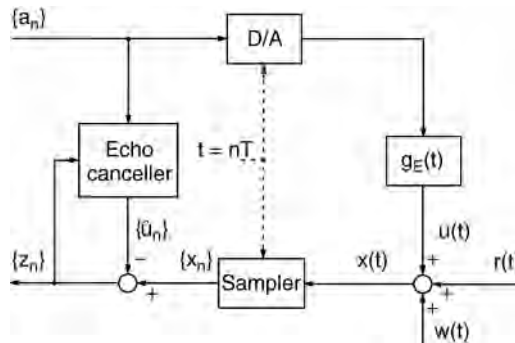

FIGURE 30.2 Configuration of an echo canceller for a PAM transmission system.

FIGURE 30.3 Model of a dual-duplex transmission system.

local-area network applications, where NEXT represents the main disturbance, the configuration of a digital NEXT canceller is also obtained as shown in Fig. 30.2, with the echo channel replaced by the crosstalk channel. For these applications, however, instead of *mono-duplex* transmission, where one pair is used to transmit only in one direction and the other pair to transmit only in the reverse direction, *dual-duplex* transmission may be adopted. Bi-directional transmission at rate Q over two pairs is then accomplished by full-duplex transmission of data streams at $Q/2$ over each of the two pairs. The lower modulation rate and/or spectral efficiency required per pair for achieving an aggregate rate equal to Q represents an advantage of dual-duplex over mono-duplex transmission. Dual-duplex transmission requires two transmitters and two receiver at each end of a link, as well as separation of the simultaneously transmitted and received signals on each pair, as illustrated in Fig. 30.3. In dual-duplex transceivers, it is therefore necessary to suppress echoes returning from the hybrids and impedance discontinuities in the cable, as well as self NEXT, by adaptive digital echo and NEXT cancellation [3]. Although a dual-duplex scheme might appear to require higher implementation complexity than a mono-duplex scheme, it turns out that the two schemes are equivalent in terms of the number of multiply-and-add operations per second that are needed to perform the various filtering operations.

One of the transceivers in a full-duplex link will usually employ an externally provided reference clock for its transmit and receive operations. The other transceiver will extract timing from the receive signal and use this timing for its transmitter operations. This is known as *loop timing*, also illustrated in Fig. 30.3. If signals were transmitted in opposite directions with independent clocks, signals received from the remote transmitter would generally shift in phase relative to the also received echo signals. To cope with this effect, some form of interpolation would be required that can significantly increase the transceiver complexity [2].

In general, we consider baseband signalling techniques such that the signal at the output of the overall channel has non-negligible excess bandwidth, i.e., non-negligible spectral components at frequencies larger than half of the modulation rate, $|f| \geq 1/2T$. Therefore, to avoid aliasing, the signal $x(t)$ is sampled at twice the modulation rate or at a higher sampling rate. Assuming a sampling rate equal to m/T , $m > 1$, the i th sample during the n th modulation interval is given by

$$\begin{aligned}
 x\left[\left(nm+i\right)\frac{T}{m}\right] &= x_{nm+i} = r_{nm+i} + u_{nm+i} + w_{nm+i}, \quad i = 0, \dots, m-1 \\
 &= \sum_{k=-\infty}^{\infty} h_{km+i} a_{n-k}^R + \sum_{k=-\infty}^{\infty} h_{E,km+i} a_{n-k} + w_{nm+i}
 \end{aligned}
 \tag{30.2}$$

where $\{h_{nm+i} \mid i = 0, \dots, m-1\}$ and $\{h_{E,nm+i} \mid i = 0, \dots, m-1\}$ are the discrete-time impulse responses of the overall channel and the echo channel, respectively, and $\{w_{nm+i} \mid i = 0, \dots, m-1\}$ is a sequence of Gaussian noise samples with zero mean and variance σ_w^2 . Equation (30.2) suggests that the sequence of samples $\{x_{nm+i} \mid i = 0, \dots, m-1\}$ be regarded as a set of m interleaved sequences, each with a sampling rate equal to the modulation rate. Similarly, the sequence of echo samples $\{u_{nm+i} \mid i = 0, \dots, m-1\}$ can be regarded as a set of m interleaved sequences that are output by m independent echo channels with discrete-time impulse responses $\{h_{E,nm+i}\}$, $i = 0, \dots, m-1$, and an identical sequence $\{a_n\}$ of input symbols [8]. Hence, echo cancellation can be performed by m interleaved echo cancellers, as shown in Fig. 30.4. Since the

FIGURE 30.4 A set of m interleaved echo cancellers.

performance of each canceller is independent of the other $m - 1$ units, in the remaining part of this section we will consider the operations of a single echo canceller.

The echo canceller generates an estimate \hat{u}_n of the echo signal. If we consider a transversal filter realization, \hat{u}_n is obtained as the inner product of the vector of filter coefficients at time $t = nT$, $\mathbf{c}_n = (c_{n,0}, \dots, c_{n,N-1})'$ and the vector of signals stored in the echo canceller delay line at the same instant, $\mathbf{a}_n = (a_n, \dots, a_{n-N+1})'$, expressed by

$$\hat{u}_n = \mathbf{c}'_n \mathbf{a}_n = \sum_{k=0}^{N-1} c_{n,k} a_{n-k} \quad (30.3)$$

where \mathbf{c}'_n denotes the transpose of the vector \mathbf{c}_n . The estimate of the echo is subtracted from the received signal. The result is defined as the cancellation error signal

$$z_n = x_n - \hat{u}_n = x_n - \mathbf{c}'_n \mathbf{a}_n \quad (30.4)$$

The echo attenuation that must be provided by the echo canceller to achieve proper system operation depends on the application. For example, for the Integrated Services Digital Network (ISDN) U-Interface transceiver, the echo attenuation must be larger than 55 dB [11]. It is then required that the echo signals outside of the time span of the echo canceller delay line be negligible, i.e., $h_{E,n} \approx 0$ for $n < 0$ and $n > N - 1$. As a measure of system performance, we consider the mean square error \mathcal{E}_n^2 at the output of the echo canceller at time $t = nT$, defined by

$$\mathcal{E}_n^2 = E\{z_n^2\} \quad (30.5)$$

where $\{z_n\}$ is the error sequence and $E\{\cdot\}$ denotes the expectation operator. For a particular coefficient vector \mathbf{c}_n , substitution of Eq. (30.4) into Eq. (30.5) yields

$$\mathcal{E}_n^2 = E\{x_n^2\} - 2\mathbf{c}'_n \mathbf{q} + \mathbf{c}'_n \mathbf{R} \mathbf{c}_n \quad (30.6)$$

where $\mathbf{q} = E\{x_n \mathbf{a}_n\}$ and $\mathbf{R} = E\{\mathbf{a}_n \mathbf{a}'_n\}$. With the assumption of i.i.d. transmitted symbols, the correlation matrix \mathbf{R} is diagonal. The elements on the diagonal are equal to the variance of the transmitted symbols, $\sigma_a^2 = (M^2 - 1)/3$. The minimum mean square error is given by

$$\mathcal{E}_{\min}^2 = E\{x_n^2\} - \mathbf{c}'_{\text{opt}} \mathbf{R} \mathbf{c}_{\text{opt}} \quad (30.7)$$

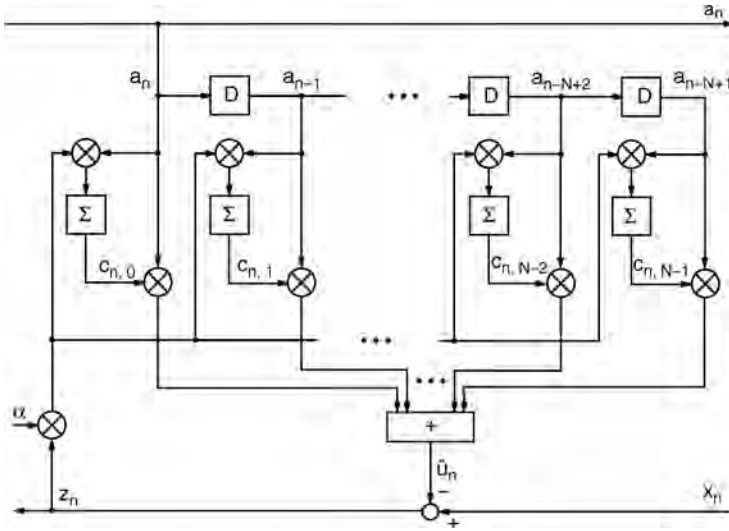

FIGURE 30.5 Block diagram of an adaptive transversal filter echo canceller.

where the optimum coefficient vector is $\mathbf{c}_{\text{opt}} = \mathbf{R}^{-1} \mathbf{q}$. We note that proper system operation is achieved only if the transmitted symbols are uncorrelated with the symbols from the remote transmitter. If this condition is satisfied, the optimum filter coefficients are given by the values of the discrete-time echo channel impulse response, i.e., $\mathbf{c}_{\text{opt},k} = h_{E,k}$, $k = 0, \dots, N - 1$.

By the decision-directed stochastic gradient algorithm, also known as the least mean square (LMS) algorithm, the coefficients of the echo canceller converge in the mean to \mathbf{c}_{opt} . The LMS algorithm for an N -tap adaptive linear transversal filter is formulated as follows:

$$\mathbf{c}_{n+1} = \mathbf{c}_n - \frac{1}{2} \alpha \nabla_c \{z_n^2\} = \mathbf{c}_n + \alpha z_n \mathbf{a}_n \quad (30.8)$$

where α is the adaptation gain and

$$\nabla_c \{z_n^2\} = \left(\frac{\partial z_n^2}{\partial c_{n,0}}, \dots, \frac{\partial z_n^2}{\partial c_{n,N-1}} \right)' = -2z_n \mathbf{a}_n$$

is the gradient of the squared error with respect to the vector of coefficients. The block diagram of an adaptive transversal filter echo canceller is shown in Fig. 30.5.

If we define the vector $\mathbf{p}_n = \mathbf{c}_{\text{opt}} - \mathbf{c}_n$, the mean square error can be expressed as

$$\mathcal{E}_n^2 = \mathcal{E}_{\min}^2 + \mathbf{p}_n' \mathbf{R} \mathbf{p}_n \quad (30.9)$$

where the term $\mathbf{p}_n' \mathbf{R} \mathbf{p}_n$ represents an excess mean square distortion due to the misadjustment of the filter settings. The analysis of the convergence behavior of the excess mean square distortion was first proposed for adaptive equalizers [14] and later extended to adaptive echo cancellers [10]. Under the assumption that the vectors \mathbf{p}_n and \mathbf{a}_n are statistically independent, the dynamics of the mean square error are given by

$$E\{\mathcal{E}_n^2\} = \mathcal{E}_0^2 [1 - \alpha N \sigma_a^2 (2 - \alpha N \sigma_a^2)]^n + \frac{2\mathcal{E}_{\min}^2}{2 - \alpha N \sigma_a^2} \quad (30.10)$$

where ϵ_0^2 is determined by the initial conditions. The mean square error converges to a finite steady-state value ϵ_∞^2 if the stability condition $0 < \alpha < 2/(N\sigma_a^2)$ is satisfied. The optimum adaptation gain that yields fastest convergence at the beginning of the adaptation process is $\alpha_{\text{opt}} = 1/(N\sigma_a^2)$. The corresponding time constant and asymptotic mean square error are $\tau_{\text{opt}} = N$ and $\epsilon_\infty^2 = 2\epsilon_{\text{min}}^2$, respectively.

We note that a fixed adaptation gain equal to α_{opt} could not be adopted in practice, since after echo cancellation the signal from the remote transmitter would be embedded in a residual echo having approximately the same power. If the time constant of the convergence mode is not a critical system parameter, an adaptation gain smaller than α_{opt} will be adopted to achieve an asymptotic mean square error close to ϵ_{min}^2 . On the other hand, if fast convergence is required, a variable gain will be chosen.

Several techniques have been proposed to increase the speed of convergence of the LMS algorithm. In particular, for echo cancellation in data transmission, the speed of adaptation is reduced by the presence of the signal from the remote transmitter in the cancellation error. To mitigate this problem, the data signal can be adaptively removed from the cancellation error by a decision-directed algorithm [6].

Modified versions of the LMS algorithm have been also proposed to reduce system complexity. For example, the sign algorithm suggests that only the sign of the error signal be used to compute an approximation of the stochastic gradient [5]. An alternative means to reduce the implementation complexity of an adaptive echo canceller consists of the choice of a filter structure with a lower computational complexity than the transversal filter.

At high data rates, very large-scale integration (VLSI) technology is needed for the implementation of transceivers for full-duplex data transmission. High-speed echo cancellers and near-end crosstalk cancellers that do not require multiplications represent an attractive solution because of their low complexity. As an example of an architecture suitable for VLSI implementation, we consider echo cancellation by a distributed-arithmetic filter, where multiplications are replaced by table lookup and shift-and-add operations [13]. By segmenting the echo canceller into filter sections of shorter lengths, various tradeoffs concerning the number of operations per modulation interval and the number of memory locations needed to store the lookup tables are possible. Adaptivity is achieved by updating the values stored in the lookup tables by the LMS algorithm.

To describe the principles of operations of a distributed-arithmetic echo canceller, we assume that the number of elements in the alphabet of input symbols is a power of two, $M = 2^W$. Therefore, each symbol is represented by the vector $(a_n^{(0)}, \dots, a_n^{(W-1)})$, where $a_n^{(i)}$, $i = 0, \dots, W-1$, are independent binary random variables, i.e.,

$$a_n = \sum_{w=0}^{W-1} (2a_n^{(w)} - 1)2^w = \sum_{w=0}^{W-1} b_n^{(w)}2^w \quad (30.11)$$

where $b_n^{(w)} = (2a_n^{(w)} - 1) \in \{-1, +1\}$. By substituting Eq. (30.11) into Eq. (30.1) and segmenting the delay line of the echo canceller into L sections with $K = N/L$ delay elements each, we obtain

$$\hat{u}_n = \sum_{\ell=0}^{L-1} \sum_{w=0}^{W-1} 2^w \left[\sum_{k=0}^{K-1} b_{n-\ell K-k}^{(w)} c_{n,\ell K+k} \right] \quad (30.12)$$

Equation (30.12) suggests that the filter output can be computed using a set of $L2^K$ values that are stored in L tables with 2^K memory locations each. The binary vectors $\mathbf{a}_{n,\ell}^{(w)} = (a_{n-(\ell+1)K+1}^{(w)}, \dots, a_{n-\ell K}^{(w)})$, $w = 0, \dots, W-1$, $\ell = 0, \dots, L-1$, determine the addresses of the memory locations where the values that are needed to compute the filter output are stored. The filter output is obtained by WL table lookup and shift-and-add operations.

We observe that $\mathbf{a}_{n,\ell}^{(w)}$ and its binary complement $\bar{\mathbf{a}}_{n,\ell}^{(w)}$ select two values that differ only in their sign. This symmetry is exploited to halve the number of values to be stored. To determine the output of a

distributed-arithmetic filter with reduced memory size, we reformulate Eq. (30.12) as

$$\hat{u}_n = \sum_{\ell=0}^{L-1} \sum_{w=0}^{W-1} 2^w b_{n-\ell K-k_0}^{(w)} \left[c_{n,\ell K+k_0} + b_{n-\ell K-k_0}^{(w)} \sum_{\substack{k=0 \\ k \neq k_0}}^{K-1} b_{n-\ell K-k}^{(w)} c_{n,\ell K+k} \right] \quad (30.13)$$

where k_0 can be any element of the set $\{0, \dots, K-1\}$. In the following, we take $k_0 = 0$. Then the binary symbol $b_{n-\ell K}^{(w)}$ determines whether a selected value is to be added or subtracted. Each table has now 2^{K-1} memory locations, and the filter output is given by

$$\hat{u}_n = \sum_{\ell=0}^{L-1} \sum_{w=0}^{W-1} 2^w b_{n-\ell K}^{(w)} d_n(i_{n,\ell}^{(w)}, \ell) \quad (30.14)$$

where $d_n(k, \ell)$, $k = 0, \dots, 2^{K-1} - 1$, $\ell = 0, \dots, L-1$, are the lookup values, and $i_{n,\ell}^{(w)}$, $w = 0, \dots, W-1$, $\ell = 0, \dots, L-1$, are the look up indices computed as follows:

$$i_{n,\ell}^{(w)} = \begin{cases} \sum_{k=1}^{K-1} a_{n-\ell K-k}^{(w)} 2^{k-1} & \text{if } a_{n-\ell K}^{(w)} = 1 \\ \sum_{k=1}^{K-1} \bar{a}_{n-\ell K-k}^{(w)} 2^{k-1} & \text{if } a_{n-\ell K}^{(w)} = 0 \end{cases} \quad (30.15)$$

We note that, as long as Eqs. (30.12) and (30.13) hold for some coefficient vector $(c_{n,0}, \dots, c_{n,N-1})$, a distributed-arithmetic filter emulates the operation of a linear transversal filter. For arbitrary values $d_n(k, \ell)$, however, a nonlinear filtering operation results.

The expression of the LMS algorithm to update the values of a distributed-arithmetic echo canceller takes the form

$$\mathbf{d}_{n+1} = \mathbf{d}_n - \frac{1}{2} \alpha \nabla_d \{ z_n^2 \} = \mathbf{d}_n + \alpha z_n \mathbf{y}_n \quad (30.16)$$

where $\mathbf{d}'_n = [\mathbf{d}'_n(0), \dots, \mathbf{d}'_n(L-1)]$, with $\mathbf{d}'_n(\ell) = [d_n(0, \ell), \dots, d_n(2^{K-1} - 1, \ell)]$, and $\mathbf{y}'_n = [\mathbf{y}'_n(0), \dots, \mathbf{y}'_n(L-1)]$, with

$$\mathbf{y}'_n(\ell) = \sum_{w=0}^{W-1} 2^w b_{n-\ell K}^{(w)} (\delta_{0, i_{n,\ell}^{(w)}} \dots \delta_{2^{K-1}-1, i_{n,\ell}^{(w)}})$$

are $L2^{K-1} \times 1$ vectors and where $\delta_{i,j}$ is the Kronecker delta. We note that at each iteration, only those values that are selected to generate the filter output are updated. The block diagram of an adaptive distributed-arithmetic echo canceller with input symbols from a quaternary alphabet is shown in Fig. 30.6.

The analysis of the mean square error convergence behavior and steady-state performance has been extended to adaptive distributed-arithmetic echo cancellers [1]. The dynamics of the mean square error are, in this case, given by

$$E\{\epsilon_n^2\} = \epsilon_0^2 \left[1 - \frac{\alpha \sigma_a^2}{2^{K-1}} (2 - \alpha L \sigma_a^2) \right]^n + \frac{2 \epsilon_{\min}^2}{2 - \alpha L \sigma_a^2} \quad (30.17)$$

The stability condition for the echo canceller is $0 < \alpha < 2/(L\sigma_a^2)$. For a given adaptation gain, echo canceller stability depends on the number of tables and on the variance of the transmitted symbols.

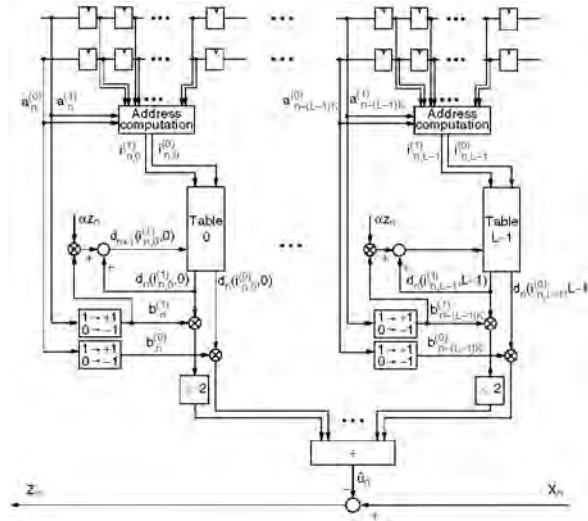

FIGURE 30.6 Block diagram of an adaptive distributed-arithmetic echo canceller.

Therefore, the time span of the echo canceller can be increased without affecting system stability, provided that the number L of tables is kept constant. In that case, however, mean square error convergence will be slower. From Eq. (30.17), we find that the optimum adaptation gain that permits the fastest mean square error convergence at the beginning of the adaptation process is $\alpha_{\text{opt}} = 1/(L\sigma_a^2)$. The time constant of the convergence mode is $\tau_{\text{opt}} = L2^{K-1}$. The smallest achievable time constant is proportional to the total number of values. The realization of a distributed-arithmetic echo canceller can be further simplified by updating at each iteration only the values that are addressed by the most significant bits of the symbols stored in the delay line. The complexity required for adaptation can thus be reduced at the price of a slower rate of convergence.

30.3 Echo Cancellation for Quadrature-Amplitude Modulation (QAM) Systems

Although most of the concepts presented in the preceding sections can be readily extended to echo cancellation for communications systems employing QAM, the case of full-duplex transmission over a voiceband data channel requires a specific discussion. We consider the system model shown in Fig. 30.7. The transmitter generates a sequence $\{a_n\}$ of i.i.d. complex-valued symbols from a two-dimensional constellation \mathcal{A} , which are modulated by the carrier $e^{j2\pi f_c nT}$, where T and f_c denote the modulation interval and the carrier frequency, respectively. The discrete-time signal at the output of the transmit Hilbert filter may be regarded as an analytic signal, which is generated at the rate of m/T samples/s, $m > 1$. The real part of the analytic signal is converted into an analog signal by a D/A converter and input to the channel. We note that by transmitting the real part of a complex-valued signal, positive- and negative-frequency components become folded. The image band attenuation of the transmit Hilbert filter thus determines the achievable echo suppression. In fact, the receiver cannot extract aliasing image-band components from desired passband frequency components, and the echo canceller is able to suppress only echo arising from transmitted passband components.

The output of the echo channel is represented as the sum of two contributions. The near-end echo $u^{\text{NE}}(t)$ arises from the impedance mismatch between the hybrid and the transmission line, as in the case of baseband transmission. The far-end echo $u^{\text{FE}}(t)$ represents the contribution due to echos that are generated at intermediate points in the telephone network. These echos are characterized by additional

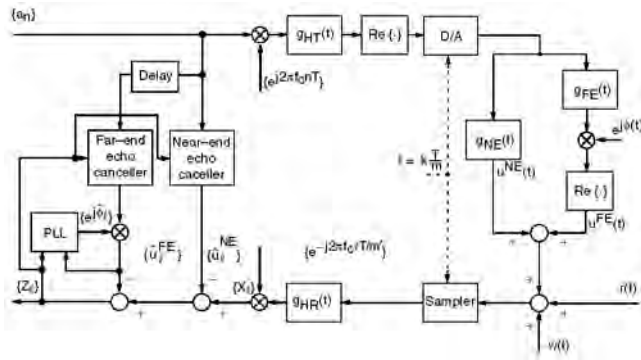

FIGURE 30.7 Configuration of an echo canceller for a QAM transmission system.

impairments, such as jitter and frequency shift, which are accounted for by introducing a carrier-phase rotation of an angle $\phi(t)$ in the model of the far-end echo.

At the receiver, samples of the signal at the channel output are obtained synchronously with the transmitter timing, at the sampling rate of m/T sample/s. The discrete-time received signal is converted to a complex-valued baseband signal $\{x_{nm'+i}, i = 0, \dots, m' - 1\}$, at the rate of m'/T samples/s, $1 < m' < m$, through filtering by the receive Hilbert filter, decimation, and demodulation. From delayed transmit symbols, estimates of the near- and far-end echo signals after demodulation, $\{\hat{u}_{nm'+i}^{NE}, i = 0, \dots, m' - 1\}$ and $\{\hat{u}_{nm'+i}^{FE}, i = 0, \dots, m' - 1\}$, respectively, are generated using m' interleaved near- and far-end echo cancellers. The cancellation error is given by

$$z_\ell = x_\ell - \hat{u}_\ell^{NE} - \hat{u}_\ell^{FE} \quad (30.18)$$

A different model is obtained if echo cancellation is accomplished before demodulation. In this case, two equivalent configurations for the echo canceller may be considered. In one configuration, the modulated symbols are input to the transversal filter, which approximates the passband echo response. Alternatively, the modulator can be placed after the transversal filter, which is then called a baseband transversal filter [15].

In the considered realization, the estimates of the echo signals after demodulation are given by

$$\hat{u}_{nm'+i}^{NE} = \sum_{k=0}^{N_{NE}-1} c_{n,km'+i}^{NE} a_{n-k}, \quad i = 0, \dots, m' - 1 \quad (30.19)$$

and

$$\hat{u}_{nm'+i}^{FE} = \left[\sum_{k=0}^{N_{FE}-1} c_{n,km'+i}^{FE} a_{n-k-D_{FE}} \right] e^{j\hat{\phi}_{nm'+i}}, \quad i = 0, \dots, m' - 1 \quad (30.20)$$

where $(c_{n,0}^{NE}, \dots, c_{n,m'N_{NE}-1}^{NE})$ and $(c_{n,0}^{FE}, \dots, c_{n,m'N_{FE}-1}^{FE})$ are the coefficients of the m' interleaved near- and far-end echo cancellers, respectively, $\{\hat{\phi}_{nm'+i}, i = 0, \dots, m' - 1\}$ is the sequence of far-end echo phase estimates, and D_{FE} denotes the bulk delay accounting for the round-trip delay from the transmitter to the point of echo generation. To prevent overlap of the time span of the near-end echo canceller with the time span of the far-end echo canceller, the condition $D_{FE} > N_{NE}$ must be satisfied. We also note that,

because of the different nature of near- and far-end echo generation, the time span of the far-end echo canceller needs to be larger than the time span of the near-end canceller, i.e., $N_{FE} > N_{NE}$.

Adaptation of the filter coefficients in the near- and far-end echo cancellers by the LMS algorithm leads to

$$c_{n+1, km'+i}^{NE} = c_{n, km'+i}^{NE} + \alpha z_{nm'+i}(a_{n-k})^* \quad (30.21)$$

$$k = 0, \dots, N_{NE} - 1, \quad i = 0, \dots, m' - 1$$

and

$$c_{n+1, km'+i}^{FE} = c_{n, km'+i}^{FE} + \alpha z_{nm'+i}(a_{n-k-D_{FE}})^* e^{-j\hat{\phi}_{nm'+i}} \quad (30.22)$$

$$k = 0, \dots, N_{FE} - 1, \quad i = 0, \dots, m' - 1$$

respectively, where the asterisk denotes complex conjugation.

The far-end echo phase estimate is computed by a second-order phase-lock loop algorithm, where the following stochastic gradient approach is adopted:

$$\begin{cases} \hat{\phi}_{\ell+1} = \hat{\phi}_{\ell} - \frac{1}{2} \gamma_{FE} \nabla_{\hat{\phi}} |z_{\ell}|^2 + \Delta \phi_{\ell} \pmod{2\pi} \\ \Delta \phi_{\ell+1} = \Delta \phi_{\ell} - \frac{1}{2} \zeta_{FE} \nabla_{\hat{\phi}} |z_{\ell}|^2 \end{cases} \quad (30.23)$$

where $\ell = nm' + i, i = 0, \dots, m' - 1$, γ_{FE} and ζ_{FE} are step-size parameters, and

$$\nabla_{\hat{\phi}} |z_{\ell}|^2 = \frac{\partial |z_{\ell}|^2}{\partial \hat{\phi}_{\ell}} = -2 \text{Im} \{ z_{\ell} (\hat{u}_{\ell}^{FE})^* \} \quad (30.24)$$

We note that algorithm (30.23) requires m' iterations per modulation interval, i.e., we cannot resort to interleaving to reduce the complexity of the computation of the far-end echo phase estimate.

30.4 Echo Cancellation for Orthogonal Frequency Division Multiplexing (OFDM) Systems

Orthogonal frequency division multiplexing (OFDM) is a modulation technique whereby blocks of M symbols are transmitted in parallel over M subchannels by employing M orthogonal subcarriers. We consider a real-valued discrete-time channel impulse response $\{h_i, i = 0, \dots, L\}$ having length $L + 1 \ll M$. To illustrate the basic principles of OFDM systems, let us consider a noiseless ideal channel with impulse response given by $\{h_i\} = \{\delta_i\}$, where $\{\delta_i\}$ is defined as the discrete-time delta function. Modulation of the complex-valued input symbols at the n th modulation interval, denoted by the vector $\mathbf{A}_n = \{A_n(i), i = 0, \dots, M - 1\}$, is performed by an inverse discrete Fourier transform (IDFT), as shown in Fig. 30.8. We assume that M is even, and that each block of symbols satisfies the Hermitian symmetry conditions, i.e., $A_n(0)$ and $A_n(M/2)$ are real valued, and $A_n(i) = A_n^*(M - i), i = 1, \dots, M/2 - 1$. Then the signals $\mathbf{a}_n = \{a_n(i),$

FIGURE 30.8 Block diagram of an OFDM system.

$i = 0, \dots, M - 1$ obtained at the output of the IDFT are real valued. After parallel-to-serial conversion, the M signals are sent over the channel at the given transmission rate, M/T , where T denotes the modulation interval. At the output of the channel, the noiseless signals are received without distortion. Serial-to-parallel conversion yields blocks of M elements, with boundaries placed such that each block obtained at the modulator output is also presented at the demodulator input. Then demodulation performed by a discrete Fourier transform (DFT) will reproduce the blocks of M input symbols. The overall input–output relationship is therefore equivalent to that of a bank of M parallel, independent subchannels.

In the general case of a noisy channel with impulse response having length greater than one, M independent subchannels are obtained by a variant of OFDM also known as discrete multitone modulation (DMT) [12]. In a DMT system, modulation by the IDFT is performed at the rate $1/T' = M/(M + L)T < 1/T$. After modulation, each block of M signals is cyclically extended by copying the last L signals in front of the block and converted from parallel to serial. The resulting $L + M$ signals are sent over the channel. At the receiver, blocks of samples with length $L + M$ are taken. Block boundaries are placed such that the last M samples depend only on the elements of one cyclically extended block of signals. The first L samples are discarded, and the vector \mathbf{x}_n of the last M samples of the block received at the n th modulation interval can be expressed as

$$\mathbf{x}_n = \Gamma_n \mathbf{h} + \mathbf{w}_n \quad (30.25)$$

where \mathbf{h} is the vector of the impulse response extended with $M - L - 1$ zeros, \mathbf{w}_n is a vector of additive white Gaussian noise samples, and Γ_n is a $M \times M$ circulant matrix given by

$$\Gamma_n = \begin{bmatrix} a_n(0) & a_n(M-1) & \cdots & a_n(1) \\ a_n(1) & a_n(0) & \cdots & a_n(2) \\ \vdots & \vdots & & \vdots \\ a_n(M-1) & a_n(M-2) & \cdots & a_n(0) \end{bmatrix} \quad (30.26)$$

Recalling that $\mathcal{F}_M \Gamma_n \mathcal{F}_M^{-1} = \text{diag}(\mathbf{A}_n)$, where \mathcal{F}_M is the $M \times M$ DFT matrix defined as $\mathcal{F}_M = [(e^{-\frac{j2\pi}{M}})^{km}]$, $k, m = 0, \dots, M - 1$, and $\text{diag}(\mathbf{A}_n)$ denotes the diagonal matrix with elements on the diagonal given by \mathbf{A}_n , we find that the output of the demodulator is given by

$$\mathbf{X}_n = \text{diag}(\mathbf{A}_n) \mathbf{H} + \mathbf{W}_n \quad (30.27)$$

where \mathbf{H} denotes the DFT of the vector \mathbf{h} , and \mathbf{W}_n is a vector of independent Gaussian random variables. Equation (30.27) indicates that the sequence of transmitted symbol vectors can be detected by assuming a bank of M independent subchannels, at the price of a decrease in the data rate by a factor $(M + L)/M$. Note that in practice the computationally more efficient inverse fast Fourier transform and fast Fourier transform are used instead of IDFT and DFT.

We discuss echo cancellation for OFDM with reference to a DMT system [7], as shown in Fig. 30.9. The real-valued discrete-time echo impulse response is $\{h_{E,i}, i = 0, \dots, N - 1\}$, having length $N < M$. We initially assume $N \leq L + 1$. Furthermore, we assume that the boundaries of the received blocks are placed such that the last M samples of the n th received block are expressed by the vector

$$\mathbf{x}_n = \Gamma_n^R \mathbf{h} + \Gamma_n \mathbf{h}_E + \mathbf{w}_n \quad (30.28)$$

where Γ_n^R is the circulant matrix with elements given by the signals from the remote transmitter, and \mathbf{h}_E is the vector of the echo impulse response extended with $M - N$ zeros. In the frequency domain, the

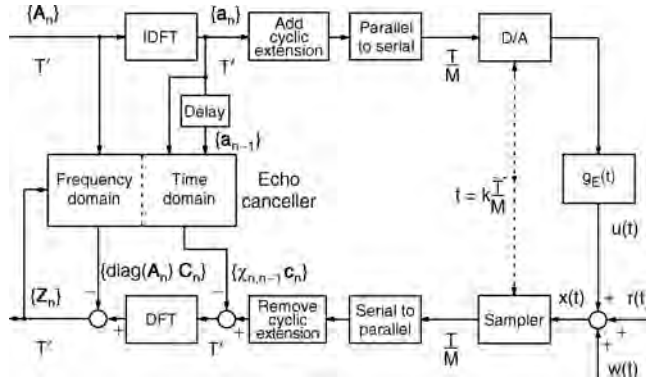

FIGURE 30.9 Configuration of an echo canceller for a DMT transmission system.

echo is expressed as $U_n = \text{diag}(A_n)H_E$, where H_E denotes the DFT of the vector h_E . In this case, the echo canceller provides an echo estimate that is given by $\hat{U}_n = \text{diag}(A_n)C_n$, where C_n denotes the DFT of the vector c_n of the N coefficients of the echo canceller filter extended with $M - N$ zeros. In practice, however, we need to consider the case $N > L + 1$. The expression of the cancellation error is then given by

$$z_n = x_n - \Psi_{n,n-1}c_n \quad (30.29)$$

where the vector of the last M elements of the n th received block is now $x_n = \Gamma_n^R h + \Psi_{n,n-1}h_E + w_n$, and $\Psi_{n,n-1}$ is an $M \times M$ Toeplitz matrix given by

$$\Psi_{n,n-1} = \begin{bmatrix} a_n(0) & a_n(M-1) & \cdots & a_n(M-L) & a_{n-1}(M-1) & \cdots & a_{n-1}(L+1) \\ a_n(1) & a_n(0) & \cdots & a_n(M-L+1) & a_n(M-L) & \cdots & a_{n-1}(L+2) \\ \vdots & & & & \text{O} & & \vdots \\ a_n(M-1) & a_n(M-2) & \cdots & a_n(M-L-1) & a_n(M-L-2) & \cdots & a_n(0) \end{bmatrix} \quad (30.30)$$

In the frequency domain, the cancellation error can be expressed as

$$Z_n = \mathcal{F}_M(x_n - \chi_{n,n-1}c_n) - \text{diag}(A_n)C_n \quad (30.31)$$

where $\chi_{n,n-1} = \Psi_{n,n-1} - \Gamma_n$ is an $M \times M$ upper triangular Toeplitz matrix. Equation (30.31) suggests a computationally efficient, two-part echo cancellation technique. First, in the time domain, a short convolution is performed and the result is subtracted from the received signals to compensate for the insufficient length of the cyclic extension. Second, in the frequency domain, cancellation of the residual echo is performed over a set of M independent echo subchannels. Observing that Eq. (30.31) is equivalent to $Z_n = X_n - \tilde{\Psi}_{n,n-1}C_n$, where $\tilde{\Psi}_{n,n-1} = \mathcal{F}_M \Psi_{n,n-1} \mathcal{F}_M^{-1}$, the echo canceller adaptation by the LMS algorithm in the frequency domain takes the form

$$C_{n+1} = C_n + \alpha \tilde{\Psi}_{n,n-1}^* Z_n \quad (30.32)$$

where α is the adaptation gain, and $\tilde{\Psi}_{n,n-1}^*$ denotes the transpose conjugate of $\tilde{\Psi}_{n,n-1}$. We note that, alternatively, echo canceller adaptation may also be performed by the algorithm $C_{n+1} = C_n + \alpha \text{diag}(A_n^*) Z_n$, which entails a substantially lower computational complexity than the LMS algorithm, at the price of a slower rate of convergence.

In DMT systems, it is essential that the length of the channel impulse response be much less than the number of subchannels, so that the reduction in data rate due to the cyclic extension may be considered negligible. Therefore, time-domain equalization is adopted in practice to shorten the length of the channel impulse response. From Eq. (30.31), however, we observe that transceiver complexity depends on the relative lengths of the echo and of the channel impulse responses. To reduce the length of the cyclic extension as well as the computational complexity of the echo canceller, various methods have been proposed to shorten both the channel and the echo impulse responses jointly [9].

Recently, multitone modulation techniques based on filter banks have been proposed, where the M -branch filters yield very high spectral containment of individual subchannel signals [4]. The filters are frequency-shifted versions of a prototype filter, designed to reduce the interchannel interference to a level that is negligible compared to the level of other noise signals, without having to resort to time-domain equalization. Echo cancellation can be performed in this case entirely in the frequency domain by taking into account, for each subchannel, only the echo generated by transmission in the opposite direction on the same subchannel. The implementation of per-subchannel echo cancellation then requires M adaptive echo cancellers.

30.5 Summary and Conclusions

Digital signal processing techniques for echo cancellation provide large echo attenuation and eliminate the need for additional line interfaces and digital-to-analog and analog-to-digital converters that are required by echo cancellation in the analog signal domain.

The realization of digital echo cancellers in transceivers for high-speed full-duplex data transmission today is possible at a low cost thanks to the advances in VLSI technology. Digital techniques for echo cancellation are also appropriate for near-end crosstalk cancellation in transceivers for transmission over voice-grade cables at rates of several megabits per second for local-area network applications.

In voiceband modems for data transmission over the telephone network, digital techniques for echo cancellation also allow a precise tracking of the carrier phase and frequency shift of far-end echos.

31.1 Computer Communications Requirements

Although in many instances computers are used to perform their intended role in a stand-alone mode, in others there is a need to interwork and exchange data with other computers—in financial applications, for example, to carry out fund transfers from one institution computer to another, in travel applications to access the reservation systems belonging to various airlines, and so on. The general requirement in all of these applications is for application programs running in different computers to cooperate to achieve a specific distributed application function. To achieve this, three basic issues must be considered. These are shown in diagrammatic form in [Fig. 31.1](#).

The fundamental requirement in all applications that involve two or more computers is the provision of a suitable data communications facility. This may comprise a **local area network** (LAN), if the computers are distributed around a single site, a **wide area network** (WAN), if the computers are situated at different sites, or an **internetwork**, if multiple interconnected network types are involved. Associated with these different network types is a set of access protocols which enables a communications path between two computers to be established and for data to be transferred across this path. Typically, these protocols differ for the different network types. In addition to these access protocols, the communication subsystem in each computer must provide additional functionality. For example, if the communicating computers are of different types, possibly with different word sizes and character sets, then a means of ensuring the transferred data is interpreted in the same way in each computer must be incorporated. Also, the computers may use different file systems and, hence, functionality to enable application programs, normally referred to as **application processes** (APs), to access these in a standardized way must also be included. All of these issues must be considered when communicating data between two computers.

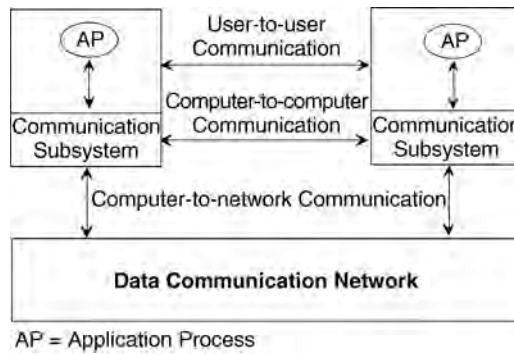

FIGURE 31.1 Computer communication schematic.

31.2 Standards Evolution

Until recently, the standards established for use in the computer industry by the various international bodies were concerned primarily with either the internal operation of a computer or the connection of a local peripheral device. The result was that early hardware and software communication subsystems offered by manufacturers only enabled their own computers, and so-called *plug-compatible systems*, to exchange information. Such systems are known as *closed systems* since computers from other manufacturers cannot exchange information unless they adhere to the (proprietary) standards of a particular manufacturer.

In contrast, the various international bodies concerned with public-carrier telecommunication networks have, for many years, formulated internationally agreed standards for connecting devices to these networks. The *V-series recommendations*, for example, are concerned with the connection of equipment, normally referred to as a *data terminal equipment (DTE)*, to a modem connected to the public switched telephone network (PSTN); the *X-series recommendations* for connecting a DTE to a public data network; and the *I-series recommendations* for connecting a DTE to the integrated services digital networks (ISDNs). The recommendations have resulted in compatibility between the equipment from different vendors, enabling a purchaser to select suitable equipment from a range of manufacturers.

Initially, the services provided by most public carriers were concerned primarily with data transmission, and, hence, the associated standards only related to the method of interfacing a device to these networks. More recently, however, the public carriers have started to provide more extensive distributed information services, such as the exchange of electronic messages (*teletex*) and access to public databases (*videotex*). To cater to such services, the standards bodies associated with the telecommunications industry have formulated standards not only for interfacing to such networks but also so-called higher level standards concerned with the format (syntax) and control of the exchange of information (data) between systems. Consequently, the equipment from one manufacturer that adheres to these standards can be interchangeable with equipment from any other manufacturer that complies with the standards. The resulting system is then known as an *open system* or, more completely, as an *open systems interconnection environment (OSIE)*.

In the mid-1970s, as different types of distributed systems (based on both public and private data networks) started to proliferate, the potential advantages of open systems were acknowledged by the computer industry. As a result, a range of standards started to be introduced. The first was concerned with the overall structure of the complete communication subsystem within each computer. This was produced by the International Standards Organization (ISO) and is known as the *ISO reference model for open systems interconnection (OSI)*.

The aim of the ISO reference model is to provide a framework for the coordination of standards development and to allow existing and evolving standards activities to be set within a common framework.

The aim is to allow an application process in any computer that supports a particular set of standards to communicate freely with an application process in any other computer that supports the same standards, irrespective of its origin of manufacture.

Some examples of application processes that may wish to communicate in an open way are the following:

- a process (program) executing in a computer and accessing a remote file system
- a process acting as a central file service (server) to a distributed community of (client) processes
- a process in an office workstation (computer) accessing an electronic mail service
- a process acting as an electronic mail server to a distributed community of (client) processes
- a process in a supervisory computer controlling a distributed community of computer-based instruments or robot controllers associated with a process or automated manufacturing plant
- a process in an instrument or robot controller receiving commands and returning results to a supervisory system
- a process in a bank computer that initiates debit and credit operations on a remote system

Open systems interconnection is concerned with the exchange of information between such processes. The aim is to enable application processes to cooperate in carrying out a particular (distributed) information processing task irrespective of the computers on which they are running.

31.3 International Standards Organization Reference Model

A communication subsystem is a complex piece of hardware and software. Early attempts at implementing the software for such subsystems were often based on a single, complex, unstructured program (normally written in assembly language) with many interacting components. The resulting software was difficult to test and often very difficult to modify.

To overcome this problem, the ISO has adopted a layered approach for the reference model. The complete communication subsystem is broken down into a number of layers, each of which performs a well-defined function. Conceptually, these layers can be considered as performing one of two generic functions, network-dependent functions and application-oriented functions. This, in turn, gives rise to three distinct operational environments:

1. The **network environment** is concerned with the protocols and standards relating to the different types of underlying data communication networks.
2. The **OSI environment** embraces the network environment and adds additional application-oriented protocols and standards to allow end systems (computers) to communicate with one another in an open way.
3. The **real systems environment** builds on the OSI environment and is concerned with a manufacturer's own proprietary software and services which have been developed to perform a particular distributed information processing task.

This is shown in diagrammatic form in [Fig. 31.2](#).

Both the network-dependent and application-oriented (network-independent) components of the OSI model are implemented as a number of layers. The boundaries between each layer and the functions performed by each layer have been selected on the basis of experience gained during earlier standardization activity.

Each layer performs a well-defined function in the context of the overall communication subsystem. It operates according to a defined protocol by exchanging messages, both user data and additional control information, with a corresponding peer layer in a remote system. Each layer has a well-defined interface between itself and the layer immediately above and below. Consequently, the implementation of a particular protocol layer is independent of all other layers.

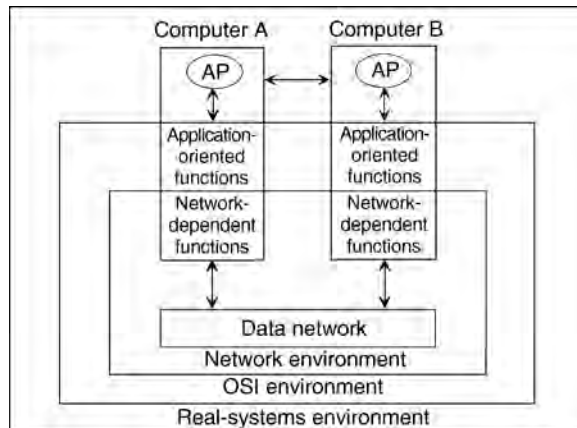

FIGURE 31.2 Operational environments.

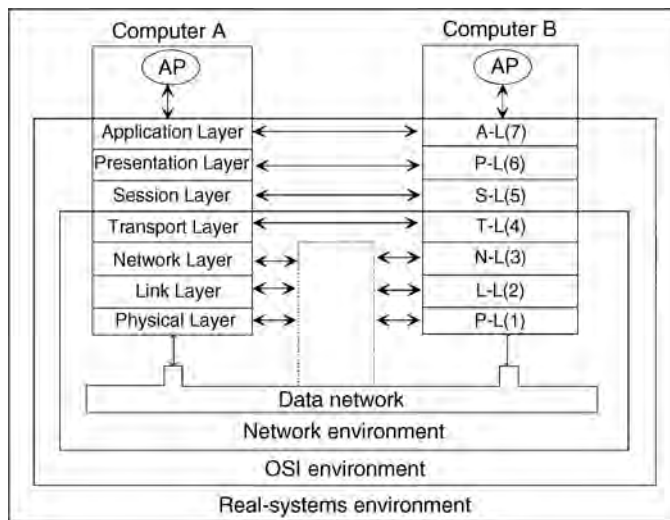

FIGURE 31.3 Overall structure of the ISO reference model.

The logical structure of the ISO reference model is made up of seven protocol layers, as shown in Fig. 31.3. The three lowest layers (1–3) are network dependent and are concerned with the protocols associated with the data communication network being used to link the two communicating computers. In contrast, the three upper layers (5–7) are application oriented and are concerned with the protocols that allow two end user application processes to interact with each other, normally through a range of services offered by the local operating system. The intermediate transport layer (4) masks the upper application-oriented layers from the detailed operation of the lower network-dependent layers. Essentially, it builds on the services provided by the latter to provide the application-oriented layers with a network-independent message interchange service.

The function of each layer is specified formally as a protocol that defines the set of rules and conventions used by the layer to communicate with a similar peer layer in another (remote) system. Each layer provides a defined set of services to the layer immediately above. It also uses the services provided by the layer immediately below it to transport the message units associated with the protocol to the remote peer layer. For example, the transport layer provides a network-independent message transport service to the session layer above it and uses the service provided by the network layer below it to transfer the set of message

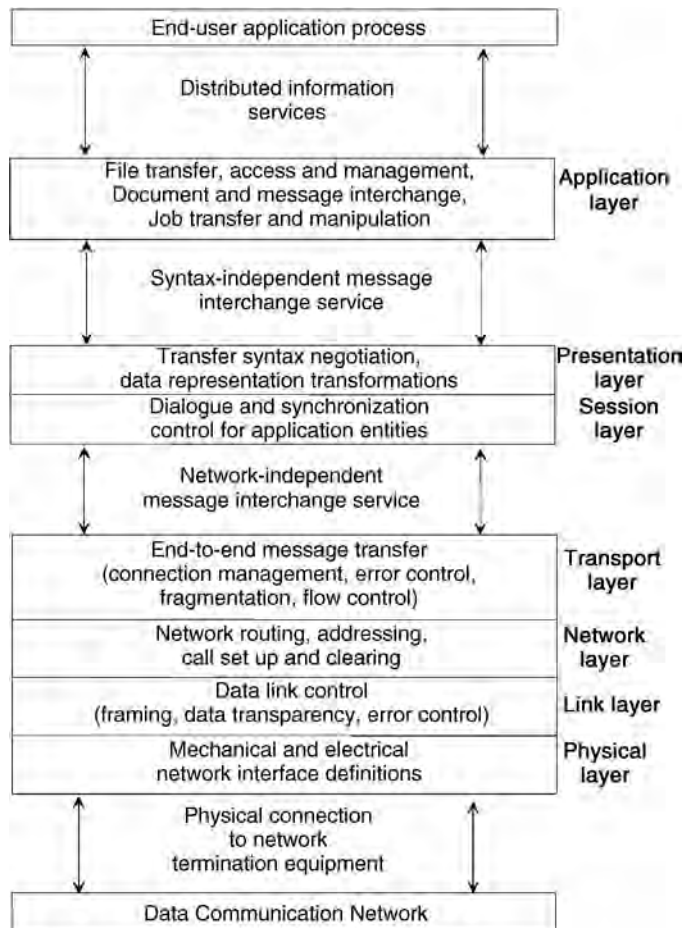

FIGURE 31.4 Protocol layer summary.

units associated with the transport protocol to a peer transport layer in another system. Conceptually, therefore, each layer communicates with a similar peer layer in a remote system according to a defined protocol. However, in practice, the resulting protocol message units of the layer are passed by means of the services provided by the next lower layer. The basic functions of each layer are summarized in Fig. 31.4.

The Application-Oriented Layers

The Application Layer

The application layer provides the user interface, normally an application program/process, to a range of networkwide distributed information services. These include file transfer access and management, as well as general document and message interchange services such as electronic mail. A number of standard protocols are either available or are being developed for these and other types of service.

Access to application services is normally achieved through a defined set of primitives, each with associated parameters, which are supported by the local operating system. The access primitives are the same as other operating system calls (as used for access to, say, a local file system) and result in an appropriate operating system procedure (process) being activated. These operating system procedures use the communication subsystem (software and hardware) as if it is a local device, similar to a disk controller, for example. The detailed operation and implementation of the communication subsystem is thus transparent to the (user) application process. When the application process making the call is

rescheduled (run), one (or more) status parameters are returned, indicating the success (or otherwise) of the network transaction that has been attempted.

In addition to information transfer, the application layer provides such services as:

- identification of the intended communication partner(s) by name or by address
- determination of the current availability of an intended communication partner
- establishment of authority to communicate
- agreement on privacy (encryption) mechanisms
- authentication of an intended communication partner
- selection of the dialogue discipline, including the initiation and release procedures
- agreement on responsibility for error recovery
- identification of constraints on data syntax (character sets, data structures, etc.)

The Presentation Layer

The presentation layer is concerned with the representation (syntax) of data during transfer between two communicating application processes. To achieve true open systems interconnection, a number of common *abstract data syntax* forms have been defined for use by application processes together with associated *transfer* (or *concrete*) *syntaxes*. The presentation layer negotiates and selects the appropriate transfer syntax(es) to be used during a transaction so that the syntax (structure) of the messages being exchanged between two application entities is maintained. Then, if this form of representation is different from the internal abstract form, the presentation entity performs the necessary conversion.

To illustrate the services provided by the presentation layer, consider a telephone conversation between a French speaking person and a Spanish speaking person. Assume each uses an interpreter and that the only language understood by both interpreters is English. Each interpreter must translate from their local language to English, and vice versa. The two correspondents are thus analogous to two application processes with the two interpreters representing presentation layer entities. French and Spanish are the local syntaxes and English is the transfer or concrete syntax. Note that there must be a universally understood language which must be defined to allow the agreed transfer language (syntax) to be negotiated. Also note that the interpreters do not necessarily understand the meaning (semantics) of the conversation.

Another function of the presentation layer is concerned with data security. In some applications, data sent by an application is first encrypted (enciphered) using a key, which is (hopefully) known only by the intended recipient presentation layer. The latter decrypts (deciphers) any received data using the corresponding key before passing it on to the intended recipient.

The Session Layer

The session layer provides the means that enables two application layer protocol entities to organize and synchronize their dialogue and manage their data exchange. It is thus responsible for setting up (and clearing) a communication (dialogue) channel between two communicating application layer protocol entities (presentation layer protocol entities in practice) for the duration of the complete network transaction. A number of optional services are provided, including the following:

- **Interaction management:** The data exchange associated with a dialogue may be duplex or half-duplex. In the latter case, it provides facilities for controlling the exchange of data (dialogue units) in a synchronized way.
- **Synchronization:** For lengthy network transactions, the user (through the services provided by the session layer) may choose periodically to establish synchronization points associated with the transfer. Then, should a fault develop during a transaction, the dialogue may be restarted at an agreed (earlier) synchronization point.
- **Exception reporting:** Nonrecoverable exceptions arising during a transaction can be signaled to the application layer by the session layer.

The Transport Layer

The transport layer acts as the interface between the higher application-oriented layers and the underlying network-dependent protocol layers. It provides the session layer with a message transfer facility that is independent of the underlying network type. By providing the session layer with a defined set of message transfer facilities, the transport layer hides the detailed operation of the underlying network from the session layer.

The transport layer offers a number of **classes of service** which cater to the varying *quality of service* (QOS) provided by different types of network.

There are five classes of service ranging from class 0, which provides only the basic functions needed for connection establishment and data transfer, to class 4, which provides full error control and flow control procedures. As an example, class 0 may be selected for use with a packet-switched data network (PSDN), whereas class 4 may be used with a local area network (LAN) providing a best-try service; that is, if errors are detected in a frame, then the frame is simply discarded.

The Network-Dependent Layers

As the lowest three layers of the ISO reference model are network dependent, their detailed operation varies from one network type to another. In general, however, the *network layer* is responsible for establishing and clearing a networkwide connection between two transport layer protocol entities. It includes such facilities as network routing (addressing) and, in some instances, flow control across the computer-to-network interface. In the case of internetworking, it provides various harmonizing functions between the interconnected networks.

The *link layer* builds on the physical connection provided by the particular network to provide the network layer with a reliable information transfer facility. It is thus responsible for such functions as error detection and, in the event of transmission errors, the retransmission of messages. Normally, two types of service are provided:

1. *Connectionless service* treats each information frame as a self-contained entity that is transferred using a best-try approach.
2. *Connection-oriented service* endeavors to provide an error-free information transfer facility.

Finally, the *physical layer* is concerned with the physical and electrical interfaces between the user equipment and the network terminating equipment. It provides the link layer with a means of transmitting a serial bit stream between the two equipments.

31.4 Open System Standards

The ISO reference model has been formulated simply as a template for the structure of a communication subsystem on which standards activities associated with each layer may be based. It is not intended that there should be a single standard protocol associated with each layer. Rather, a set of standards is associated with each layer, each offering different levels of functionality. Then, for a specific open systems interconnection environment, such as that linking numerous computer-based systems in a fully automated manufacturing plant, a selected set of standards is defined for use by all systems in that environment.

The three major international bodies actively producing standards for computer communications are the ISO, the American Institute of Electrical and Electronic Engineers (IEEE), and the International Telegraph and Telephone Consultative Committee (CCITT). Essentially, the ISO and IEEE produce standards for use by computer manufacturers, whereas the CCITT defines standards for connecting equipment to the different types of national and international public networks. As the degree of overlap between the computer and telecommunications industries increases, however, there is an increasing level of cooperation and commonality between the standards produced by these organizations.

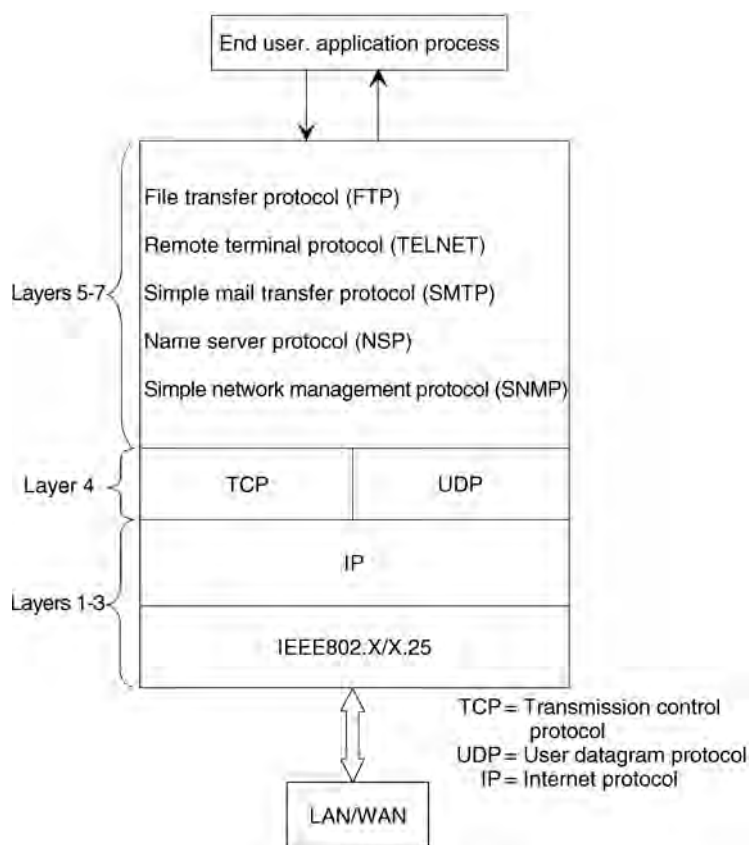

FIGURE 31.5 TCP/IP protocol suite.

In addition, prior to and concurrent with ISO standards activity, the U.S. Department of Defense has for many years funded research into computer communications and networking through its Defense Advanced Research Projects Agency (DARPA). As part of this research, the computer networks associated with a large number of universities and other research establishments were linked to those of DARPA. The resulting internetwork, known as ARPANET, has been extended to incorporate internets developed by other government agencies. The combined internet is now known simply as the Internet.

The protocol suite with the Internet is known as **transmission control protocol/internet protocol (TCP/IP)**. It includes both network-oriented protocols and application support protocols. Because TCP/IP is in widespread use with an existing internet, many of the TCP/IP protocols have been used as the basis for ISO standards. Moreover, since all of the protocol specifications associated with TCP/IP are in the public domain, and hence no licence fees are payable, they have been used extensively by commercial and public authorities for creating open system networking environments. In practice, therefore, there are two major open system (vendor-independent) standards: the TCP/IP protocol suite and those based on the evolving ISO standards.

Figure 31.5 shows some of the standards associated with the TCP/IP protocol suite. As can be seen, since TCP/IP has developed concurrently with the ISO initiative, it does not contain specific protocols relating to all of the seven layers in the OSI model.

Moreover, the specification methodology used for the TCP/IP protocols differs from that used for the ISO standards. Nevertheless, most of the functionality associated with the ISO layers is embedded in the TCP/IP suite. A range of standards has been defined by the ISO/CCITT and a selection of these is shown in Fig. 31.5. Collectively, they enable the administrative authority that is establishing the open system

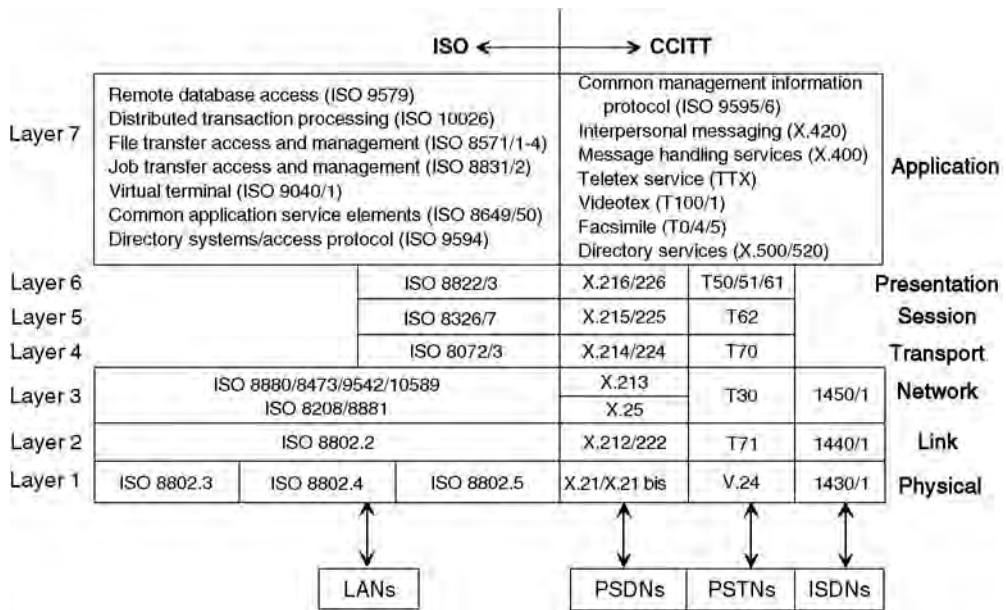

FIGURE 31.6 Standards summary.

environment to select the most suitable set of standards for the application. The resulting protocol suite is known as the *open system interconnection profile*. A number of such profiles have now been defined, including TOP, a protocol set for use in technical and office environments, MAP, for use in manufacturing automation, U.S. and U.K. GOSIP, for use in U.S. and U.K. government projects, respectively, and a similar suite used in Europe known as the CEN functional standards. The latter has been defined by the Standards Promotion and Application Group (SPAG), a group of 12 European companies.

As Fig. 31.6 shows, the lower three layers vary for different network types. CCITT has defined V, X, and I series standards for use with public-carrier networks. The V series is for use with the existing switched telephone network (PSTN), the X series for use with existing switched data networks (PSDN), and the I series for use with the integrated services digital networks (ISDN). Those produced by ISO/IEEE for use with local area networks are known collectively as the 802 (IEEE) or 8802 (ISO) series.

31.5 Summary

This chapter has reviewed the requirements for the communications subsystem in each of a set of interconnected computers that enables them to communicate in an open way to perform various distributed application functions. The philosophy behind the structure of the ISO reference model for open systems interconnection has been presented and the functionality of the seven layers that make up the reference model has been described. Finally, a selection of the ISO/CCITT standards that were defined have been identified.

Defining Terms

Internetwork: A collection of different network types that are linked together.

Local area network (LAN): Network used to link computers that are distributed around a single site.

Open system interconnection (OSI): A standard set of communication protocols that are independent of a specific manufacturer.

Transmission control protocol/Internet protocol (TCP/IP): The standard set of communication protocols that are used by each computer that is connected to the Internet.

Wide area network (WAN): Network used to link computers that are situated at different sites.

32.1 Overview

The term ethernet describes a collection of hardware, software, and control algorithms that together provide a technique for interconnecting dozens of nodes, spread over hundreds of meters, at aggregate rates ranging from 1 to 100 Mb/s. These nodes are typically computer work stations or peripheral devices that are part of a community of users that frequently exchange files, messages, and other types of data among each other. Shielded coaxial cables and unshielded twisted pairs have been used for the physical interconnection.

The primary hardware element used in an ethernet network is the *network interface card* (NIC). These cards are attached to a computer bus at one end and to a *media attachment unit* (MAU) at the other end via an attachment unit interface (AUI) cable. An MAU is an active device that includes transceivers and other elements matched to the nature of the physical transmission medium. Some vendors consolidate two or more of these elements into a single package, thereby rendering certain elements, such as AUI cables, unnecessary. *Repeaters* are sometimes used to regenerate signals to ensure reliable communication. The NICs perform a number of control functions in software; chief amongst these is the execution of a random access protocol for exchanging packets of information.

Nodes attached to an ethernet network exchange packets of information by broadcasting on a common communication channel. Simultaneous transmission by two or more nodes results in a detectable collision that triggers a collision resolution protocol. This decentralized protocol induces a stochastic rescheduling of the retransmission instants of the colliding nodes. If the overall traffic on the network is below a certain threshold, eventual delivery of all new and previously collided messages is guaranteed. The value of the threshold establishes the maximum aggregate information transfer rate that can be sustained. This threshold is influenced by the span of the network, the length of the packets, latency in collision detection, and the dynamics of the external traffic, as well as the rate at which bits can be transported over the physical medium. The aggregate information transfer rate can never exceed the bit transfer rate on the physical medium, but understanding the impact of the other variables has been the subject of many studies.

Standards bodies stipulate the values of some of these variables. For example, both the 10BASE2 and 1BASE5 versions of the IEEE 802.3 standards restrict packet lengths to values between 512 and 12,144 b. The 10BASE2 version restricts the network span to 925 m and relies on a bit transfer rate of 10 Mb/s over 50-W coaxial cable with a diameter of 5 mm, whereas 1BASE5 restricts the span to 2.5 kms and

relies on a bit transfer rate of 1 Mb/s over unshielded twisted pair. It is not uncommon to observe aggregate information transfer rates of 1.5 Mb/s or less in a 10BASE2 installation.

32.2 Historical Development

Ethernet evolved from a random access protocol that was developed at the University of Hawaii in the 1970s for use in the packet-switched Aloha broadcast radio network. The Aloha network was meant to serve many users that generated infrequent and irregularly spaced bursts of data. Techniques such as synchronous time-division multiplexing that require nodes to access a common channel only during precoordinated, nonoverlapping intervals of time are ill suited to serving many bursty users. This drawback motivated the development of the Aloha random access protocol, in which users access a common channel freely and invoke a collision resolution process only when collisions occur.

Spurred by the success of Aloha, efforts were undertaken to make the protocol more efficient. Early refinements included the use of a common clock to avoid partial collisions (slotted Aloha) as well as the development of hybrid protocols that combined elements of random access with reservations (reservation Aloha). Another series of refinements became possible in the context of limited span local area networks (LANs) that use low-noise communication links, such as coaxial cables, for the transmission medium. In such environments, a node can accurately and quickly sense ongoing transmissions on the cable. This first led to the development of carrier sense multiple access (CSMA) in which nodes withhold transmissions whenever they sense activity on the channel, thereby reducing the occurrence of collisions and improving efficiency. The next refinement for the LAN environment was based on a node's ability to detect a collision in less time than is required for a complete packet transmission. Early collision detection allows the colliding users to abort the transmission of colliding packets, thereby reducing the duration of collisions and further improving efficiency.

The ethernet protocol uses carrier sense multiple access with collision detection (CSMA/CD). The topology of an ethernet network may differ from the Aloha packet radio network. The Aloha packet radio network was configured with a controller node at the center of the network. The member nodes transmitted to the controller on a common inbound frequency band. On a different outbound frequency band, the controller broadcasts to the member nodes all of the packets it received as well as information, from which the occurrence of a collision could be inferred. In contrast, in some types of ethernet networks, nodes attach to a common communication channel and directly monitor it for carrier sensing and collision detection, as well as to transmit and receive packets. There is, thus, no central controller in some ethernet networks.

Ethernet was conceived at Xerox Palo Alto Research Center (PARC) in 1973 and described in a 1976 Association for Computing Machinery (ACM) article by Robert M. Metcalfe and David R. Boggs. The first prototype, also developed at Xerox PARC, operated at a speed of 3 Mb/s. In 1980, the Digital-Intel-Xerox 10 Mb/s ethernet was announced. The non-proprietary nature of the technology contributed to its widespread deployment and use in local area networks. By the mid-1980s, the Institute of Electrical and Electronics Engineers/American National Standards Institute (IEEE/ANSI) standards effort resulted in a set of CSMA/CD standards that were all based on the original ethernet concept.

32.3 Standards

In the terminology of the open systems interconnections (OSI) protocol architecture, the 802.3 series of standards are media access control (MAC) protocols. There exists a separate logical link control (LLC) sublayer, called the 802.2, which is above the MAC layer and, together with the MAC layer, forms a data link layer.

Currently, there are five IEEE/ANSI MAC standards in the 802.3 series. They are designated as 10BASE5, 10BASE2, 10BROAD36, 1BASE5, and 10BASET. A new version called 100BASET is currently under study. The numeric prefix in these designations refers to the speed in megabits per second. The term BASE refers

to baseband transmissions and the term BROAD refers to transmission over a broadband medium. The numeric suffix, when it appears, is related to limits on network span.

All 802.3 MAC standards share certain common features. Chief among them is a common MAC framing format for the exchange of information. This format includes a fixed preamble for synchronization, destination and source addresses for managing frame exchanges, a start of frame delimiter and length of frame field to track the boundaries of the frames, a frame check sequence to detect errors, and a data field and pad field, which have a role related to collision detection, which is explained further in the section on operation. In addition to a common framing format, all of the 802.3 MAC protocols constrain the frame lengths to be between 512 and 12,144 b. A 32-b jam pattern is used to enforce collisions. An interframe gap of $9.6 \mu\text{s}$ is used with the the 10-Mb/s standard and a gap of $96 \mu\text{s}$ is used with the 1 Mb/s standard. The parameters that characterize the retransmission backoff algorithm are also the same.

The primary difference between the various 802.3 standards is with regard to the physical communication medium used and consequences thereof.

10BASE5

This was the first of the IEEE/ANSI 802.3 standards to be finalized. A 10-mm coaxial cable with a characteristic impedance of 50Ω is the physical medium. The length of any one segment cannot exceed 500 m, but a maximum of five segments can be attached together, through the use of four repeaters, to create a network span of 2.5 km. There can be no more than 100 attachments to a segment, and the distance between successive attachments to this cable must be at points that are multiples of 2.5 m to prevent reflections from adjacent taps from adding in phase. In view of the inflexibility of the 10-mm cable, a separate transceiver cable is used to connect the network interface cards to the coaxial cable. Transmitting nodes detect collisions when voltages in excess of the amount that can be attributed to their transmission are measured. Nontransmitting nodes can detect collisions when voltages in excess of the amount that can be produced by any one node is detected.

10BASE2

10BASE2 networks are based on a coaxial cable that has a characteristic impedance of 50Ω and a diameter of 5 mm. The flexibility of the thinner cable makes it possible to dispense with the transceiver cable and directly connect the coaxial cable to the network interface card through the use of a *T*-connector. Furthermore, nodes can be spaced as close as 0.5 m. On the other hand, signals on the thinner cable are less immune to noise and suffer greater degradation. Consequently, segment lengths cannot exceed 185 m and no more than 30 nodes can be attached to a segment. As with 10BASE5, up to five segments can be attached together with repeaters to create a maximum network span of 925 m. The 10BASE2 and 10BASE5 segments can be attached together as long as the less robust 10BASE2 segments are at the periphery of the network.

10BROAD36

The 10BROAD36 networks are based on standard cable TV coaxial cables with a characteristic impedance of 75Ω . The 10BROAD36 networks operate in a manner that is closer to the original Aloha network than 10BASE2 or 10BASE5. Nodes on a 10BROAD36 generate differential phaseshift keyed (DPSK) RF signals. A head-end station receives these signals and repeats them on a different frequency band. Thus, sensing and transmissions are done on two different channels just as in the Aloha network. The distance between a node and the head-end station can be as much as 1.8 km for a total network span of 3.6 km. A separate band of frequencies is set aside for the transmission of a collision enforcement signal. Interestingly, in this environment, there is a possibility that when two signals collide, one of the two may be correctly captured by some or even all of the stations. Nonetheless, 10BROAD36 requires that transmitting

stations compare their uplink transmissions with the downlink head-end transmission and broadcast a collision enforcement signal whenever differences are observed.

1BASE5

Also referred to as StarLAN, 1BASE5 networks operate at the lower rate of 1 Mb/s over unshielded twisted pair cables whose diameters range between 0.4 and 0.6 mm. The 1BASE5 networks are physically configured in the shape of a star. Each node is attached to a hub via two separate pairs of unshielded twisted wires: one pair is for transmissions to the hub, and the other pair is for receptions from the hub. Neither of these pairs is shared with any other node. A hub has multiple nodes attached to it and detects collisions by sensing activity on more than one incoming port. It is responsible for broadcasting all correctly received packets on all outgoing links or broadcasting a collision presence signal when one is detected. The 1BASE5 standard does not constrain the number of nodes that can be attached to a hub.

It is also possible to cascade hubs in a five-layer hierarchy with one header hub and a number of intermediate hubs. The node-to-hub distance and the inter-hub distances are limited to 250 m and, therefore the largest network span that can be created is limited to 2.5 kms. In view of the lower speed of 1BASE5 networks, they can not be easily integrated with the other IEEE 802.3 networks.

10BASET

The 10BASET network is similar to the older 1BASE5 network in that both use unshielded twisted pairs, but 10BASET networks can sustain data rates of 10 Mb/s. This is accomplished partly by limiting individual segment lengths to 100 m. Instead of the hierarchical hubs used in 1BASE5, 10BASET uses multiport repeater sets, which are connected together in exactly the same way as nodes are connected to a repeater set. Two nodes on a 10BASET network can be separated by up to four repeater sets and up to five segments. Of the five segments, no more than three can be coaxial cable-based 10BASE2 or 10BASE5 segments; the remaining segments can be either unshielded twisted pair, point-to-point links of length less than 100 m each, or fiber optic point-to-point links of length less than 500 m each. The network span that can be supported depends on the mix of repeater sets and segments used.

100BASET

Currently, there is an effort to create a 100-Mb/s standard in the 802.3 series. The 100 BASET network will use multiple pairs of unshielded twisted pairs, a more efficient code for encoding the data stream, and a slightly faster clock rate to generate the tenfold increase in bit transfer rates.

32.4 Operation

The core algorithm used in all of the 802.3 series of MAC standards and the original ethernet is essentially the same. The MAC layer receives LLC data and encapsulates into MAC frames. Of particular interest in the MAC frame is the pad field, whose role is related to collision detection and will be explained. Prior to transmitting frames, the MAC layer senses the physical channel. If transmission activity is detected, the node continues to monitor until a break is detected, at which time the node transmits its frame. In spite of the prior channel sensing performed, it is possible that the frame will collide with one or more other frames. Such collisions may occur either because two or more nodes concurrently initiate transmissions following the end of the previous transmission or because propagation delays prevent a node from sensing the transmission initiated by another node at an earlier instant.

Colliding users detect collisions through physical mechanisms that depend on the nature of the attachment to the underlying communication medium. As described in the section on standards, in

10BASE2 and 10BASE5 networks, transmitting nodes recognize electrical currents in excess of what they injected into the coaxial cable. In 1BASE5 and 10BASET networks, nodes recognize activity on both the transmitter and receiver ports, and in 10BROAD36 networks, nodes spot differences in the transmitted and received waveforms. All of these collision sensing methods rely on a node's knowledge of its own transmission activity. Since this information is not available to all of the other nodes, the disposition of some partially received MAC frames may be in doubt. Therefore, to enforce a common view of the channel outcome, colliding users transmit a jam pattern as soon as they sense a collision.

Thus, the full duration of a collision is the sum of the maximum collision detect time and the jam pattern. The first of these two components, the time to detect a collision, is primarily determined by the time it takes for signals to propagate between any two nodes on the cable. By constraining the span of a network, standards such as the IEEE 802.3 limit the maximum collision detect time. The second component, the jam pattern length, is also constrained by standards. Thus, the longest period of collision activity, which can be thought of as an invalid frame, is limited. The pad field of the MAC frame can then be used to ensure that valid frames are larger than the longest invalid frame that may occur as a result of collisions. This provides a simple mechanism by which nodes that were not involved in a collision can also sense the collision.

In order to resolve collisions, ethernet nodes retransmit after a randomly chosen delay. Further more, the probability distribution of the retransmission delay of a given packet is updated each time the packet experiences a collision. The choice of the initial probability distribution of the retransmission delay and the dynamics of its updates determines whether or not the total population of new and retransmitted users can transmit successfully. Thus, the retransmission algorithm lies at the heart of the ethernet protocol.

The IEEE 802.3 standard specifies the use of a truncated binary exponential backoff algorithm. In this algorithm, a packet that has collided n times is withheld for a duration that is proportional to a quantity that is uniformly distributed between 0 and $2^m - 1$, where $m = \min(10, n)$. The constant of proportionality is chosen to be large enough to ensure that nodes that choose to withhold for different durations do not collide, regardless of their location on the cable. Furthermore, when the number of times a packet has collided exceeds a user-defined threshold, which is commonly chosen to be 16, it is rejected by the MAC layer and has to be resubmitted at a later time by a higher layer.

As a consequence of the collision resolution process, the order in which ethernet serves packets depends on the traffic intensity. During periods of very light traffic, service is first come first served. During periods of heavy contention, some colliding users will defer their transmissions into the future even as some later arrivals transmit sooner. Because of this, packet delivery in ethernet may occur out of sequence and has to be rectified at the receiver.

The lack of first come first served service and the stochastic nature of the rescheduling algorithm are sometimes considered to be weaknesses of the ethernet network. On the other hand, the ability to use unshielded twisted pair wires for 10-Mb/s communication, the large installed base of users, and the promise of even faster communication at rates of 100 Mb/s over multiple pairs of unshielded twisted pair wires makes ethernet networks very attractive.

33.1 Introduction

Fiber distributed data interface (FDDI) is an American National Standards Institute (ANSI) standard for a 100-Mb/s fiber optic token ring network. High-transmission speed and a bounded access time [Sevcik and Johnson, 1987] make FDDI very suitable for supporting real-time applications. Furthermore, FDDI employs a dual-loop architecture, which enhances its reliability; in the event of a fault on one loop, the other loop can be used for transmission. Several new civil and military networks have adopted FDDI as the backbone network.

In order to achieve efficiency, a high-speed network such as an FDDI network requires simple (i.e., low overhead) protocols. In a token ring network, the simplest protocol is the *token passing* protocol. In this protocol, a node transmits its message whenever it receives the token. After it completes its transmission, the node passes on the token to the next neighboring node. Although it has the least overhead, the token passing protocol cannot bound the time between two consecutive visits of the token to a node (called the *token rotation time*), which makes it incapable of guaranteeing message delay requirements. The *timed token protocol*, proposed by Grow [1982], overcomes this problem. This protocol has been

adopted as a standard for the FDDI networks. The idea behind the timed token protocol is to control the token rotation time. As a result, FDDI is able to support real-time applications.

In the rest of this chapter, we will first introduce the architecture of FDDI networks and discuss its fault management capabilities. We then address how to use FDDI to support time-critical applications.

33.2 Architecture and Fault Management

FDDI is a token ring network. The basic architecture of an FDDI network consists of nodes connected by two counter-rotating loops, as illustrated in Fig. 33.1(a). A node in an FDDI network can be a single attachment station (SAS), a dual attachment station (DAS), a single attachment concentrator (SAC), or a dual attachment concentrator (DAC). Whereas stations constitute the sources and destinations for user frames, the concentrators provide attachments to other stations. The single attachment stations and concentrators are so called because they connect to only one of the two loops. The two fiber loops of an FDDI network are usually enclosed in a single cable. These two loops will be collectively referred to as the FDDI *trunk ring*.

The FDDI standards have been influenced by the need to provide a certain degree of built-in fault tolerance. The station management (SMT) layer of the FDDI protocol deals with initialization/control, monitoring, and fault isolation/recovery in FDDI networks [Jain, 1994]. In ring networks such as FDDI, faults are broadly classified into two categories: node faults and link faults. The FDDI standard specifies explicit mechanisms and procedures for detection of and recovery from both kinds of faults. These fault management capabilities of FDDI provide a foundation for capabilities of FDDI enabled fault-tolerant operation. We present here a brief sketch of FDDI's fault management capabilities. For a comprehensive discussion, see ANSI [1992].

To deal with node faults, each node in FDDI is equipped with an optical bypass mechanism. Using this mechanism, a faulty node can be isolated from the ring, thus letting the network recover from a node fault. Link faults are handled by exploiting the dual-loop architecture of FDDI. Many FDDI networks use one loop as the primary loop and the other as a backup. In the event of a fault on the primary loop, the backup loop is used for transmission [Fig. 33.1(b)].

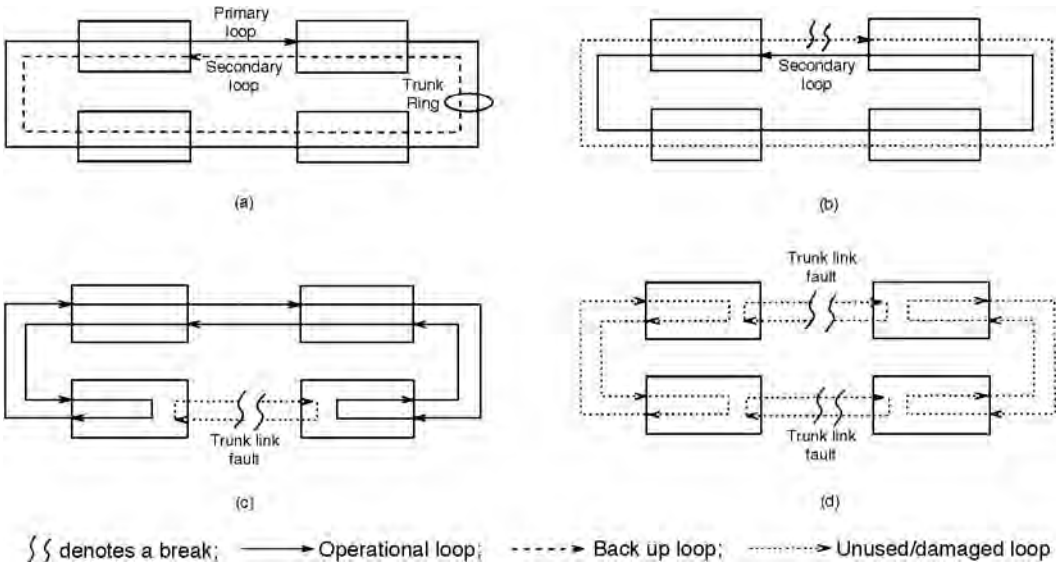

FIGURE 33.1 Architecture and fault management: (a) FDDI trunk ring consists of primary and secondary loops; (b) a fault on the primary loop, secondary loop used for transmission; (c) single trunk link fault, primary and secondary loops wrap up to form a new operational loop; and (d) two trunk link faults segment the network, no loop connects all the nodes.

Because of the proximity of the two fiber loops, a link fault on one loop is quite likely to be accompanied by a fault on the second loop as well, at approximately the same physical location. This is particularly true of faults caused by destructive forces. Such link faults, with both loops damaged, may be termed as *trunk link faults*.

An FDDI network can recover from a single trunk link fault using the so called *wrap-up* operation. This operation is illustrated in Fig. 33.1(c). The wrap-up operation consists of connecting the primary loop to the secondary loop. Once a link fault is detected, the two nodes on either side of the fault perform the wrap-up operation. This process isolates the fault and restores a single closed loop.

The fault detection and the wrap-up operation is performed by a sequence of steps defined by FDDI's link fault management. Once the network is initialized, each node continuously executes the link fault management procedure. The flow chart of the link fault management procedure is shown in Fig. 33.2. Figure 33.2 only presents the gist of the fault management procedure. For details, the reader is referred

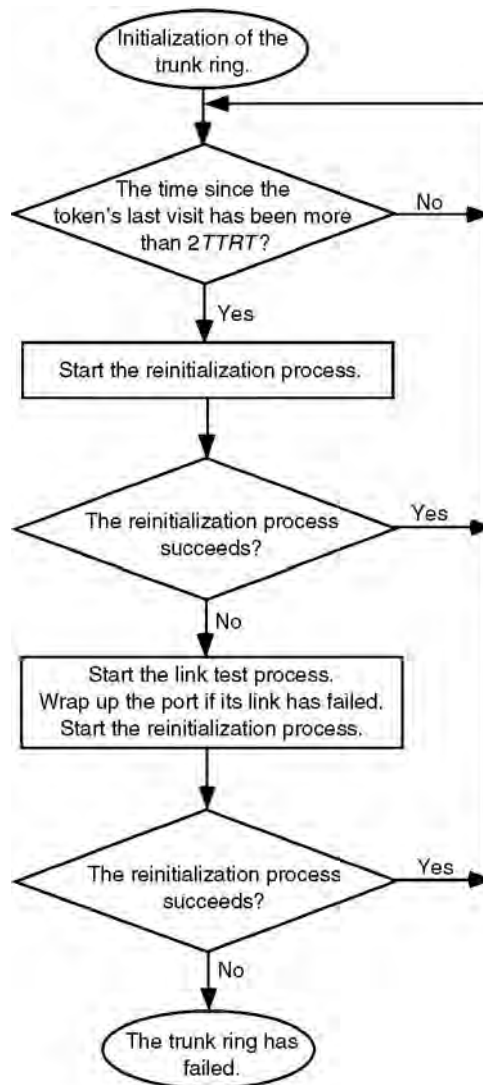

FIGURE 33.2 Flow chart of FDDI link fault management procedure.

to ANSI [1992]. The major steps of this procedure are as follows:

- An FDDI node detects a fault by measuring the time elapsed since the previous token visit to that node. At network initialization time, a constant value is chosen for a protocol parameter called the target token rotation time ($TTRT$). The FDDI protocol ensures that under fault-free operating conditions, the duration between two consecutive token visits to any node is not more than $2TTRT$. Hence, a node initiates the fault tracing procedure when the elapsed time since the previous token arrival at the node exceeds $2TTRT$.
- The node first tries to reinitialize the network (using claim frames). If the fault was temporary, the network will recover. Several nodes may initiate the reinitialization procedure asynchronously. However, the procedure converges within $TTRT$ time (which is usually on the order of a few milliseconds). The details of this procedure are beyond the scope of this chapter. The reader is referred to ANSI [1992].
- If the reinitialization procedure times out, then the node suspects a permanent fault in the trunk ring. The nodes then execute a series of further steps in order to locate the ring's fault domain. The nodes within the fault domain perform link tests to check the status of the links on all their ports. If a link is faulty, the ring is wrapped up at the corresponding port. The node then tries to reinitialize the wrapped up ring. Once again, note that these operations are carried out concurrently and asynchronously by all the nodes in the trunk ring. That is, any of them may initiate the series of fault recovery steps, but their actions will eventually converge to locate and recover from the fault(s).
- In the event that the last step has also failed, the network is considered unrecoverable. It is possible that operator intervention is required to solve the problem.

With the basic fault management mechanism just described, an FDDI network may not be able to tolerate two or more faults. This is illustrated in Fig. 33.1(d), where two trunk link faults leave the network disconnected. Hence, the basic FDDI architecture needs to be augmented to meet the more stringent fault tolerance requirements of mission-critical applications. In addition, the bandwidth of a single FDDI ring may not be sufficient for some high-bandwidth applications. FDDI-based reconfigurable networks (FBRNs) provide increased fault tolerance and transmission bandwidth as compared to standard FDDI networks. See Agrawal, Kamat, and Zhao [1994]; Chen, Kamart, and Zhao [1995]; and Kamat, Agrawal, and Zhao [1994] for a discussion of this subject.

33.3 The Protocol and Its Timing Properties

FDDI uses the timed token protocol [Grow, 1982]. The timed token protocol is a token passing protocol in which each node gets a guaranteed share of the network bandwidth. Messages in the timed token protocol are segregated into two separate classes: the *synchronous* class and the *asynchronous* class [Grow, 1982]. Synchronous messages are given a guaranteed share of the network bandwidth and are used for real-time communication.

The idea behind the timed token protocol is to control the token rotation time. During network initialization, a protocol parameter called the target token rotation time ($TTRT$) is determined, which indicates the expected token rotation time. Each node is assigned a portion of the $TTRT$, known as its *synchronous bandwidth* (H_i), which is the maximum time a node is permitted to transmit synchronous messages every time it receives the token. When a node receives the token, it transmits its synchronous messages, if any, for a time no more than its allocated synchronous bandwidth. It can then transmit its asynchronous messages only if the time elapsed since the previous token departure from the same node is less than the value of $TTRT$, that is, only if the token arrives earlier than expected.

In order to use the timed token protocol for real-time communications, that is, to guarantee that the deadlines of synchronous messages are met, parameters such as the synchronous bandwidth, the target

token rotation time, and the buffer size must be chosen carefully.

- The synchronous bandwidth is the most critical parameter in determining whether message deadlines will be met. If the synchronous bandwidth allocated to a node is too small, then the node may not have enough network access time to transmit messages before their deadlines. Conversely, large synchronous bandwidths can result in a long token rotation time, which can also cause message deadlines to be missed.
- Proper selection of $TTRT$ is also important. Let τ be the token walk time around the network. The proportion of time taken due to token walking is given by $\tau/TTRT$. The maximum network utilization available to user applications is then $1 - \tau/TTRT$ [Ulm, 1982]. A smaller $TTRT$ results in less available utilization and limits the network capacity. On the other hand, if $TTRT$ is too large, the token may not arrive at a node soon enough to meet message deadlines.
- Each node has buffers for outgoing and incoming synchronous messages. The sizes of these buffers also affect the real-time performance of the network. A buffer that is too small can result in messages being lost due to buffer overflow. A buffer that is too large is wasteful of memory.

In [Section 33.4](#), we will discuss parameter selection for real-time applications. Before that, we need to define network and message models and investigate protocol properties.

The Network and the Message Models

The network contains n nodes arranged in a ring. Message transmission is controlled by the timed token protocol, and the network is assumed to operate without any faults. Outgoing messages at a node are assumed to be queued in first-in-first-out (FIFO) order.

Recall that the token walk time is denoted by τ , which includes the node-to-node delay and the token transmission time. Here τ is the portion of $TTRT$ that is not available for message transmission. Let α be the ratio of τ to $TTRT$, that is, $\alpha = \tau/TTRT$. Then α represents the proportion of time that is not available for transmitting messages.

There are n streams of synchronous messages, S_1, \dots, S_n , with stream S_i originating at node i . Each synchronous message stream S_i may be characterized as $S_i = (C_i, P_i, D_i)$:

- C_i is the maximum amount of time required to transmit a message in the stream. This includes the time to transmit both the payload data and the message headers.
- P_i is the interarrival period between messages in the synchronous message stream. Let the first message in stream S_i arrive at node i at time $t_{i,j}$. The j th message in stream S_i will arrive at node i at time $t_{i,j} = t_{i,1} + (j - 1) P_i$, where $j \geq 1$.
- D_i is the *relative deadline* of messages in the stream. The relative deadline is the maximum amount of time that may elapse between a message arrival and completion of its transmission. Thus, the transmission of the j th message in stream S_i , which arrives at $t_{i,j}$, must be completed by $t_{i,j} + D_i$, which is the *absolute deadline* of the message. To simplify the discussion, the terms relative and absolute will be omitted in the remainder of the chapter when the meaning is clear from the context.

Throughout this chapter, we make no assumptions regarding the destination of synchronous message streams. Several streams may be sent to one node. Alternatively, multicasting may occur in which messages from one stream are sent to several nodes.

If the parameters (C_i, P_i, D_i) are not completely deterministic, then their worst-case values must be used. For example, if the period varies between 80 and 100 ms, a period of 80 ms must be assumed. Asynchronous messages that have time constraints can have their deadlines guaranteed by using pseudosynchronous streams. For each source of time-constrained asynchronous messages, a corresponding synchronous message stream is created. The time-constrained asynchronous messages are then promoted to the synchronous class and sent as synchronous messages in the corresponding synchronous message stream.

Each synchronous message stream places a certain load on the system. We need a measure for the load. We define the *effective utilization* U_i of stream S_i as follows:

$$U_i = \frac{C_i}{\min(P_i, D_i)} \quad (33.1)$$

Because a message of length C_i arrives every P_i time, $U_i = C_i/P_i$ is usually regarded as the load presented by stream S_i . An exception occurs when $D_i < P_i$. A message with such a small deadline must be sent relatively urgently, even if the period is very large. Thus, $U_i = C_i/D_i$ is used to reflect the load in this case.

The total effective utilization U of a synchronous message set can now be defined as

$$U = \sum_{i=1}^n U_i \quad (33.2)$$

The total effective utilization is a measure of the demands placed on the system by the entire synchronous message set. In order to meet message deadlines, it is necessary that $U \leq 1$.

Constraints

The timed token protocol requires several parameters to be set. The synchronous bandwidths, the target token rotation time, and the buffer sizes parameters are crucial in guaranteeing the deadlines of synchronous messages. Any choice of these parameters must satisfy the following constraints.

The Protocol Constraint

This constraint states that the total bandwidth allocated to synchronous messages must be less than the available network bandwidth, that is,

$$\sum_{i=1}^n H_i \leq TTRT - \tau \quad (33.3)$$

This constraint is necessary to ensure stable operation of the timed token protocol.

The Deadline Constraint

This constraint simply states that every synchronous message must be transmitted before its (absolute) deadline. Formally, let $s_{i,j}$ be the time that the transmission of the j th message in stream S_i is completed. The deadline constraint requires that for $i = 1, \dots, n$ and $j = 1, 2, \dots$,

$$S_{i,j} \leq t_{i,j} + D_i \quad (33.4)$$

where $t_{i,j}$ is the arrival time and D_i is the (relative) deadline. Note that in this inequality, $t_{i,j}$ and D_i are given by the application, but $s_{i,j}$ depends on the synchronous bandwidth allocation and the choice of $TTRT$.

The Buffer Constraint

This constraint states that the size of the buffers at each node must be sufficient to hold the maximum number of outgoing or incoming synchronous messages that could be queued at the node. This constraint is necessary to ensure that messages are not lost due to buffer overflow.

Timing Properties

According to Eq. (33.4), the deadline constraint of message M is satisfied if and only if the minimum synchronous bandwidth available to M within its deadline is bigger than or equal to its message size. That is, for a given $TTRT$, whether or not deadline constraints can be satisfied is solely determined by

bandwidth allocation. In order to allocate appropriate synchronous bandwidth to a message stream, we need to know the worst-case available synchronous bandwidth for a stream within any time period.

Johnson and Sevcik [1987] showed that the maximum amount of time that may pass between two consecutive token arrivals at a node can approach $2TTRT$. This bound holds regardless of the behavior of asynchronous messages in the network. To satisfy the deadline constraint, it is necessary for a node to have at least one opportunity to send each synchronous message before the message deadline expires. Therefore, in order for the deadline constraint to be satisfied, it is necessary that for $i = 1, \dots, n$,

$$D_i \geq 2TTRT \quad (33.5)$$

It is important to note that Eq. (33.5) is only a necessary but not a sufficient condition for the deadline constraint to be satisfied. For all message deadlines to be met, it is also crucial to choose the synchronous bandwidths H_i appropriately.

Further studies on timing properties have been performed in Chen, Li, and Zhao [1994] and the results can be summarized by the following theorem.

Theorem 33.1. Let $X_i(t, t+I, \mathbf{H})$ be the minimum total transmission time available for node i to transmit its synchronous message within the time interval $(t, t+I)$ under bandwidth allocation $\mathbf{H} = (H_1, H_2, \dots, H_n)^T$ then

$$= \begin{cases} \left\lfloor \frac{I}{TTRT} - 1 \right\rfloor \cdot H_i + \max \left(0, \min \left(r_i - \tau - \sum_{j=1, \dots, n, j \neq i} H_j, H_i \right) \right) & \text{if } I \geq TTRT \\ 0 & \text{otherwise} \end{cases} \quad (33.6)$$

where $r_i = I - \left\lfloor \frac{I}{TTRT} \right\rfloor \cdot TTRT$.

Using Theorem 33.1, deadline constraint (33.4) is satisfied if and only if, for $i = 1, \dots, n$,

$$X_i(t, t+D_i, H) \geq C_i \quad (33.7)$$

33.4 Parameter Selection for Real-Time Applications

To support real-time applications on FDDI, we have to properly set the following three types of parameters: synchronous bandwidth, $TTRT$, and buffer size. We address this parameter selection problem in this section.

Synchronous Bandwidth Allocation

In FDDI, synchronous bandwidths are assigned by a synchronous bandwidth allocation scheme. This subsection examines synchronous bandwidth allocation schemes and discusses how to evaluate their effectiveness.

A Classification of Allocation Schemes

Synchronous bandwidth allocation schemes may be divided into two classes: local allocation schemes and global allocation schemes. These schemes differ in the type of information they may use. A local synchronous bandwidth allocation scheme can only use information available locally to node i in allocating H_i . Locally available information at node i includes the parameters of stream S_i (i.e., C_i , P_i , and D_i). $TTRT$ and τ are also locally available at node i because these values are known to all nodes. On the other hand, a global synchronous bandwidth allocation scheme can use global information in its allocation of synchronous bandwidth to a node. Global information includes both local information and information regarding the parameters of synchronous message streams originating at other nodes.

A local scheme is preferable from a network management perspective. If the parameters of stream S_i change, then only the synchronous bandwidth H_i of node i needs to be recalculated. The synchronous bandwidths at other nodes do not need to be changed because they were calculated independently of S_i . This makes a local scheme flexible and suited for use in dynamic environments where synchronous message streams are dynamically initiated or terminated.

In a global scheme, if the parameters of S_i change, it may be necessary to recompute the synchronous bandwidths for all nodes. Therefore, a global scheme is not well suited for a dynamic environment. In addition, the extra information employed by a global scheme may cause it to handle more traffic than a local scheme. However, it is known that local schemes can perform *very closely* to the optimal synchronous bandwidth allocation scheme when message deadlines are equal to message periods. Consequently, given the previously demonstrated good performance of local schemes and their desirable network management properties, we concentrate on local synchronous bandwidth allocation schemes in this chapter.

A Local Allocation Scheme

Several local synchronous bandwidth allocation schemes have been proposed for both the case of $D_i = P_i$ [Agrawal, Chen, and Zhao, 1993] and the case of $D_i \neq P_i$ [Malcolm and Zhao, 1993; Zheng and Shin, 1993]. These schemes all have similar worst-case performance. Here we will consider the scheme proposed in Malcolm and Zhao [1993]. With this scheme, the synchronous bandwidth for node i is allocated according to the following formula:

$$H_i = \frac{U_i D_i}{\left[\frac{D_i}{TTRT} - 1 \right]} \quad (33.8)$$

Intuitively, this scheme follows the flow conservation principle. Between the arrival of a message and its absolute deadline, which is D_i time later, node i will have at least $\left[\frac{D_i}{TTRT} - 1 \right] H_i$ of transmission time available for synchronous messages by Eq. (33.6). This transmission time is available regardless of the number of asynchronous messages in the network. During the D_i time, $U_i D_i$ can loosely be regarded as the load on node i . Thus, the synchronous bandwidth in Eq. (33.8) is just sufficient to handle the load on node i between the arrival of a message and its deadline.

The scheme defined in Eq. (33.8) is a simplified version of those in Malcolm and Zhao [1993] and Zheng and Shin [1993]. In the rest of this chapter, we assume this scheme is used because it is simple, intuitive, and well understood. Another reason for concentrating on this scheme is that it has been adopted for use with the SAFENET standard, and thus will be used in distributed real-time systems in the future.

Schedulability Testing

We now consider schedulability testing. A message set is schedulable if the deadlines of its synchronous messages can be satisfied. This can be determined by referring to the tests that both the protocol and deadline constraints [Eqs. (33.3) and (33.4) or Eq. (33.7)] are satisfied.

Testing to see if the protocol constraint is satisfied is very straightforward. But the test of deadline constraints is more complicated and requires more information. This test can be greatly simplified if the bandwidths are allocated according to Eq. (33.8). It was shown that if this scheme is used, the protocol constraint condition defined in Eq. (33.3) implies the deadline constraint condition Eq. (33.4). Testing the protocol constraint alone is sufficient to ensure that both constraints are satisfied. This is a big advantage of using the allocation scheme defined in Eq. (33.8).

A second method of schedulability testing is to use the *worst-case achievable utilization* criteria. This criteria has been widely used in real-time systems. For a synchronous bandwidth allocation scheme, the worst-case achievable utilization U^* defines an upper bound on the effective utilization of a message set: if the effective utilization is no more than the upper bound, both the protocol and the deadline constraints

FIGURE 33.3 U^* vs. D_{\min} .

are always satisfied. The worst-case achievable utilization U^* for the scheme defined in Eq. (33.8) is

$$U^* = \frac{\left\lfloor \frac{D_{\min}}{TTRT} \right\rfloor - 1}{\left\lfloor \frac{D_{\min}}{TTRT} \right\rfloor + 1} (1 - \alpha) \quad (33.9)$$

where $TTRT$ is the target token rotation time and D_{\min} is the minimum deadline. For any message set, if its effective utilization Eq. (33.2) is less than U^* , both the protocol and deadline constraints are guaranteed to be satisfied.

We would like to emphasize that, in practice, using this criteria can simplify network management considerably. The parameters of a synchronous message set can be freely modified while still maintaining schedulability, provided that the effective utilization remains less than U^* .

Let us examine the impact of $TTRT$ and D_{\min} on the worst-case achievable utilization given in Eq. (33.9). Figure 33.3 shows the worst-case achievable utilization vs. D_{\min} for several different values of $TTRT$. This figure was obtained by plotting Eq. (33.9) with τ taken to be 1 ms (a typical value for an FDDI network). Several observations can be made from Fig. 33.3 and formula (33.8).

1. For a fixed value of $TTRT$, the worst-case achievable utilization increases as D_{\min} increases. From Eq. (33.9) it can be shown that when D_{\min} approaches infinity, U^* approaches $(1 - \alpha) = (1 - \tau/TTRT)$. That is, as the deadlines become larger, the worst-case achievable utilization approaches the available utilization of the network.
2. In Agrawal, Chen, and Zhao [1993], it was shown that for a system in which all relative deadlines are equal to the corresponding message periods ($D_i = P_i$), a worst-case achievable utilization of $\frac{1}{3}(1 - \alpha)$ can be achieved. That result can be seen as a special case of Eq. (33.9): if $D_{\min} = 2TTRT$, we have $\left\lfloor \frac{D_{\min}}{TTRT} \right\rfloor = 2$ and $U^* = \frac{1}{3}(1 - \alpha)$.
3. $TTRT$ clearly has an impact on the worst-case achievable utilization. From Fig. 33.3, we see that when $D_{\min} = 50$ ms, the case of $TTRT = 5$ ms gives a higher worst-case achievable utilization than the other plotted values of $TTRT$. When $D_{\min} = 125$ ms, the case of $TTRT = 10$ ms gives a higher U^* than the other plotted values of $TTRT$. This observation provides motivation for maximizing U^* by properly selecting $TTRT$ once D_{\min} is given.

FIGURE 33.4 U^* vs. $TTRT$.

Selection of Target Token Rotation Time

Recall that $TTRT$, the target token rotation time, determines the expected value of the token rotation time. In contrast to the synchronous bandwidths of individual nodes, $TTRT$ is common to all of the nodes and should be kept constant during run time. As we observed in the last section, $TTRT$ has an impact on the worst-case achievable utilization. Thus, we would like to choose $TTRT$ in an optimal fashion so that the worst-case achievable utilization U^* is maximized. This will increase the amount of real-time traffic that can be supported by the network.

The optimal value of $TTRT$ has been derived in Malcolm and Zhao [1993] and is given by

$$TTRT = \frac{D_{\min}}{-3 + \sqrt{9 + \frac{8D_{\min}}{\tau}}} \quad (33.10)$$

The impact of an appropriate selection of $TTRT$ is further evident from Fig. 33.4, which uses Eq. (33.10) to show U^* vs. $TTRT$ for several different values of D_{\min} . As with Fig. 33.3, τ is taken to be 1 ms. From Fig. 33.4, the following observations can be made:

1. The curves in Fig. 33.4 verify the prediction of the optimal $TTRT$ value given by Eq. (33.10). For example, consider the case of $D_{\min} = 40$ ms. By Eq. (33.10), the optimal value of $TTRT$ is 5 ms. The curve clearly indicates that at $TTRT = 5$ ms, the worst-case achievable utilization is maximized. Similar observations can be made for the other cases.
2. As indicated in Eq. (33.10), the optimal $TTRT$ is a function of D_{\min} . This coincides with the expectations from the observations of Fig. 33.3. A general trend is that as D_{\min} increases, the optimal $TTRT$ increases. For example, the optimal values of $TTRT$ are approximately 2.5 ms for $D_{\min} = 10$ ms, 4 ms for $D_{\min} = 20$ ms, 5 ms for $D_{\min} = 40$ ms, and 6.67 ms for $D_{\min} = 80$ ms.
3. The choice of $TTRT$ has a large effect on the worst-case achievable utilization U^* . Consider the case of $D_{\min} = 40$ ms shown in Fig. 33.4. If $TTRT$ is too small (say, $TTRT = 2$ ms), U^* can be as low as 45%. If $TTRT$ is too large (say, $TTRT = 15$ ms), U^* can be as low as 31%.

However, when the optimal value of $TTRT$ is used (i.e., $TTRT = 5$ ms), U^* is 62%. This is an improvement of 17% and 31%, respectively, over the previous two cases.

FIGURE 33.5 U^* vs. D_{\min} with optimal $TTRT$.

The effect of choosing an optimal value for $TTRT$ is also shown in Fig. 33.5. Figure 33.5 shows the worst-case achievable utilization vs. D_{\min} when an optimal value of $TTRT$ is used. For ease of comparison, the earlier results of Fig. 33.3 are also shown in Fig. 33.5.

Buffer Requirements

Messages in a network can be lost if there is insufficient buffer space at either the sending or the receiving node. To avoid such message loss, we need to study the buffer space requirements.

There are two buffers for synchronous messages on each node. One buffer is for messages waiting to be transmitted to other nodes and is called the *send buffer*. The other buffer is for messages that have been received from other nodes and are waiting to be processed by the host. This buffer is called the *receive buffer*.

We consider the send buffer first.

- Case of $D_i \leq P_i$. In this case, a message must be transmitted within the period in which it arrives. At most, one message will be waiting. Hence, the send buffer need only accommodate one message.
- Case of $D_i > P_i$. In this case, a message may wait as long as D_i time without violating its deadline constraint. At node i , messages from stream S_i arrive every P_i time, requesting transmission. During the D_i time following the arrival of a message, there will be further $\lfloor \frac{D_i}{P_i} \rfloor$ message arrivals. Thus, the send buffer may potentially have to accommodate $\lfloor \frac{D_i}{P_i} \rfloor + 1$ messages. When the deadline is very large (tens or hundreds times larger than the period, for example, which can occur in voice transmission), this might become a problem in practice due to excessive buffer requirements.

However, when the synchronous bandwidths are allocated as in Eq. (33.8), the impact of D_i on required buffer size is limited: it can be shown that if Eq. (33.8) is used, the waiting time of a message from stream S_i is bounded by $\min(D_i, P_i + 2TTRT)$ [Malcolm, 1994]. Thus, the maximum number of messages from S_i that could be queued at node i is no more than $\lfloor \frac{\min(D_i, P_i + 2TTRT)}{P_i} \rfloor$. This allows us to reduce the required size of the send buffer. Let BS_i denote the send buffer size at node i . The send buffer will never overflow if

$$BS_i \geq \left\lceil \frac{\min(D_i, P_i + 2TTRT)}{P_i} \right\rceil B_i \quad (33.11)$$

where B_i is the number of bytes in a message of stream S_i .

An interesting observation is that if $D_i \geq P_i + 2TTRT$, then

$$BS_i \geq \left\lceil \frac{P_i + 2TTRT}{P_i} \right\rceil B_i \quad (33.12)$$

That is, the send buffer requirements for stream S_i are independent of the deadline D_i . As mentioned earlier, one would expect that increasing the deadline of a stream could result in increased buffer requirements. When the scheme in Eq. (33.8) is used, however, the buffer requirements are not affected by increasing the deadline once the deadline reaches certain point.

Now let us consider the receive buffer size. Suppose that node j is the destination node of messages from nodes j_1, \dots, j_k . This means that messages from streams S_{j_1}, \dots, S_{j_k} are being sent to node j . The size of the receive buffer at node j depends not only on the message traffic from these streams but also on the speed at which the host of node j is able to process incoming messages from other nodes. The host at node j has to be able to keep pace with the incoming messages, otherwise the receive buffer at node j can overflow. When a message from stream S_{j_i} arrives at node j , we assume that the host at node j can process the message within P_{j_i} time.

Assuming that the host is fast enough, then it can be shown that the number of messages from S_{j_i} that could be queued at the destination node is bounded by $\left\lceil \frac{\min(D_{j_i}, P_i + 2TTRT)}{P_{j_i}} \right\rceil + 1$. With this bound, we can derive the space requirements for the receive buffer at node j . Let BR_j denote the receive buffer size at node j . The receive buffer will never overflow if

$$BR_j \geq \sum_{i=1}^k \left\lceil \frac{\min(D_{j_i}, P_i + 2TTRT)}{P_{j_i}} + 1 \right\rceil B_{j_i} \quad (33.13)$$

As in the case of the send buffer, we can observe from Eq. (33.13) that if the deadlines are large, the required size of the receive buffer will not grow as the deadlines increase.

33.5 Final Remarks

In this chapter, we introduced the architecture of FDDI and discussed its fault-tolerant capability. We presented a methodology for the use of FDDI networks for real-time applications. In particular, we considered methods of selecting the network parameters and of schedulability testing. The parameter selection methods are compatible with current standards. The synchronous bandwidth allocation method has the advantage of only using information local to a node. This means that modifications in the characteristics of synchronous message streams, or the creation of new synchronous message streams, can be handled locally without reinitializing the network. Schedulability tests that determine whether the time constraints of messages will be met were presented. They are simple to implement and computationally efficient.

The materials presented in this chapter complement much of the published work on FDDI. Since the early 1980s, extensive research has been done on the timed token protocol and its use in FDDI networks [Albert and Jayasumana, 1994; Jain, 1994; Mills, 1995; Shah and Ramakrishnan, 1994]. The papers by Ross [1989], Iyer and Joshi [1985], and others [Mccool, 1988; Southard, 1988; Stallings, 1987] provided comprehensive discussions on the timed token protocol and its use in FDDI. Ulm [1982] discussed the protocol performance with respect to parameters such as the channel capacity, the network cable length, and the number of stations. Dykeman and Bux [1988] developed a procedure for estimating the maximum total throughput of asynchronous messages when using single and multiple asynchronous priority levels. The analysis done by Pang and Tobagi [1989] gives insight into the relationship between the bandwidth allocated to each class of traffic and the timing parameters. Valenzo, Montuschi, and Ciminiera [1990] concentrated on the asynchronous throughput and the average token rotation time when the asynchronous

traffic is heavy. The performance of the timed token ring depends on both the network load and the system parameters. A study of FDDI by Jain [1991] suggests that a value of 8 ms for *TTRT* is desirable as it can achieve 80% utilization on all configurations and results in around 100 ms maximum access delay on typical rings. Further studies have been carried out by Sankar and Yang [1989] to consider the influence of the target token rotation time on the performance of varying FDDI ring configurations.

34.1 Introduction

The local area network (LAN) became a permanent fixture of the computer world during the 1980s, having achieved penetration primarily in the form of the Institute of Electrical and Electronics Engineers (IEEE) 802.3 ethernet* LAN. Thereafter, other types of LANs, such as the IEEE 802.5 token ring and the American National Standards Institute (ANSI) X3T9.5 fiber distributed data interface (FDDI), also established themselves as lesser—though potent—players. These LANs now form the dominant communications infrastructures that connect computers and related devices within individual enterprises. They provide the transmission substrate for common services such as file transfer, network file services, network window service, electronic mail, hypertext transfer, and others.

The installed base of ethernet, token ring, and FDDI LANs consists fundamentally of shared-media broadcast networks in which each node's transmission may be heard by all other nodes on the LAN. In any such **shared-media** LAN, a **media-access control protocol** must be provided to coordinate the different nodes' transmissions, lest they interfere adversely with one another. The most serious drawback of shared-media LANs is that, as more nodes are added, each node receives a proportionally smaller share of the media's bandwidth. The bandwidth of the media is, therefore, a limiting resource. This inability to scale up to meet increased demands for bandwidth makes shared-media LANs inherently unsuitable for new classes of communications services, such as the transmission of high-resolution image and video data. Furthermore, the nature of their media-access control protocols, which can introduce substantial and variable delays into transmissions, often makes shared-media LANs unable to meet the tight **latency** and **jitter** requirements of real-time video and audio transmission.

To address the problems of bandwidth scalability and real-time transmission, a new type of LAN, called the **broadband local area network (BLAN)**, has been steadily taking root. BLANs are designed to accommodate increases in traffic demand by modular expansion. They are also capable of dedicating a set amount

*Originally, ethernet referred to a specific product offering, whereas the IEEE 802.3 LAN was formally known as the carrier sense multiple access with collision detection LAN. The two LANs differ minutely, and henceforth we consider them to be the same.

of bandwidth to a requesting application, guaranteeing that the latency of the application's transmissions is bounded and unvarying, if required. The BLAN will thus carry integrated traffic, comprising data, voice, and video. In this respect, the BLAN is a local manifestation of the **broadband integrated services digital network (BISDN)**, which is intended for deployment in the global telecommunications system. The common ground of the BLAN and the BISDN is their reliance on **asynchronous transfer mode (ATM)**. Special considerations, however, distinguish the BLAN from the BISDN, including different cost structures, the need to support different services, and different approaches to network management and security.

This chapter will describe the common approaches to BLANs, including discussion of the major requirements and the hardware and software technologies essential to their operation. The central role of ATM networks in BLANs as well as other less well-known network technologies, will be covered. The protocols used in BLANs themselves will also be discussed. Finally, some of the new applications being enabled by BLANs will be presented.

34.2 User Requirements

BLAN users expect to run network-based applications that require services not provided by conventional LANs. These requirements include bandwidth scalability, integrated support for different traffic classes, multicasting, error recovery, manageability, and security.

To meet the increased demand for bandwidth that accompanies the addition of new nodes and the replacement of old nodes by more-capable equipment, bandwidth scalability in shared-media LANs has been achieved by segmenting users into distinct **collision domains**, which are interconnected by bridges and routers so that intrasegment traffic is filtered out before leaving its originating domain, and intersegment traffic is forwarded to its destination. This approach is, however, not truly scalable, and the resulting web of LANs becomes fundamentally unmanageable. To overcome this difficulty, packet switches replace the collision domains, and each node is connected to its switch by a dedicated link. Growth of the network is then accomplished by adding switches or selectively replacing the interfaces between switches and nodes with higher speed interfaces.

Network traffic is traditionally divided into three classes: **isochronous**, **synchronous**, and **asynchronous** traffic. Isochronous traffic flows at a constant rate and has a strict timing relationship between any consecutively transmitted units of data. An example is periodically sampled fixed-size data blocks such as one would encounter in the transmission of a video frame buffer every 1/30 of a second. Synchronous traffic flows at a variable rate and has a loose timing relationship between consecutively transmitted units of data. An example is the transmission of a compressed video frame buffer every 1/30 of a second. Asynchronous traffic flows at a variable rate but has no definite timing relationship among its data units. An example is file transfer. Although all conventional LANs provide support for asynchronous traffic, few support synchronous traffic. Support for isochronous traffic is not common in conventional LANs. Currently, only BLANs support all three classes of traffic.

Users who desire to run video applications will use a BLAN that supports **multicasting**, a generalization of broadcasting in which a sender may transmit the same message to a number of different receivers without sending multiple copies. Easily supported in shared-media LANs, this capability must be designed in to switch-based networks. Multicasting is not only used in disseminating video broadcasts, but has become entrenched into the way that shared-media LANs operate, for example, in registering addresses. Thus, it must be supported in BLANs to accommodate legacy protocols.

As components of a complex system—such as a BLAN—fail, the system should continue to provide service with a minimum of interruption. Having assumed the responsibility for transporting nearly all of the traffic in an enterprise, the BLAN of necessity must be robust enough to provide continuous service even in the face of failures. Given that a BLAN can fail in many different ways, it is essential that error-recovery procedures are integrated into its design. The BLAN must detect transmission errors and notify the system administrator of them. Failures of resource (e.g., a switch or link) must also be recognized and bypassed. Since failures or oversubscription can cause congestion, there must be the means to recognize and clear congestion from the network.

Owned and operated by a single enterprise, the BLAN usually falls under the responsibility of a specialized department charged with its management. It is often necessary to track all resources within the BLAN so that the network manager knows the precise disposition of all equipment at any given time. Each resource also must be monitored continuously to assess its level of performance. Resources also are controlled and configured by the network manager. For the convenience of the network manager, these functions are normally concentrated in a network-management platform. The dynamically changing state of all resources within the BLAN is referred to as the **management information base (MIB)**, which may be viewed as a readable and writable distributed database through which the network is monitored and controlled. User information may be extracted from the MIB in order to produce usage and billing information.

Although the BLAN resides within the relatively friendly confines of an enterprise, external and internal attacks on the BLAN's computers are a threat that cannot be ignored. External attacks on a BLAN connected to a larger public network are effectively controlled by use of a network firewall, which bars unauthorized outside access to the enterprise's computers. Because sensitive information might have to be denied to internal users, it is also necessary to provide for privacy within some BLANs. Techniques for encrypting stored or transmitted data and for providing access controls are then required. To enhance security further, it also could be necessary to provide intrusion-detection software, which passively monitors BLAN resources for internal and external attacks.

34.3 BLAN Technologies

The spread of BLANs has been promoted by technological advances on several fronts. Fast packet switching has been one of the enabling technologies. So, too, has been high-speed transmission technology. Other important software technologies in BLANs are routing, signalling, and network management.

Packet switching networks are composed of switching nodes connected by links. The switches forward input packets to the appropriate output links after reading the packets' header information and possibly buffering packets temporarily to resolve contention for common output links. The move to packet switching LANs was motivated by the realization that shared-media LANs do not scale, because the total throughput of all nodes can never exceed the bandwidth of the media. Similarly, latency and jitter grow as nodes are added to a shared-media LAN because the media-access control protocol tends to perform like a single-server queueing system, in which the mean and variance of delay increase as the server's workload increases. Switching plays a key role in BLANs because a **mesh topology**, which consists of switches connected by links, is necessary to overcome the bandwidth bottleneck of the shared-media LAN, as illustrated in Fig. 34.1. In the shared-media LAN only one node at a time can transmit

FIGURE 34.1 The mesh-topology LAN provides higher bandwidth and supports more nodes than the shared-media LAN.

FIGURE 34.2 Packet switch architectures.

information, but in the mesh-topology LAN several nodes can transmit information simultaneously. The result is a dramatic increase in the throughput of the mesh-topology LAN, compared to the shared-media LAN. If one can build a packet switch with a sufficient number of input/output ports, then a mesh network may be easily expanded by adding new nodes, switches, and links without significantly reducing the amount of bandwidth that is available to other nodes. It is also true that latency and jitter in a mesh topology may be kept low, since the capacity of the network is an increasing function of the number of nodes.

Paced by advances in integrated circuits, switch technology has progressed rapidly. Packet switching fabrics based on high-speed backplane buses, shared memory, or multistage interconnection networks (MINs), such as delta, omega, shuffle-exchange, or Clos networks [Tobagi, 1990], can be constructed to switch pre-established connections with a throughput of several gigabits per second. Examples of each of these switch architectures are shown in Fig. 34.2. To increase switch throughput, buses may be replicated and shared memories interleaved. Although backplane-bus fabrics cannot switch more than a few dozen input and output ports, because the electrical limits on bus length restrict the number of modules that may be attached, two-by-two switching elements can be combined in very deep configurations to implement MINs with arbitrary numbers of input and output ports. Switch latency can be reduced by the use of cut-through routing, which permits the head of a packet to emerge from the switch before its tail has even entered the switch. This is especially beneficial for long packets, but the switch design is more complex and special facilities must often be added to prevent deadlock. Bus-based switching fabrics support multicasting easily. MIN-based switching fabrics have also been implemented to support multicasting by forking copies of a packet at various stages or using a separate copy network [Turner, 1987]. Today's nonblocking, output-queued MIN-based fabrics can achieve very low latency and high throughput [Hluchyj and Karol, 1988].

High-performance microprocessors—increasingly with reduced instruction set computer architectures—often form an integral part of switch and interface architectures. These provide necessary decision-making and housekeeping functions such as routing-table maintenance and call processing. They also may be used for such functions as segmenting messages into smaller transmission units at the sender and then reassembling the message at the receiver. Such segmentation and reassembly functions are sometimes performed by special-purpose hardware under the control of the microprocessor. High-speed random-access and first-in-first-out memories are also critical for storage and packet buffering.

Examples of chipsets that support high-speed switching are found in Denzel, Engbersen, and Iliadis [1995] and Collivignarelli et al. [1994]. Supporting chipsets are generally implemented as complementary metal-oxide-semiconductor devices. As higher switching and transmission speeds are needed, however, it is expected that supporting chipsets will be implemented as gallium arsenide or bipolar devices, which operate in a much faster regime.

Hand in hand with fast packet switching technology comes high-speed transmission technology. The enabling technology in this area has been optical fiber technology, which can achieve link speeds of several gigabits per second. The principal transmission technology for BLANs is multimode optical fibers (MOFs). Using infrared signals with a 1.3- μm wavelength, BLANs can achieve data rates of more than

100 Mb/s over distances of up to 2000 m. Transmitters are usually light-emitting diodes, receivers are photodiodes, and fibers are 125- μm cladding/62.5- μm core multimode silica fibers. To transmit over greater distances or at higher data rates, 100- μm cladding/9- μm core single-mode silica fibers are used with 1.3- or 1.5- μm wavelength laser-diode transmitters. Because LANs are of limited geographical reach, single-mode optical fibers can carry information at rates of several gigabits per second without the need for optical amplification or regeneration. Optical fiber BLAN links typically operate with direct direction and return-to-zero, 4B/5B, or 8B/10B encoding ($n\text{B}/m\text{B}$ denotes a scheme in which n data bits are encoded as m transmission bits). Error-detecting or -correcting codes are used sparingly because the transmission quality is normally very high.

The relatively high cost of optical systems and the installed base of metallic-wire systems make the use of inexpensive metallic-wire media very desirable. Most conventional LANs now use category-3 twisted-pair 24-gauge insulated wires, deployed in a manner similar to telephone wires. By upgrading to category-5 wires or using multiple category-3 wires, it is possible to transmit data at rates up to 155 Mb/s. BLANs are beginning to use category-5 twisted-pair wires for transmission at data rates greater than 100 Mb/s. This is especially attractive for linking office or laboratory equipment to telecommunications closets, which are designed to be situated no more than 100 m away from their users. Switches located inside distinct telecommunications closets are then usually connected to each other by means of optical fibers, which enjoy a greater geographical span and lower error rates than electronic links. To reduce electromagnetic interference, it is sometimes necessary to scramble high-speed data traveling over twisted-pair wires. Higher data rates can be achieved more easily by shielding wires to reduce crosstalk and electromagnetic emission. However, unshielded twisted-pair wires are desirable for BLANs because they are compatible with the type of wire used to connect desktop telephones to telecommunications closet equipment.

LANs, being complex systems, require substantial software to operate properly. This is even more true of BLANs, which require more sophisticated control to support all features of conventional LANs, as well as traffic integration. Common software technologies for BLANs include routing, signalling, and network management. Routing implies the ability to discover paths to a destination, signalling the ability to reserve resources along the best path, and network management implies the ability to monitor and control the state of those resources.

Wireless and mobile technologies are on the verge of being introduced into BLANs, but prototypes have yet to appear.

34.4 ATM BLANs

ATM occupies the dominant position among BLANs. Originally conceived as a method for transferring information over the public telecommunications network, ATM was quickly accepted as a way to provide high bandwidth within the premises of a private enterprise. Vendors arose to provide ATM products specialized for LAN use. This includes inexpensive switches, computer-interface cards, and software.

A factor that militates against the spread of ATM BLANs is the incomplete state of ATM standardization. ATM standards are officially under the aegis of the International Telecommunications Union—Telecommunications Standardization Sector (ITU-T). The overall framework of BISDN falls within the ITU's purview. The ATM Forum, a large consortium of organizations whose purpose is to accelerate the acceptance of ATM networking by producing agreements among its members on how to implement specific standards, augments the contributions of the ITU-T. The ATM Forum has defined many of the physical- and link-layer standards for ATM, including 100/140-Mb/s transparent asynchronous transceiver interface (TAXI) and 25-Mb/s Desktop 25 link protocols, which operate on MOFs and twisted pairs, respectively. The Internet Engineering Task Force (IETF) also plays a role in ATM BLANs by its consideration of how to integrate ATM into the Internet protocol suite. It produced the standard for running the classical internet protocol (IP) over ATM.

ATM is a **connection-oriented protocol**, in which a caller requests to exchange data with a recipient. The network is responsible for finding the route and reserving any resources needed to complete the exchange.

Once the call has been established, each hop of the call is associated with a virtual path identifier/virtual circuit identifier (VPI/VCI). The VPI/VCI has only local significance at switches or interfaces and is used to map an incoming cell (the 53-octet [an octet equals 8 bits] fixed-length ATM packet) to its output port. The connection guarantees a specific **quality of service** (QOS), which specifies a contract between the network and the user that the network will satisfy the bandwidth, delay, and jitter requirements of the user provided that the user's traffic meets the constraints of the contract. Several QOS classes may be specified:

- Constant bit rate (CBR), which supports isochronous traffic
- Variable bit rate/real time (VBR/RT), which supports synchronous traffic
- Variable bit rate/nonreal time (VBR/NRT), which supports asynchronous traffic that requires a minimum bandwidth guarantee
- Available bit rate (ABR), which supports asynchronous traffic with no QOS guarantees (best effort) but increases and reduces bandwidth according to competing demands of other connections
- Unspecified bit rate (UBR), which supports asynchronous traffic but possibly also drops cells

ABR and UBR correspond most closely to the QOS provided by existing LANs. CBR will be needed to carry uncompressed video, whereas VBRRT will be used to carry compressed video.

An important consideration is to be able to coexist with existing software packages. For IP-based networks, this largely means supporting applications that have been written using the UNIX sockets application program interface. This type of BLAN uses the classical-IP-over-ATM approach defined by the IETF. For other networks, such as those based on Novell Netware or AppleTalk protocols, the answer is to use the LAN emulation (LANE) standard developed by the ATM forum. Both of these approaches attempt to hide from the application the fact that its underlying network is a connection-oriented ATM BLAN rather than a connectionless ethernet or token ring shared-media LAN. One of the central difficulties in achieving this is that ATM must mimic the broadcasting that is used by the older LANs.

ATM BLANs may use a variety of media. Currently, the most popular media are optical fibers, but unshielded twisted pair (UTP) is fast becoming the media of choice for ATM desktop connection. MOFs frequently use the synchronous digital hierarchy (SDH) to carry synchronous transport signal (STS) level-3 concatenated (STS-3c) frames, which consist of 2430 octets sent every 125 μ s for an overall transmission rate of 155.5 Mb/s. In the U.S., SDH is known as synchronous optical network (SONET) and SDH-3c is known as optical carrier level 3 concatenated (OC-3c). The maximum reach of a segment must be less than 2000 m. STS-3c may also be used with UTP, but the maximum reach of a segment is only 100 m.

Many ATM BLAN devices were based on the TAXI standard, a 100-Mb/s MOF interface with 4B/5B encoding that was made popular by the FDDI standard. The appeal of TAXI for ATM reflected the fact that several TAXI chipsets were available at the time of initial ATM BLAN introduction. Also used were 140-Mb/s TAXI devices. The TAXI devices, however, have rapidly been supplanted by SDH devices because of their more universal appeal.

A host of other physical interfaces have been defined for ATM BLANs. These include the Fibre Channel—compatible 155.5-Mb/s MOF and shielded twisted-pair interfaces with 8B/10B encoding. The STS-1/2 interface—also known as Desktop 25—is a 25.9-Mb/s category-3 UTP interface. An STS-1 UTP interface operates at 51.8 Mb/s. None of these interfaces is widely used in BLANs at this time.

Two principal types of ATM BLAN interfaces are the **private user-network interface** (PUNI) and the **private network–node interface** (PNNI), where private designates that the interfaces do not impinge on public networks. The PUNI is an interface between user equipment and BLAN switches, whereas the PNNI is an interface between BLAN switches. Each type of interface has a protocol associated with it to implement signalling, routing, connection admission control, traffic shaping, traffic policing, and congestion control. These protocols use reserved VCIs to communicate among peers.

Because of their popularity, a great deal of effort has gone into developing special protocols for ATM BLANs. As most networks use IP, the classical-IP-over-ATM protocol was designed to permit connectionless IP to establish a new ATM virtual connection or bind to an existing one by means of an address

resolution protocol similar to that used in shared-media LANs. To support multicasting, the ATM forum has also defined leaf-initiated join protocols that allow point-to-multipoint multicast trees to be grown from the destination leaves to the source root; this is important for LANE operations, which rely heavily on multicasting. Security is also an important concern for BLAN administrators, and the U.S. government-sponsored Fastlane device allows key-agile end-to-end encryption and decryption of cells on a virtual-connection-by-virtual-connection basis [Stevenson, 1995].

34.5 Other BLANs

Although ATM offers the most capable and widely deployed approach to implementing BLANs, several other approaches are available. These approaches are IEEE 802.3 ethernet, IEEE 802.9 isochronous ethernet, and IEEE 802.12 100VG-AnyLAN.

Given ethernet's popularity, it is not surprising that there should be ethernet-based BLANs. Ethernet originally was designed to use the carrier sense multiple access with collision detection protocol, which allows a node to share a LAN segment with other nodes by transmitting only when the medium is inactive and randomly deferring transmission in the event of a collision (simultaneous transmission by two or more nodes). The inefficiency and nondeterminism that accompany this protocol can be partially overcome by partitioning the LAN so that each node resides on its own dedicated segment. The simplest ethernet BLAN consists of 10-Mb/s IEEE 802.3 10BaseT dedicated links connecting nodes to switching hubs. Using ethernet in this way, one can implement a BLAN that delivers 10 Mb/s of bandwidth directly to each user if the switch has adequate packet buffers and the user interface can keep up. Although they provide no mechanisms for supporting specific levels of QOS, such switched ethernets are able to support high and scalable throughput. Nevertheless, the need of some applications for more than 10 Mb/s of bandwidth justifies the same switched-ethernet approach but with 100-Mb/s IEEE 802.3 links. The IEEE 802.3 100-Mb/s ethernet (sometimes called fast ethernet) is virtually identical to the 10-Mb/s standard, except that the data rate has been increased tenfold and almost all time constants have been decimated. User nodes are attached to switching or nonswitching hubs (the latter of which merely acts as a shared medium) either by UTPs or MOFs. The 100BaseTX option uses two category-5 UTPs with 4B/5B encoding, the 100BaseT4 option uses four category-3 UTPs with 8B/6T encoding (which encodes 8 b as six ternary digits), and the 100BaseFX option uses two MOFs with 4B/5B encoding. Moreover, all of these options (including 10BaseT) may be mixed in a single switching hub. Fast ethernet is rapidly gaining wide acceptance, and several vendors supply ethernet and fast ethernet BLAN equipment.

A drawback of using switched ethernet for a BLAN is that there is no explicit support for isochronous traffic. Isochronous ethernet (isoethernet), as defined by IEEE 802.9, overcomes those drawbacks. Isoethernet maintains compatibility with the 10BaseT wiring infrastructure and interoperates with 10BaseT at the hub level. Isoethernet multiplexes onto a category-3 UTP a 10-Mb/s ethernet and a 6.14-Mb/s ISDN stream. Using 4B/5B encoding, these streams are mapped into a 125- μ s frame, which dedicates specific quartet (a quartet equals 4 bit) positions of the frame to ethernet or ISDN traffic. The ethernet subframe is subject to the usual collision-backoff-retransmit cycle, but the ISDN subframe can be allocated to several CBR connections, which have a fundamental frequency of 8000 Hz. Its signalling protocol is similar to ATM's. The isoethernet BLAN has not yet been widely deployed.

The IEEE 802.12 100VG-AnyLAN standard is designed to be run over voice-grade (hence, VG) wiring infrastructure. It uses four category-3 bidirectional UTPs to connect user nodes to repeaters, which may be cascaded in a tree configuration. Repeaters poll user nodes for transmission requests, which are granted in a round-robin discipline. Transmissions are not restricted to any single protocol (hence, AnyLAN) and can, therefore, support traffic integration. Transmission requests have either a low or high priority, with high-priority requests pre-empting those of lower priority. The 100VG-AnyLAN BLAN has not been widely deployed.

The complete replacement of a legacy LAN being impractical, it is not uncommon to build a BLAN with a mix of technologies. A backbone ATM network is frequently the point of access for 802.3 LANs,

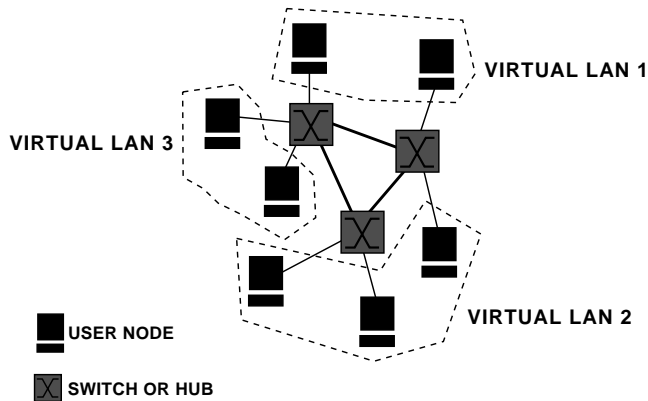

FIGURE 34.3 Virtual LANs.

which can provide from 10 to 100 Mb/s bandwidth to the desktop. User nodes that have higher bandwidth requirements or need a specific QoS may be attached directly to the ATM backbone. The attachment equipment in the backbone—called an edge device—provides ATM and other BLAN interfaces. Working together, these edge devices have the capability to form virtual LANs (VLANs) of nodes logically joined regardless of their physical locations, as shown in Fig. 34.3. Each VLAN forms a unique broadcast domain, in which broadcasts of a node in the VLAN are forwarded to all other members of the VLAN but prevented from propagating to nonmembers. In principle, VLANs should simplify BLAN administration and enhance security and performance. The edge devices and the configurations of VLANs that they support may be managed through MIB variables specially designed to manipulate VLANs. VLAN creation by address, by attachment port, or by several other attributes is currently supported.

34.6 New Applications

Conventional LANs are used principally for a narrow range of client–server applications. BLANs open the door to new computing applications.

Multimedia computing, which processes data, video, image, and audio, is the driving application area for BLANs. The local distribution of video to computer users requires the bandwidth and QoS of a BLAN. With the use of corporate video servers growing, it is essential to have a BLAN that can transport several simultaneous video streams. Such servers are commonly used in training and film production. Other applications include videoconferencing, with workstation-based frame grabbers, cameras, microphones, and electronic whiteboards.

The success of hypermedia browsers, especially those based on the hypertext transport protocol (HTTP), has given rise to the phenomenon of intranetworking, in which enterprises use HTTP to share data among members. As HTTP browsers embrace more functions such as audio, animation, video, and image transfer, the need for higher bandwidth LANs grows. Given the unparalleled traffic growth on the Internet that resulted from HTTP usage, it is reasonable to expect an intranet to experience similar growth. Deployment of BLANs within these intranets thus becomes imperative.

Today, most enterprise LANs are collections of segmented collision domains interconnected by bridges and hubs. A cost-effective strategy for expanding a LAN is to use an ATM BLAN as the backbone. In this manner, existing LANs can be attached to the ATM backbone and power users can also be attached as the need arises. The use of VLAN technology and edge devices just described makes it relatively simple to link existing LANs through an ATM BLAN.

Coupled with high-performance workstations, BLANs make it possible to approximate the power of special-purpose supercomputers for a small fraction of the cost. Needing high throughput and low latency between communicating processes, parallel–distributed computations of hundreds of processes can tax

conventional LANs. The use of networks of workstations (NOWs) to perform tasks formerly delegated to expensive supercomputers demands the power of a BLAN. Experimental NOWs based on ATM BLANs are proving the effectiveness of this approach.

34.7 Conclusion

Although still in its infancy, the BLAN is gaining wide acceptance for upgrading legacy LANs and enabling new applications that require a range of QOS. A wide variety of technologies is used to implement the BLAN, including high-speed integrated circuits, electronic and optical links, and high-level protocol software. By providing guaranteed bandwidth on demand, BLANs enable the integration of different classes of traffic in a single network. This, in turn, makes possible a host of new applications, such as video servers, image servers, hypermedia browsing, and parallel-distributed computing.

ATM has taken the early lead in the race to become the leading BLAN technology. Strong contenders, however, are fast ethernet, isoethernet, and 100BaseVG-AnyLAN. Moreover, these different technologies are often mixed together in edge switches to realize hybridized BLANs.

Although much of the hardware technology behind the BLAN is relatively mature, the complex software-based protocols needed to support broadband applications are only partially complete. Advances in signalling, QOS management, resource reservation, and internetworking must continue before BLANs become permanently established.

Defining Terms

Asynchronous traffic: Traffic with no particular timing relationship between successive transmission units.

Asynchronous transfer mode: A broadband network technology based on fast cell switching.

Broadband integrated services digital network: The cell-relay based technology upon which the next-generation telecommunications infrastructure is to be based.

Broadband local area network: A high-speed LAN that carries integrated traffic.

Collision domains: A group of nodes that share a single broadcast medium.

Connection-oriented protocol: A protocol that must establish a logical association between two communicating peers before exchanging information and then release the association after the exchange is complete.

Desktop 25: A low-speed (25-Mb/s) link protocol for use in desktop ATM networks.

Isochronous traffic: Constant-rate traffic in which successive transmission units have a strictly fixed timing relationship.

Jitter: The amount of variation in the time between successive arrivals of transmission units of a data stream.

Latency: The delay from transmission of a packet by the source until its reception by the destination.

Management information base: The collection of a network's parameters monitored and controlled by a network management system.

Media-access control protocol: The link-layer protocol in a shared-media LAN that guarantees fair and orderly access to the media by nodes with packets to transmit.

Mesh topology: An arrangement of packet switches connected by dedicated links.

Multicasting: Transmitting a packet within a network so that it will be received by a specified group of nodes.

Quality of service: The bandwidth, latency, and error characteristics provided by a network to a group of users.

Shared-media topology: Refers to a network in which any transmission is heard by all nodes.

Synchronous traffic: Variable-rate traffic in which successive transmission must be delivered within a specific deadline.

Transparent asynchronous transceiver interface: A 100-Mb/s link protocol originally developed for FDDI and later adopted for use in ATM networks.

Virtual path/circuit identifier: A pair of designators in an ATM cell which uniquely identifies within a switch the logical connection to which the cell belongs.

35.1 Introduction

Modern computer communications networks, particularly local area networks (LANs) and metropolitan area networks (MANs), employ multiple access communications methods to share their communications resources. A **multiple-access** communications channel is a network system whose communications media are shared among distributed stations (terminals, computers, users). The stations are distributed in the sense that there exists no relatively low-cost and low-delay mechanism for a single controlling station to gain access to the status of all stations. If such a mechanism exists, the resulting sharing mechanism is identified as a **multiplexing system**.

The procedure used to share a multiple access communications medium is the **multiple access algorithm**. The latter provides for the control, coordination, and supervision of the sharing of the system's communications resources among the distributed stations, which transport information across the underlying multiple access communications network system.

In the following, we present a categorization of the various medium access control (MAC) methods employed for the sharing of multiple access communications channel systems. We demonstrate these schemes by considering applications to many different classes of computer communication networks, including wired and wireless local and metropolitan area networks, satellite communications networks, and local area optical communications networks.

35.2 Features of Medium Access Control Systems

Typically employed topologies for shared-medium communications networks are shown in Fig. 35.1 and are characterized as follows [Rubin and Baker, 1990].

A *star* topology, under which each station can directly access a single central node, is shown in Fig. 35.1(a). A switching star network results when the star node provides store and forward buffering and switching functions, whereas a broadcast star network involves the employment of the star node as an unbuffered repeater, which reflects all of the incoming signals into all outgoing links. A wired star configuration is shown in Fig. 35.1(a1). In Fig. 35.1(a2), we show a wireless cell which employs radio channels for the mobile terminals to communicate with a central base station. The terminals use a multiple access algorithm

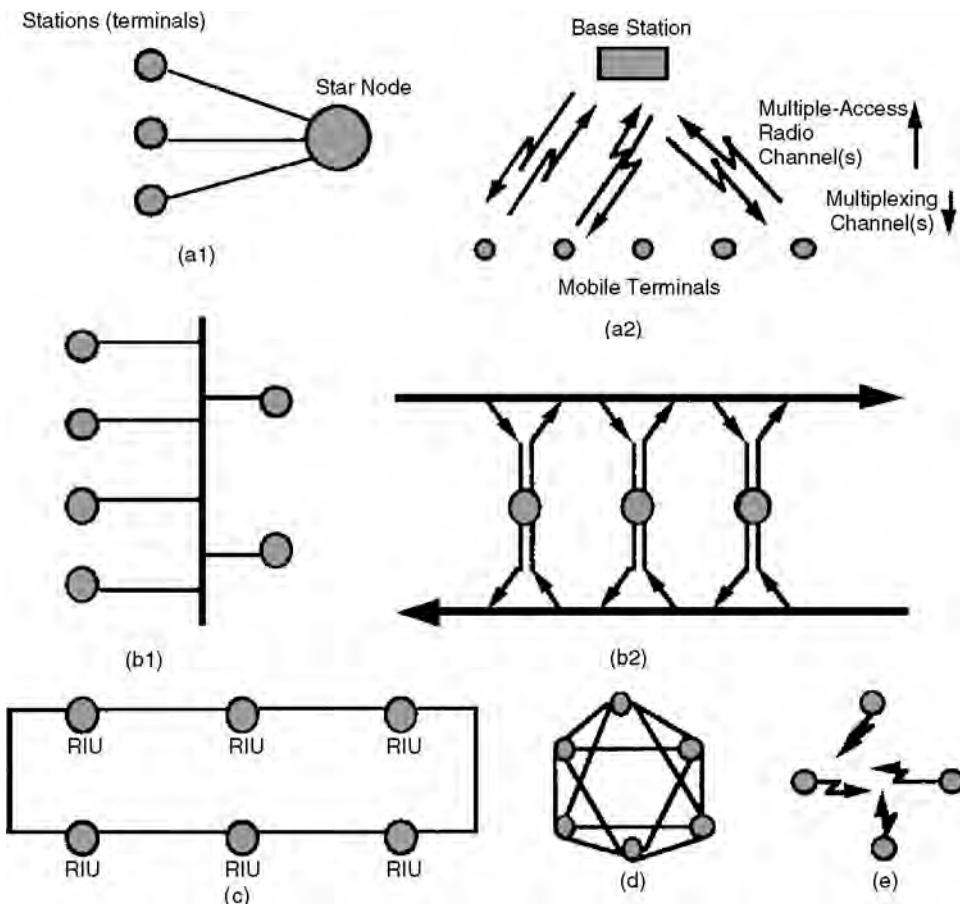

FIGURE 35.1 Multiple-access network topologies: (a) star, (b) bus, (c) ring, (d) mesh, and (e) broadcast radio net.

to gain access to the shared (mobile to base station, reverse access) radio channel(s), whereas the base-station employs a multiplexing scheme for the transmission of its messages to the mobile terminals across the (base-station to terminals, forward access) communications channels.

A *bus* topology, under which stations are connected to a bus backbone channel, is shown in Fig. 35.1(b). Under a logical bus topology, each station's message transmissions are broadcast to all network stations. Under a physical bus implementation, the station is passively connected to the bus, so that a station's failure does not interfere with the operation of the bus network. The station is then able to sense and receive all transmissions that cross its interface with the bus; however, it is not able to strip information off the bus or to properly overwrite information passed along the bus; it can transmit its own messages across the bus when assigned to do so by the employed MAC protocol.

It is noted that when fiber links are used, due to the unidirectional nature of the channel, to achieve full station-to-station connectivity, a bus network implementation necessitates the use of two buses. As depicted in Fig. 35.1(b2), a common approach is to employ two separate counterdirectional buses. Stations can then access each fiber bus through the use of a proper read (sense) tap followed by a write tap.

A *ring* topology, under which the stations are connected by point-to-point links in, typically, a closed-loop topology, is shown in Fig. 35.1(c). In a physical ring network implementation, each station connects to the ring through an active interface, so that transmissions across the ring pass through and are delayed in the register of the ring interface units (RIUs) they traverse. To increase network reliability, such implementations include special circuits for ensuring a rapid elimination of a failed RIU, to prevent such a failure from leading to a prolonged overall network failure. Because of the use of an active interface, the station is now able to strip characters or messages it receives off the medium, as well as to overwrite onto symbols and messages transmitted across the medium, when the latter pass its interface.

An active interface into the medium further enables the station to amplify the signals it passes along, thus leading to considerable reduction of the insertion loss. This is of particular importance in interfacing a fiber optic medium, whereby a passive interface causes a distinct insertion loss, thus leading to a significant limitation in the number of stations that can be passively connected to a fiber bus, without the incorporation of optical amplifiers.

For fiber optic links, electrical amplification and MAC processing at the active interface involve double conversion: optical-to-electronic of the received signal and electronic-to-optical of the amplified transmitted signal. As a result, the station's access burst rate needs to be selected so that it is compatible with the electronics processing rate at the station interface, so that no rate mismatch exists at the electronics/optics interfaces between the potentially very high transmission burst rate across the optical channel and the limited processing rate capacity of the electronically based very large-scale integrated (VLSI) access processor at the station's medium interface unit.

A *mesh* topology is one under which the stations are connected by point-to-point links in a more diverse and spatially distributed (mesh) topology [Fig. 35.1(d)]. To traverse a mesh topology, switching nodes are required. Through the use of cross-connect switches, multiple embedded multiple-access subnetworks are constructed. These subnetworks can be dynamically reconfigured (by adjusting the cross-connect matrices at the switches) to adapt to variations in network loading conditions and in interconnection patterns and to allow the support of private virtual networks. Such an architecture, as demonstrated by the SMARTNet optical network, is presented in Section. 35.7.

A *broadcast* multiaccess radio net, as shown in Fig. 35.1(e) provides, by the physical features of the radio propagation across the shared medium, a direct link between any pair of nodes (assuming the terrain topography to induce no blockages in the node-to-node line-of-sight clearances). A packet transmitted by a single station (node) will be received directly by all other stations. Note that this broadcast property is physically achieved also by the wireline two-way bus network systems shown in Figs. 35.1(b1) and 35.1(b2). In turn, the other network topologies shown in Fig. 35.1 require signal repeating or retransmission protocols to be used to endow them with the broadcast property.

In considering general high-speed local and metropolitan area networks, the following frame distribution topologies can be distinguished for basic implementations: broadcast (logical bus) topology and mesh (switching) topology.

Broadcast (Logical Bus) Topology

Under such a distribution method, station messages are routed through the use of a broadcasting method. Since each message frame (the MAC level protocol data unit) contains addressing information, it is copied automatically from the medium by the intended destination station or stations, so that MAC routing is automatically achieved. Typically, bus, ring, or broadcast star topologies are used to simplify the characterization of the broadcasting path.

The communications link is set up as a bus (for a physical bus implementation), or as a point-to-point link (for a physical ring implementation). The corresponding station interface unit (SIU) acts as a passive or active MAC repeater. A passive MAC node does not interfere with ongoing transmissions along the bus, while being able to copy the messages transmitted across the bus system.

An active MAC station interface unit operates in one out of two possible modes: (1) *repeat mode*, whereby it performs as a repeater, serving to repeat the frame it receives, and (2) *nonrepeat mode*, under which the SIU is not repeating the information it receives from the medium. In the latter case, under a logical bus configuration, the SIU is also typically set to be in a *stripping mode*, stripping from the medium the information it receives. During this time, the SIU is able to transmit messages across the medium, provided it gains permission to do so from the underlying MAC protocol. Note that if the SIU is provided with a store-and-forward capability, it can store all of the information it receives while being in a nonrepeat mode and retransmit this information, if so desired, at a subsequent time.

A logical-bus topology can also be associated with an active interface of the station onto the fiber bus/buses. This is, for example, the case for the Institute of Electrical and Electronics Engineers (IEEE) 802.6 distributed queue dual bus (DQDB) implementation [Rubin and Baker, 1990]. Under DQDB, the station can overwrite each passing bus bit through optical to electrical conversion, an electrical OR write operation, and an electrical to optical reconversion. The active interface of the station can provide it with the capacity to also strip bits, and thus message frames, off the bus.

MAC procedures for logical bus configurations can also be characterized by the following features relating to the method used for removing message frames and the constraints imposed upon the number of simultaneous transmissions carried along the medium. As to the latter feature, we differentiate between the following implementations.

Frame Transmission Initiations in Relation to the Number of Simultaneous Transmissions Along the Logical Bus

Single Message Frame Transmission Across the Medium

A single MAC-frame transmission is permitted across the medium at any time instant; thus, no more than one station can initiate a transmission onto the medium at any given time instant, and no other station can initiate a transmission until this later transmission is removed from the medium.

This is the technique employed by the IEEE 802.5 token ring LAN under a late token release mode, whereby a station holding the token does not release it until it receives its own frame (following the latter's full circulation around the ring). This simplifies the operation of the protocol and provides the station with the ability to review its acknowledged message frame prior to releasing the token, thus enabling it to immediately retransmit its MAC message frame if the latter is determined to have not been properly received by the destination.

The latter token ring LAN uses twisted-pair or coaxial media at transmission rates of 4–16 Mb/s. At 10 Mb/s, the transmission time of a 1000-b frame is equal to 100 μ s, which is longer than the typical propagation time across the medium when the overall LAN length is shorter than 20 km, considering a propagation rate of about 5 μ s/km.

In turn, when considering a 100-Mb/s LAN or MAN fiber-optic based system, such as the fiber distribution data interface (FDDI) token ring or the DQDB reservation bus systems, which can span longer distances of around 100 km, the corresponding frame transmission time and networkwide propagation delay are equal to 10 and 500 μ s, respectively. For a corresponding MAN system, which operates

at a channel rate of 1 Gb/s, the propagation delay of 500 μ s is much larger than the frame transmission time of 1 μ s. Thus, under such high-transmission rate conditions, each message transmission occupies only a small physical length of the logical bus network medium. Therefore, it is not efficient, from message delay and channel bandwidth MAC utilization considerations, to provide for only a single transmission at a time across the logical bus medium. The following mode of operation is thus preferred. [The following mode, single transmission initiation, can also be used for the token-ring network under the early token release option, which can lead to performance improvements at the higher data rate levels.]

Multiple Simultaneous Frame Transmissions Along the Logical Bus Medium

While permitting multiple frame transmissions across the medium, we can consider two different procedures as it relates to whether a single or multiple simultaneous message frame transmission initiations are allowed.

A *single transmission initiation* is allowed at any instant of time. When a fiber optic-based token ring MAC scheme, such as FDDI, is used, the station releases the token immediately following the transmission of the station's message, rather than waiting to fully receive its own message prior to releasing the token. In this manner, multiple simultaneous transmissions can take place across the bus, allowing for a better utilization of the bus spatial-bandwidth resources.

A slotted access scheme is often used for logical bus linear topologies. Under such a scheme, a bus controller is responsible for generating successive time slots within recurring time cycles. A slot propagates along the unidirectional fiber bus as an idle slot until captured by a busy station; the slot is then designated as busy and is used for carrying the inserted message segment. A busy station senses the medium and captures an available idle slot, which it then uses to transmit its own message segment. For fairness reasons, a busy station may be allowed to transmit only a single segment (or a limited maximum number of segments) during each time cycle. In this manner, such a MAC scheme strives to schedule busy station accesses onto the medium such that one will follow the other as soon as possible, so that a message train is generated efficiently utilizing the medium bandwidth and space (length) dimensions. However, note that no more than a single station is allowed at any time to initiate transmissions onto the unidirectional medium; transmission initiations occur in an order that matches the positional location of the stations along the fiber. As a result, the throughput capacity of such networks is limited by the shared medium's data rate.

Multiple simultaneous frame transmission initiations are included in the MAC protocol. In using such a MAC scheduling feature, multiple stations are permitted to initiate frame transmissions at the same time, accessing the medium at sufficiently distant physical locations, so that multiple transmissions can propagate simultaneously in time along the space dimension of the shared medium. The underlying MAC algorithm needs to ensure that these simultaneous transmissions do not cause any frame overlaps (collisions).

In a ring system, such a procedure can involve the proper use of multiple tokens or ring buffer insertions at each station's interface. In a logical bus operation, when a *slotted* channel structure is employed, such an operation can be implemented through the designation of slots for use by a proper station or group of stations, in accordance with various system requests and interconnectivity conditions. For example, in the DQDB MAN, stations indicate their requests for channel slots so that propagating idle slots along each fiber bus can be identified with a proper station to which they are oriented; in this manner, multiple simultaneous frame transmission initiations and on-going message propagations can take place. Similarly, when time-division multiple access (TDMA) and demand-assigned circuit or packet-switched TDMA MAC schemes are used.

Further enhancements in bandwidth and space utilization can be achieved by incorporating in the MAC scheme an appropriate message frame removal method, as indicated in the following.

Frame Removal Method

When considering a logical bus network with active SIUs, the removal of frames from the logical bus system can be carried out in accordance with the following methods.

Source Removal

Considering loop topologies, under a source removal method the source station is responsible for the removal of its own transmitted frames. This is, as previously noted, the scheme employed by the IEEE 802.5 and fiber-based FDDI token ring systems. Such a MAC feature permits the source station (following the transmission of a frame) to receive an immediate acknowledgment from its destination station (which is appended as a frame trailer), or to identify immediate no-response when the destination station is not operative.

Destination Removal

Under such a scheme, a station, upon identifying a passing frame destined for itself, removes this frame from the medium. Under such a removal policy, a frame is not broadcast across the overall length of medium but just occupies a space segment of the medium that spans the distance between the source and destination stations. Such a method can lead to a more complex MAC protocol and management scheme. Improvement in delay and throughput levels can, however, be realized through spatial reuse, particularly when a noticeable fraction of the system traffic flows among stations that are closely located with respect to each other's position across the network medium.

To apply such a scheme to a token ring system, multiple tokens are allowed and are properly distributed across the ring. When two closely located stations are communicating, other tokens can be used by other stations, located away from the occupied segment(s), to initiate their own nonoverlapping communications paths. Concurrent transmissions are also attained by the use of a slotted access scheme or through the use of a buffer insertion ring architecture, as illustrated later.

When such a scheme is applied to a bus system with actively connected SIUs, which is controlled by a *slotted* access scheme, the destination station is responsible for stripping the information contained in the slot destined to itself from the bus and for releasing the corresponding slot for potential use by a downstream station.

Removal by Supervisory Nodes

It can be beneficial to employ special supervisory nodes, located across the medium, to remove frames from the medium. In this manner, the frame destination removal process can be implemented in only supervisory nodes, relieving regular nodes of this task.

Using such frame removal supervisor nodes, the system interconnectivity patterns can be divided (statically or dynamically) into a number of modes. Under an extensively divisive mode, the supervisory stations allow only communications between stations that are located between two neighboring supervisory stations to take place. Under a less divisive connectivity mode, the system is divided into longer disjoint communications segments. Under a full broadcast mode, each frame is broadcast to all network stations. Depending on the network traffic pattern, time cycles can be defined such that a specific mode of operation is invoked during each time cycle.

If such supervisory stations (or any station) are operated as store-and-forward buffered switching units, then clearly the distribution processes across the medium segments can be isolated, and inter-segment message frames would then be delivered across the logical bus system in a *multiple-hop* (multi-retransmission) fashion. This is the role played by buffer-insertion ring architectures for the specialized ring topology and, in general, by the mesh switching architectures discussed in the following.

Mesh (Switching) Topology

Under a mesh (switching) topology, the network topology can be configured as an arbitrary mesh graph. The network nodes provide buffering and switching services. Communications channels are set up as point-to-point links interconnecting the network nodes. Messages are routed through the network through the use of specially developed routing algorithms.

Depending on whether the switching node performs store-and-forward or cross-connect switching functions, we distinguish between the following architectures.

Store-and-Forward Mesh Switching Architecture

Under a store-and-forward mesh switching architecture, the nodal switches operate in a store-and-forward fashion as packet switches. Thus, each packet received at an incoming port of the switch is examined, and based on its destination address it is queued, switched, and forwarded on the appropriate outgoing port. Each point-to-point channel in such a mesh network needs to be efficiently shared among the multitude of messages and connections that are scheduled to traverse it. A statistical multiplexing scheme is selected (and implemented at each switch output module) for dynamically sharing the internodal links.

Cross-Connect Mesh Switching Architecture

In this case, each switching node operates as a cross-connect switch. The latter serves as a circuit (or virtual circuit) switch, which transfers the messages belonging to an established circuit (or virtual circuit) from their incoming line and time slot(s) [or logical connection groups for cross-connect virtual path switches used by asynchronous transfer mode (ATM) networks] to their outgoing line and time slot(s) (or logical group connections). The cross-connect matrix used by the node to implement this switching function is either preset and kept constant, or it can be readjusted periodically, as traffic characteristics vary, or even dynamically in response to the setup and establishment of end-to-end connections. (See also [Section 35.7](#) for such an optical network identified as SMARTNet.)

Hybrid Mesh Switching Architecture

The nodal switch can integrate fixed assigned and statistical operations in multiplexing traffic across the mesh topology links. For example, in supporting an integrated circuit switched and packet-switched implementation, a time cycle (time frame) is typically defined, during which a number of slots are allocated to the supported circuits that use this channel, while the remainder of the cycle slots are allocated for the transmission of the packets waiting in the buffers feeding this channel. Frequently, priority-based disciplines must be employed in statistically multiplexing the buffered packets across the packet-switched portion of the shared link, so that packets belonging to different service classes can be guaranteed their desired quality of service, as it relates to their characteristic delay and throughput requirements. For example, voice packets must subscribe to strict end-to-end time delay and delay jitter limits, whereas video packets induce high throughput support requirements. Asynchronous transfer mode network structures, which employ combined virtual path and virtual circuit switches, serve as another example.

Hybrid Logical Bus and Buffered Switching Topologies

High-speed multigigabit communications networking architectures that cover wider areas often need to combine broadcast (logical bus) and mesh (switching) architectures to yield an efficient, reliable, and responsive integrated-services fiber-based network.

In considering logical-bus topologies with active SIUs, we previously noted that certain nodes can be designated to act as store-and-forward processors and to also serve as frame removal supervisory nodes. Thus, such nodes actually operate as MAC bridge gateways. These gateways serve to isolate the segments interconnecting them, each segment operating as an independent logical bus network. These gateways act to filter MAC bridge interconnections between these segments. The individual segments can operate efficiently when they serve a local community of stations, noting that each segment spans a shorter distance, thus reducing the effect of the end-to-end propagation delay on message performance. To ensure their timely distribution, it can be effective to grant access priority, in each segment, to the intersegment packets that traverse this segment.

Layered Protocols and the Medium Access Control Sublayer

In relation to the open systems interconnect (OSI) reference model, the data link layer of multiple access (such as typical LAN and MAN) networks is subdivided into the MAC lower sublayer and the logical link control (LLC) upper sublayer. Services provided by the MAC layer allow the local protocol entity to exchange MAC message frames (which are the MAC sublayer protocol data units) with remote MAC entities.

In considering typical LAN and MAN systems, we note that the MAC sublayer provides the following services:

1. MAC sublayer services are provided to the higher layer (such as the LLC sublayer for LAN and MAN systems). LLC service data units (SDUs) are submitted to the MAC sublayer for transmission through proper multiple-access medium sharing. In turn, MAC protocol data units (PDUs) received from the medium and destined to the LLC are transferred to the LLC sublayer as proper LLC-SDUs. The underlying LLC SDUs include source and destination addresses, the data itself, and service class and quality of service parameters.
2. MAC sublayer services are similarly provided to directly connected isochronous and nonisochronous (connection-oriented circuit and packet-switched) channel users (CUs) allowing a local CU entity to exchange CU-data units with peer CU entities. These are connection-oriented services, whereby after an initial connection set-up, the channel user is able to directly access the communications channel through the proper mediation of the MAC sublayer. The CU generates and receives its data units through the MAC sublayer over an existing connection on an isochronous or nonisochronous basis. Such CU-SDUs contain the data itself and possibly service quality parameters; no addressing information is needed since an established connection is involved.

Corresponding services are provided for connectionless flows.

3. MAC sublayer services are provided to the local MAC station management entity via the local MAC layer management interface.

Examples of services include: the opening and closing of an isochronous or nonisochronous connection; its profile, features, and the physical medium it should be transmitted on; and the establishment and disestablishment of the binding between the channel user and the connection endpoint identifier.

The MAC sublayer requires services from the physical layer that provide for the physical transmission and reception of information bits. Thus, in submitting information (MAC frames) to the physical layer, the MAC sublayer implements the medium access control algorithm, which provides its clients (the LLC or other higher layer messages) access to the shared medium. In receiving information from the physical layer, the MAC sublayer uses its implemented access control algorithm to select the MAC frames destined to itself and then to provide them to the higher layer protocol entities. MAC layer addresses are used by the MAC layer entity to identify the destination(s) of a MAC frame.

Figure 35.2 shows the associated layers as implemented by various local and metropolitan area networks, as they relate to the OSI data link and physical layers.

35.3 Categorization of Medium Access Control Procedures

A multitude of access control procedures are used by stations to share a multiaccess communications channel or network system. We provide in this section a classification of MAC schemes.

Medium Access Control Dimensions

The multiple-access communications medium resource can be shared among the network stations through the allocation of a number of key resource dimensions. The assignment space considered is the $(T, F, C, S) = \{\text{time, frequency, code, space}\}$ space. The allocation of access to the shared medium is provided to stations' messages and sessions/calls through the assignment of slots, segments, and cells of the time, frequency, code, and space dimensions.

1. *Time-division scheduling.* Stations share a prescribed channel frequency band by having their transmissions scheduled to take place at different segments of time. Typically, only a single message can be transmitted successfully across the designated channel at any instant of time.
2. *Frequency- and wavelength-division allocation.* The bandwidth of the communications channel is divided into multiple disjoint frequency bands (and wavelength channels for an optical channel)

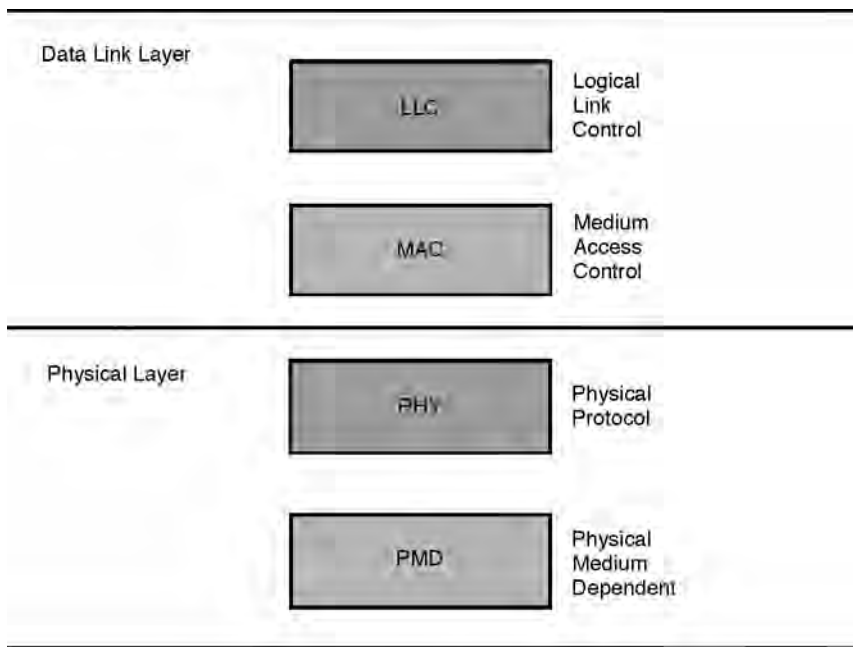

FIGURE 35.2 The MAC sublayer and its interfacing layers across the OSI data link and physical layers.

so that a station can be allocated a group, consisting of one or more frequency/wavelength bands, for use in accessing the medium. Multiple time-simultaneous transmissions can take place across the channel, whereby each message transmission occupies a distinct frequency/wavelength channel.

3. *Code-division multiple access (CDMA)*. Each station's message is properly encoded so that multiple messages can be transmitted simultaneously in time in a successful manner using a single frequency band of the shared communications channel, so that each message transmission is correctly received by its destined station. Typically, orthogonal (or nearly orthogonal) pseudonoise sequences are used to randomly spread segments of a message over a wide frequency band (frequency hopping method) or to time correlate the message bit stream (direct sequencing method). A message can be encoded by an address-based key sequence that is associated with the identity of the source, the destination, the call/connection, or their proper combination. A wider frequency band is occupied by such code-divided signals. In return, a common frequency band can be used by network stations to successfully carry, simultaneously in time, multiple message transmissions.
4. *Space-division multiple access*. Communications channels are shared along their space dimension. For example, this involves the sharing of groups of physically distinct links or multiple space segments located across a single high-speed logical bus network.

Considering the structure of the access control procedure from the dimensional allocation point of view, note the similarity between the space-division and frequency/wavelength-division methods in that they induce a *channel selection* algorithm that provides an allocation of distinct frequency/wavelength or physical channels to a user or to a group of users. In turn, once a user has been assigned such a frequency/wavelength band, the sharing of this band can be controlled in accordance with a time-division and/or a code-division MAC method. Thus, under a combined use of these dimensions, the medium access control algorithm serves to schedule the transmission of a message by an active station by specifying the selected channel (in a frequency/wavelength-division or space-division manner) and subsequently specifying the time slot(s) and/or multiple-access codes to be used, in accordance with the employed time-division and/or code-division methods.

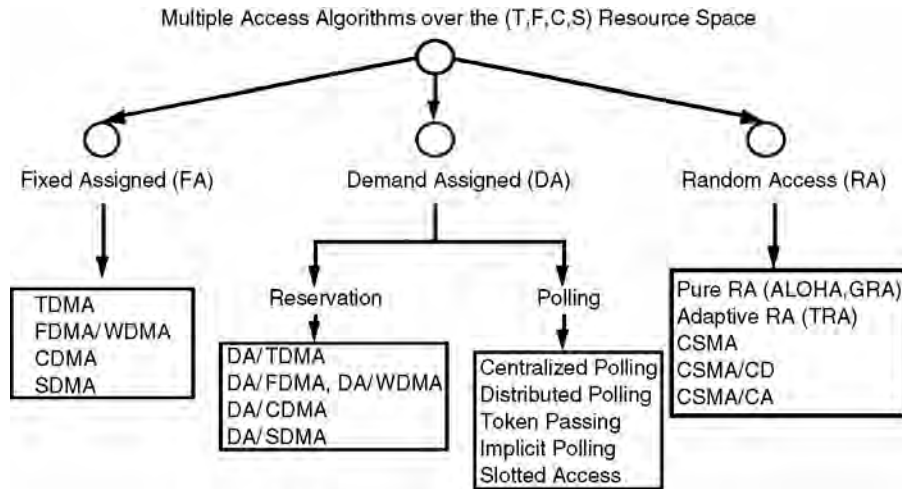

FIGURE 35.3 Classes of medium access control schemes with illustrative access procedures noted for each class.

Medium Access Control Categories

In Fig. 35.3, we show our categorization of medium access control procedures over the previously defined (T, F, C, S) assignment space. Three classes of access control policies are identified: **fixed assignment** (FA), **demand assignment** (DA), and **random access** (RA). Within each class, we identify the signalling (SIG) and control component and the information transmission (IT) method used. Note that within each class, circuit-switching as well as packet-switching mechanisms (under connectionless and/or connection-oriented modes) can be used, in isolation or in an integrated fashion.

Under a *fixed-assignment* scheme, a station is dedicated, over the (T, F, C, S) space, a communications channel resource, which it can permanently use for accessing the channel. Corresponding access control procedures thus include **time-division multiple access (TDMA)**, **frequency-division multiple access (FDMA)**, **wavelength-division multiple access (WDMA)**, **code-division multiple access (CDMA)**, and **space-division multiple access (SDMA)** schemes. A corresponding signalling/control procedure is implemented to ensure that station transmission boundaries are well recognized by the participating stations along the respective (T, F, C, S) dimensions.

Medium resources (along each dimension) can be assigned on a fixed basis to specified sessions/connections, to a station, or to a group of stations. When allocated to a connection/call, such schemes provide the basis for the establishment of isochronous circuits and can lead to efficient sharing of the medium-bandwidth resources for the support of many voice, video, high-speed data, and real-time session connections, when a steady traffic stream of information is generated. Effective channel sharing can also result when such channel resources are dedicated for the exclusive use by a station or a group of stations, provided the latter generate steady traffic streams which can efficiently utilize the dedicated resources at an acceptable quality of service level.

For example, under a TDMA procedure, a station is allocated a fixed number of slots during each frame. Under a packet-switched TDMA (PS-TDMA) operation, the station is accessing the shared medium by multiplexing its packets into the allocated slots. In turn, under a circuit-switched TDMA (CS-TDMA) operation, the station uses its allocated time slots to establish circuits. A circuit can consist of a fixed number of the station's time slots allocated in each time frame (e.g., a single slot per frame). Connections are assigned by the station's available circuits at the requested rate. The messages generated by a connection are then transmitted in the time slots belonging to the circuit allocated to this connection.

Under a *random-access* scheme, stations contend for accessing the communications channel in accordance with an algorithm that can lead to time-simultaneous (overlapping, colliding) transmissions by several stations across the same frequency band, causing at times the retransmission of certain packets.

Under fixed random-access schemes, a station transmits its message frame across the channel at a random time, in a slotted or unslotted fashion, without coordinating its access with other stations. A station that detects (through channel sensing, or through nonreceipt of a positive acknowledgment from its destination) its transmission to collide with another transmission, will retransmit its message after a properly computed random retransmission delay (whose duration may depend on the estimated channel state of congestion). Under an adaptive channel-sensing random-access algorithm, a ready station first senses the channel to gain certain channel state information and then uses this information to schedule its message for transmission in accordance with the underlying protocol, again without undertaking full access coordination with all other network stations. Various fixed (such as ALOHA [Abramson, 1973] and group random access [Rubin, 1978]) and adaptive channel-sensing random-access algorithms such as carrier sense multiple access (CSMA) [Kleinrock and Tobagi, 1975], carrier sense multiple access/collision detection (CSMA/CD), dynamic group random access (DGRA) [Rubin, 1983], tree-random-access collision resolution-based [Capetanakis, 1979] and others [Sachs, 1988; Maxemchuk, 1982; Stallings, 1993] can be invoked.

In general, random-access schemes are not well suited as information transmission methods for governing the access of information messages onto a very high-speed fiber communications channel, unless provisions are made to considerably limit the extent of message overlaps due to collisions or to limit the use of this access technique to certain low-throughput messaging classes.

A random-access procedure is typically employed for supporting packet-switching services. At higher normalized throughput levels, high packet delay variances can occur. A proper flow control regulation mechanism must be employed to guarantee maximum delay limits for packets associated with isochronous and real-time based services.

Nonchannel-sensing random-access procedures yield low channel utilization levels. In turn, the efficiency of a channel-sensing random-access procedure critically depends upon the timeliness of the sensed channel occupancy information and, thus, upon the overhead durations associated with sensing the channel. For high-speed logical-bus systems, when channel-sensing type random-access schemes are used, performance degradation is caused by the very high ratio of the channel propagation delay to the packet transmission time. An active station is required to obtain the channel state prior to initiating a transmission. However, since a station's transmission must propagate across the total logical-bus medium before its existence can be sensed by all network stations, and since stations make uncoordinated access decisions under a random-access scheme, these decisions can be based on stale channel state information; as a result, this can lead to the occurrence of excessive message collisions.

The degrading effects of the propagation delay to message transmission time ratio can be somewhat reduced by the following approaches.

Limit the overall propagation delay by dividing the overall network into multiple tiers or segments, as illustrated by the double-tier LAN and MAN architecture presented in Rubin and Tsai [1987]. The network stations are divided into groups. A shared backbone medium can be used to provide interconnection between groups (on a broadcast global basis using repeaters as gateways, or on a store-and-forward bridged/routing basis) using a noncontention (nonrandom-access)-based MAC algorithm. A random-access MAC strategy can be used for controlling the access of messages across the shared group (segment) medium, which now spans a much shorter distance and thus involves considerably reduced propagation delays. Similarly, such a network configuration is realized by interconnecting LAN (such as ethernet) segments by routers, bridges, or switches.

While the propagation delay depends on the conducting medium and is independent of the transmission speed, the packet transmission time is reduced as the transmission speed is increased. The MAC message frame transmission time can be increased by using FDMA/WDMA or SDMA methods to replace the single-band high-bandwidth medium with a group of shared multiple channels, each of lower bandwidth [Chlamtac and Ganz, 1988]. Clearly, this will provide an improvement only if the underlying services can be efficiently supported over such a reduced bandwidth channel when a random-access (or other MAC) scheme is used.

Random-access schemes can serve, as part of other MAC architectures, as effective procedures for transmitting signalling packets for demand-assigned schemes. Random-access schemes can also be used in conjunction with CDMA and spread spectrum multiple access (SSMA) procedures over high-speed channels.

Random-access protocols are further presented and discussed in [Section 35.5](#).

Under a *demand-assigned* scheme, a signalling procedure is implemented to allow certain network entities to be informed about the transmission and networking needs and demands of the network stations. Once these network entities are informed, a centralized or distributed algorithm is used to allocate to the demanding stations communications resource segments over the (T, F, C, S) assignment space.

The specific methods used in establishing the signalling channel and in controlling the access of individual demanding stations onto this channel characterize the features of the established demand-assignment scheme.

The signalling channel can be established as an out-of-band or in-band fixed channel to which communications resources are dedicated, as is the case for many DA/TDMA, DA/FDMA, or DA/WDMA schemes. In turn, a more dynamic and adaptive procedure can be used to announce the establishment of a signalling channel at certain appropriate times, as is the case for the many polling, implicit polling, slotted, and packet-train-type access methodologies.

The schemes used to provide for the access of stations onto the signalling channel can be divided into two categories: **polling** and **reservation** procedures.

Under a reservation scheme, it is up to the individual station to generate a reservation packet and transmit it across the signalling (reservation) channel to inform the network about its needs for communications resources. The station can identify its requirements as they occur or in advance, in accordance with the type of service required (isochronous vs. asynchronous, for example) and the precedence level of its messages and sessions/connections. Reservation and assignment messages are often transmitted over an in-band or out-of-band multiple-access channel so that a MAC procedure must be implemented to control the access of these MAC-signalling messages.

Under a polling procedure, it is the responsibility of the network system to query the network stations so that it can find out their transmission needs, currently or in advance. Polling and polling-response messages can be transmitted over an in-band or out-of-band multiple-access channel, so that a MAC procedure must be implemented to control the access of these MAC-signalling messages.

Under an implicit polling procedure, stations are granted access into the medium (one at a time or in a concurrent noninterfering fashion) when certain network state conditions occur; such conditions can be deduced directly by each station without the need to require the station to capture an explicit polling message prior to access initiation. Such schemes are illustrated by slotted bus systems whereby the arrival of an idle slot at a station serves as an implicit polling message, and by buffer-insertion schemes whereby a station is permitted to access the ring if its ring buffer is empty. Additional constraints are typically imposed on the station regarding utilizing these implicit polling messages for access to the channel to ensure a fair allocation of communications network bandwidth resources. Such constraints often guarantee that a station can transmit a quota of packets within a properly defined cycle.

A multitude of access policies can be adopted in implementing integrated services polling and reservation algorithms. Note that polling techniques are used in implementing the IEEE 802.4 token bus and IEEE 802.5 token ring LANs, the FDDI fiber LAN, and many other fiber bus and ring network systems. Reservation techniques are employed by the IEEE 802.6 DQDB metropolitan area network (whereby a slotted positional priority implicit polling access procedure is used to provide access to reservation bits [Newman and Hullett, 1986]), by demand-assigned TDMA, FDMA, CDMA, and WDMA systems, and many other multiple-access network systems. Integrated reservation and polling schemes are also used. See the following section for further discussion of polling and implicit polling methods.

35.4 Polling-Based Multiple Access Networks

In this section, we describe a number of multiple-access networks whose medium access control architectures are based on polling procedures.

Token-Ring Local Area Network

The token-ring network is a local area network whose physical, MAC, and link layer protocol structures are based on the IEEE 802.5 Standard. The ring interface units are connected by point-to-point directional links, which operate at data rates of 4 Mb/s or 16Mb/s. A distributed polling mechanism, known as a **token passing** protocol, is used as the medium access control scheme. A polling packet, known as a token, is used to poll the stations (through their RIUs). When a station receives the token (buffering it for a certain number of bit times to allow the station to identify the packet as a token message and to react to its reception), it either passes the token along to its downstream neighboring station (when it has no message waiting for transmission across the ring network) or it seizes the token. A captured token is thus removed from the ring so that only a single station can hold a token at a time. The station holding the token is then allowed to transmit its ready messages. The dwell time of this station on the ring is limited through the setting of the station's token holding timer. When the latter expires, or when the station finishes transmitting its frames, whichever occurs first, the station is required to generate a new token and pass it to its downstream neighboring station. The transmitted frames are broadcasted to all stations on the ring; they fully circulate the ring and are removed from the ring by their source station. Such a procedure is also known as a source removal mechanism. The token-ring protocol permits a message priority-based access control operation. For this purpose, the token contains a priority field. A token of a certain priority level can be captured by only those stations which wish to transmit across the medium a message of a priority level equal to or higher than the token's priority level. Furthermore, stations can make a reservation for the issue of a token of a higher priority level by setting a priority request tag in a reservation field contained in circulating frames (such tags can also be marked in the reservation field of a busy token, which is a token that has been captured but not yet removed from the ring, and tagged as busy by the station which has seized it). Upon its release of a new idle token, the releasing station marks the new token at a priority level which is the highest of all of those levels included in the recently received reservations. At a later time, when no station is interested in using a token of such a high-priority level, this station is responsible for downgrading the priority of the token. In setting priority-based timeout levels for the token holding timer, different timeout values can be selected for different priority levels.

The *throughput capacity* attainable by a polling scheme, including a token passing distributed polling mechanism such as the token ring LAN, is dependent on the *walk time* parameter. The system *walk time* is equal to the total time it takes for the polling message (the token) to circulate around the network (the ring) when no station is active. For a token ring network, the walk time is thus calculated as the sum of the transmission times, propagation delay, and ring buffer delays incurred by the token in circulating across an idle ring. Clearly, the throughput inefficiency of the network operation is proportional to the ratio between the walk time and the overall time occupied by message transmissions during a single rotation of the token around the ring. The network's maximum achievable throughput level, also known as the network's throughput capacity, is denoted as $L(C)$ (b/s); the normalized throughput capacity index is set to $s(C) = L(C)/R$, where R (b/s) denotes the data rate of each network link, noting that $0 \leq s(C) \leq 1$. Thus, if $s(C) = 0.8$, the network permits a maximum throughput level that is equal to 80% of the link's data rate. To assess the network's throughput capacity level, we assume the network to be highly loaded so that all stations have frames ready for transmission across the ring. In this case, each cycle (token circulation around the ring) has an average length of $E(C) = NK(F/R) + W$, where N denotes the number of ring stations (RIUs), K denotes the maximum number of frames that a station is allowed to transmit during a single visit of the token, F is the frame's average length (in bits), so that F/R represents the average frame transmission time across a ring's link, whereas W denotes the average duration (in seconds) of the token's walk time. The network's normalized throughput capacity index is thus given by $s(C) = NK(F/R)/E(C)$. Clearly, higher throughput levels are attained as the walk time durations (W) are reduced. Note that $W = R(p)L + (T/R) + N(M/R)$, where $R(p)$ denotes the propagation delay per unit-distance across the medium (typically equal to $5 \mu\text{s}/\text{km}$ for wired links); L (km) is the distance spanned by the ring network so that $R(p)L$ represents the overall propagation delay around the ring; T is the token's length, so that T/R represents the token's transmission time; M denotes the number of bit time

delays incurred at the RIU's interface buffer, so that $N(M/R)$ expresses the overall delay incurred by a frame in being delayed at each interface around the ring.

The delay-throughput performance behavior exhibited by polling systems, such as the distributed polling token-passing scheme of the token-ring LAN, follows the behavior of a single server queueing system in which the server dynamically moves from one station to the next, staying (for a limited time) only at those stations that have messages requiring service (i.e., transmission across the shared medium). This is a stable operation for which message delays increase with the overall loading on the network, as long as the latter is lower than the throughput capacity level $L(C)$. As the loading approaches the latter capacity level, message delays rapidly increase and buffer overflows can be incurred.

The Fiber Data Distribution Interface Network

The fiber data distribution interface network also employs a token passing access control algorithm. It also uses a ring topology. Two counter-rotating fiber optic rings are used (one of which is in a standby mode) so that, upon the failure of a fiber segment, the other ring is employed to provide for a closed-loop topology. The communications link operates at a data rate of 100 Mb/s. The network can span a looped distance of up to 200 km.

As previously described for the token ring network, on the receipt of a token, an idle station passes it to its downstream station after an interface delay. If the station is busy, it will capture the token and transmit its frames until its token holding timer times out. As for the token-ring network, a source removal mechanism is used so that the transmitted frames are broadcasted to all stations on the ring; they fully circulate the ring and are removed from the ring by their source station. The timeout mechanism and the priority support procedure used by FDDI are different than those employed by the token ring network and are described subsequently. When a station terminates its dwell time on the medium, it immediately releases the token. This is identified as an *early token release* operation. For lower speed token-ring implementations, a late token release operation can be selected. Under the latter, the token is released by the station only after it has received all of its transmitted messages and removed them from the ring. Such an operation leads to throughput performance degradations when the network uses higher speed links since then the station holds the token for an extra time, which includes as a component the ring's propagation delay. The latter can be long relative to the frame's transmission time. As a result, higher speed token-ring networks are generally set to operate in the early token release mode.

The FDDI MAC scheme distinguishes between two key FDDI service types: synchronous and asynchronous. Up to eight priority levels can be selected for asynchronous services. To date, most commonly employed FDDI adapter cards implement only the asynchronous priority 1 service; some also provide a synchronous priority service.

The access of frames onto the medium is controlled by a *timed token rotation* (TTR) protocol. Each station continuously records the time elapsed since it has last received the token (denoted as the token rotation time). An initialization procedure is used to select a target token rotation time (TTRT) through a bidding process whereby each station bids for a token rotation time (TRT) and the minimum such time is selected. As previously noted, two classes of service are defined: synchronous, under which a station can capture the token whenever it has synchronous frames to transmit, and asynchronous, which permits a station to capture a token only if the current TRT is lower than the established TTRT. To support multiple priority levels for asynchronous frames, additional time thresholds are defined for each priority level. In this manner, a message of a certain priority level is allowed to be transmitted by its station, when the latter captures the token, only if the time difference between the time this station has already used (at this ring access) for transmitting higher priority messages and the time since the token last visited this station is higher than the corresponding time threshold associated with the underlying message priority level. This priority-based access protocol is similar to the one used for the IEEE 802.4 token bus LAN system.

Using this procedure, stations can request and establish guaranteed bandwidth and response time for synchronous frames. A guaranteed maximum cycle latency-based response time is established for the

ring, since the arrival time between two successive tokens at a station can be shown to not exceed the value of $2 \times \text{TTRT}$.

As a polling scheme, the performance of the FDDI network is limited by the ring walk (W) time. The ring throughput is thus proportional to $1 - W/\text{TTRT}$. While lower TTRT values (such as 4–8 ms) yield lower guaranteed cycle response times (token intervisit times lower than 8–16 ms), higher TTRT values need to be selected to provide for better bandwidth utilization under higher load conditions. The ring latency varies from a small value of 0.081 ms for 50 stations, 10-km LAN, to a value of 0.808 ms for 500 stations, 100-km LAN. Using a TTRT value of 50 ms for a LAN that supports 75 stations and 30 km of fiber, and having a ring latency $W = 0.25$ ms, a maximum utilization of 99.5% can be achieved [Ross, 1986].

To provide messages their desired delay performance behavior across the FDDI ring network, it is important to calibrate the FDDI network so that acceptable levels of queueing delays are incurred at the stations' access queues for each service class [Shah et al., 1992]. This can be achieved by the proper selection of the network's MAC parameters, such as the TTRT level, the timeout threshold levels when multipriority asynchronous services are used, and the station synchronous bandwidth allocation level when a station's FDDI adapter card is set also to provide a synchronous FDDI service. The latter service is effective in guaranteeing quality of service support to real-time streams, such as voice, compressed video, sensor data, and high-priority critical message processes, which require strictly limited network delay jitter levels [Shah et al., 1992]. Note that when a token is received by a station that provides an FDDI synchronous service, the station is permitted to transmit its frames that receive such a service (for a limited time, which is equal to a guaranteed fraction of the TTRT) independently of the currently measured TRT. When no such messages are queued at the station at the arrival of the token, the token immediately starts to serve messages which receive asynchronous service, so that the network's bandwidth is dynamically shared among all classes of service.

The delay-throughput performance features of the FDDI networks follow the characteristics of a distributed polling scheme already discussed. The FDDI performance results reported in Shah et al. [1992] were obtained by using the PLANYSTTM tool developed by the IRI Corporation. This tool has been also used to calibrate the parameters of FDDI networks through the use of its expert-based analytical routines.

Implicit Polling Schemes

Under an implicit polling multiple-access mechanism, the network stations monitor the shared medium and are then granted access to it by identifying proper status conditions or tags. To illustrate such structures, we consider the slotted channel, register-insertion, positional-priority, and collision-avoidance access protocols.

Under a *slotted channel access protocol*, the shared medium link(s) are time shared through the generation of time slots. Each time slot contains an header which identifies it as busy or idle. In addition, time slots may also be reserved to connections, so that a circuit-switched mode can be integrated with the packet-switched multiple-access mode described in the following. To regulate station access rates, to assign time circuits, and to achieve a fair allocation of channel resources, the time slots are normally grouped into recurring time frames (cycles). A ready station, with packets to transmit across the medium, monitors the medium. When this station identifies an idle slot, which it is allowed to capture, it marks it to be in a busy state and inserts a single segment into this slot. Clearly, in transmitting a packet, a station must break it into multiple segments, whereby the maximum length of a segment is selected such that it fits into a single slot. The packet segments must then be assembled into the original packet at the destination station.

To be able to insert packets into moving slots, the station must actively interface the medium by inserting an active buffer into the channel. A common configuration for such a network is the slotted ring topology. A slotted access protocol can also be used in sharing a linear logical bus topology with active station interfaces. The later configuration is used by the distributed queue dual-bus MAN defined

by the IEEE 802.6 standard. The latter uses a fiber optic-based dual-bus configuration so that each station is connected to two counterdirectional buses.

To regulate the maximum level of bandwidth allocated to each station, in accordance with the class of service provided to the station, and to control the fair allocation of network resources among stations that receive the same class of service, the access algorithm can limit (statically or dynamically) the number of slots that can be captured by a station during each frame. For the DQDB network, a reservation subchannel is established for stations to insert reservation tags requesting for slots to be used for the transmission of their packets. A station is allowed to capture an idle slot which passes its interface only if it has satisfied all of the earlier requests it has received signifying slot reservations made by other stations. The DQDB network also integrates a circuit-switched mode through the establishment of isochronous circuits as part of the call setup procedure. A frame header is used to identify the slots that belong to dedicated time circuits.

Under a *register-insertion* configuration, each station's medium interface card includes a register (buffer), which is actively inserted into the medium. Each packet is again broken down into segments. A station is permitted to insert its segment(s) into the medium when its register contains no in-transit segments (thus deferring the transmission of its own segments until no in-transit segments are passing by) or when the gap between in-transit segments resident in its register is sufficiently long. In-transit packets arriving at the station's interface when the station is in the process of transmitting its own segment are delayed in the register. To avoid register overflows, its size is set to be equal to at least the maximum segment length. The IBM Metaring/Orbit [Cidon and Ofek, 1989] network is an example of such a network system which employs a ring topology as well as the destination removal spatial reuse features to be presented.

At higher speeds, to further increase the throughput efficiency of the shared medium network, a *destination removal* mechanism is used. This leads to *spatial reuse* since different space segments of the network's medium can be used simultaneously in time by different source–destination pairs. For example, for a spatial-reuse slotted channel network (such as slotted ring or bus-based topologies), once a segment has reached its destination station, the latter marks the slot as idle, allowing it to be reused by subsequent stations it visits. Similarly, the use of an actively inserted buffer (as performed by the register-insertion ring network) allows for operational isolation of the network links, providing spatial reuse features.

To assess the increase in throughput achieved by spatial reuse ring networks, assume the traffic matrix to be uniform (so that the same traffic loading level is assumed between any source–destination pair of stations). Also assume that the system employs two counter-rotating rings, so that a station transmits its segment across the ring that offers the shortest path to the destination. Clearly, the maximum path length is equal to half the ring length, while the average path length is equal to one-quarter of the ring length. Hence, an average of four source–destination station pairs simultaneously communicate across the dual ring network. As a result, the normalized throughput capacity achieved by the spatial reuse dual ring network is equal to 400% (across each one of the rings), as compared with a utilization capacity of 100% (per ring) realized when a destination removal mechanism is used. Hence, such spatial reuse methods lead to substantial throughput gains, particularly when the network links operate at high speeds. They are thus especially important when used in ultra-high-speed optical networks, as noted in [Section 35.7](#).

Positional-Priority and Collision Avoidance Schemes

Under a hub-polling (centralized polling) positional-priority scheme, a central station (such as a computer controller) polls the network stations (such as terminals) in an order which is dictated by their physical position in the network (such as their location on a ring network with respect to the central station), or by following a service order table [Baker and Rubin, 1987]. Stations located in a higher position in the ordering list are granted higher opportunities for access to the network's shared medium. For example, considering a ring network, the polling cycle starts with the controller polling station 1

(the one allocated highest access priority). Subsequently, station 2 is polled. If the latter is found to be idle, station 1 is polled again.

In a similar manner, a terminal priority-based distributed implicit polling system is implemented. Following a frame start tag, station 1 is allowed to transmit its packet across the shared medium. A ready station 2 must wait a single slot of duration T (which is sufficiently long to allow station 1 to start transmitting and for its transmission to propagate throughout the network so that all stations monitoring the shared channel can determine that this station is in the process of transmission) before it can determine whether it is allowed to transmit its packet (or segment). If this slot is monitored by station 2 to be idle, it can immediately transmit its packet (segment). Similarly, station i must wait for $(i - 1)$ idle slots (giving a chance to the $i - 1$ higher priority terminals to initiate their transmissions) following the end of a previous transmission (or following a frame start tag when the channel has been idle) before it can transmit its packet across the shared communications channel.

Such a multiple-access mechanism is also known as a collision avoidance scheme. It has been implemented as part of a MAC protocol for high-speed back-end LANs (which support a relatively small number of nodes) such as HyperChannel. It has also been implemented by wireless packet radio networks, such as the TACFIRE field artillery military nets. In assessing the delay-throughput behavior of such an implicit polling distributed control mechanism, we note that the throughput efficiency of the scheme depends critically on the monitoring slot duration T , whereas the message delay behavior depends on the terminal's priority level [Rubin and Baker, 1986]. At lower loading levels, when the number of network nodes is not too large, acceptable message delays may be incurred by all terminals. In turn, at higher loading levels, only higher priority terminals will manage to attain timely access to the network while lower priority ones will be effectively blocked from entering the shared medium.

Probing Schemes

When a network consists of a large number of terminals, each generating traffic in a low duty cycle manner, the polling process can become highly inefficient in that it will require relatively high bandwidth and will occupy the channel with unproductive polling message transmissions for long periods of time. This is induced by the need to poll a large number of stations when only a few of them will actually have a packet to transmit.

A probing [Hayes, 1984] scheme can then be employed to increase the efficiency of the polling process. For this purpose, rather than polling individual stations, groups of stations are polled. The responding individual stations are then identified through the use of a collision resolution algorithm. For example, the following *tree-random-access* [Capetanakis, 1979; Hayes, 1984] algorithm can be employed. Following an idle state, the first selected polling group consists of all of the net stations. A group polling message is then broadcasted to all stations. All stations belonging to this group which have a packet to transmit then respond. If multiple stations respond, a collision will occur. This will be recognized by the controller, which will subsequently subdivide the latest group into two equal subgroups. The process will proceed with the transmission of a subgroup polling message. Using such a binary search type algorithm, all currently active stations are eventually identified. At this point, the probing phase has been completed and the service phase is initiated. All stations which have been determined to be active are then allocated medium resources for the transmission of their messages and streams.

Note that this procedure is similar to a reservation scheme in that the channel use temporally alternates between a signalling period (which is used to identify user requests for network support) and a service period (during which the requesting stations are provided channel resources for the transmission of their messages). Under a reservation scheme, the stations themselves initiate the transmission of their requests during the signalling periods. For this purpose, the stations may use a random-access algorithm or other access methods. When the number of network stations is not too large, dedicated minislots for the transmission of reservation tags can be used.

35.5 Random-Access Protocols

In this section, we describe a number of random-access protocols which are commonly used by many wireline and wireless networks. Random-access protocols are used for networks which require a distributed control multiple-access scheme, avoiding the need for a controller station which distributes (statically or dynamically) medium resources to active network stations. This results in a survivable operation, which avoids the need for investment of significant resources into the establishment and operation of a signalling subnetwork. This is of particular interest when the shared communications medium supports a relatively large number of terminals, operating each at a low duty cycle. When a station has just one or a few packets, it needs to transmit in a timely manner (at low delay levels) on infrequent occasions; it is not effective to allocate to the station a fixed resource of the network (as performed by a fixed assignment scheme). It is also not effective to go through a signalling procedure to identify the station's communications needs prior to allocating it a resource for the transport of its few packets (as performed by demand-assigned polling and reservation schemes). As a consequence, for many network systems, particularly for wireless networks, it is effective to use random-access techniques for the transport of infrequently generated station packets or, when active connections must be sustained, to use random-access procedures for the multiaccess transport of signalling packets.

The key differences among the random-access methods described subsequently are reflected by the method used in performing shared medium status monitoring.

When stations use full-duplex radios and the network is characterized by a broadcast communications medium (so that every transmission propagates to all stations), each station receives the transmissions generated by the transmitting station, including the transmitting station itself. Stations can then rapidly assess whether their own transmission is successful (through data comparison or energy detection). This is the situation for many local area network implementations. In turn, when stations are equipped with half-duplex transceivers (so that they need to turn around their radios to transition between a reception mode and a transmission mode) and/or when a fully broadcast channel is not available (as is the case for mobile radio nets for which topographical conditions lead to the masking of certain stations, lacking line-of-sight connections between certain pairs of stations), the transmitting station cannot automatically determine the status of its transmission. The station must then rely on the receipt of a positive acknowledgment packet from the destination station.

ALOHA Multiple Access

Under the ALOHA random-access method, the network stations do not monitor the status of the shared communications channel. When a ready station receives a packet, it transmits it across the channel at any time (under an unslotted ALOHA scheme) or at the start of time slot (under a slotted ALOHA algorithm, where the length of a slot is set equal to the maximum MAC frame length). If two or more stations transmit packets (frames) at the same time (or at overlapping times), the corresponding receivers will not usually be able to correctly receive the involved packets, resulting in a destructive collision. (Under communications channel capture conditions, the stronger signal may capture the receiver and may be received correctly, while the weaker signals may be rejected.) When a station has determined that its transmitted packet has collided, it then schedules this packet for retransmission after a random retransmission delay. The latter delay can be selected at random from an interval whose length is dynamically determined based on the estimated level of congestion existing across the shared communications channel. Under a binary exponential backoff algorithm, each station adapts this retransmission interval on its own by doubling its span each time its packet experiences an additional collision.

The throughput capacity of an unslotted ALOHA algorithm is equal to $s(C) = 1/(2e) = 18.4\%$, whereas that of a slotted ALOHA scheme is equal to $s(C) = 1/e = 36.8\%$. The remainder of the shared channel's used bandwidth is occupied by original and retransmitted colliding packets. In effect, to reduce the packet delay level and the delay variance (jitter), the loading on the medium must be reduced significantly below

the throughput capacity level. Hence, the throughput efficiency of ALOHA channels is normally much lower than that attainable by fixed-assigned and demand-assigned methods. The random-access network system is, however, more robust to station failures and is much simpler to implement, not requiring the use of complex signalling subnetworks.

The ALOHA shared communications channel exhibits a bistable system behavior. Two distinctly different local equilibrium points of operation are noted. Under sufficiently low-loading levels the system state resides at the first point, yielding acceptable delay-throughput behavior. In turn, under high-loading levels, the system can transition to operate around the second point. Loading fluctuations around this point can lead to very high packet delays and diminishing throughput levels. Thus, under high-loading bursts, the system can experience a high level of collisions, which in turn lead to further retransmissions and collisions, causing the system to produce very few successful transmissions. To correct this unstable behavior of the random-access multiaccess channel, flow control mechanisms must be used. The latter regulate admission of new packets into the shared medium at times during which the network is congested. Of course, this in turn induces an increase in the packet blocking probability or in the delay of the packet at its station buffer.

Carrier Sense Multiple-Access

Under the CSMA random-access method, the network stations monitor the status of the shared communications channel to determine if the channel is busy (carrying one or more transmissions) or is idle. A station must listen to the channel before it schedules its packet for transmission across the channel.

If a ready station senses the channel to be busy, it will avoid transmitting its packet. It then either (under the nonpersistent CSMA algorithm) takes a random delay, after which it will remonitor the channel, or (under the 1-persistent CSMA algorithm) it will keep persisting on monitoring the channel until it becomes idle.

Once the channel is sensed to be idle, the station proceeds to transmit its packet. If this station is the only one transmitting its packet at this time, a successful transmission results. Otherwise, the packet transmission normally results in a destructive collision. Once the station has determined that its packet has collided, it schedules its packet for retransmission after a random retransmission delay.

Many local and regional area packet-radio multiaccess networks supporting stationary and mobile stations, including those using half-duplex radio transceivers, have been designed to use a CSMA protocol. The performance efficiency of CSMA networks is determined by the *acquisition delay index* $a = t(a)/T(P)$, where $T(P)$ denotes the average packet transmission time and $t(a)$ denotes the system's acquisition time delay. The latter is defined as the time elapsed from the instant that the ready station initiates its transmission (following the termination of the last activity on the channel) to the instant that the packet's transmission has propagated to all network stations so that the latter can sense a transmitting station and thus avoid initiating their own transmissions. The acquisition delay $t(a)$ includes as components the network's end-to-end propagation delay, the radio turn-around time, radio detection times of channel busy-to-idle transitions, radio attack times (times to build up the radio's output power), various packet preamble times, and other components. As a result, for half-duplex radios, the network's acquisition delay $t(a)$ may assume a relatively large value. The efficiency of the operation is, however, determined by the factor a , which is given as the ratio of $t(a)$ and the packet transmission time $T(P)$, since once the station has acquired the channel and is the only one currently active on the channel [after a period of length $t(a)$], it can proceed with the uninterrupted transmission of its full packet [for a period of duration $T(P)$].

Clearly, this can be a more efficient mechanism for packet radio networks which operate at lower channel transmission rates. As the transmission rate increases, $T(P)$ decreases while the index a increases so that the delay-throughput efficiency of the operation rapidly degrades. A CSMA network will attain good delay-throughput performance behavior for acquisition delay index levels lower than about 0.05. For index levels around or higher than 0.2, the CSMA network exhibits a throughput level that is lower than that obtained by a slotted (or even unslotted) ALOHA multiaccess net. Under such conditions, the

channel sensing mechanism is relatively ineffective since the window of vulnerability for collisions [$t(a)$] is now relatively too long. It is thus highly inefficient to use a CSMA mechanism for higher data rate channels as well as for channels which induce relatively long-propagation delays (such as a satellite communication network) or for systems which include other mechanisms that contribute to an increase in the value of the acquisition delay index.

As for the ALOHA scheme, a CSMA network exhibits a bistable behavior. Thus, under loading bursts, the channel can enter a mode under which the number of collisions is excessive so that further loading of the channel results in diminishing throughput levels and higher packet delays. A flow control-based mechanism can be used to stabilize the behavior of the CSMA dynamic network system.

CSMA/CD Local Area Networks

A local area network that operates by using a CSMA/CD access control algorithm incorporates into the CSMA multiple-access scheme previously described the capability to perform collision detection (CD). The station's access module uses a full-duplex radio and appends to its CSMA-based sensing mechanism a CD operation. Once the ready station has determined the channel to be idle, it proceeds to transmit its packet across the shared channel while at the same time it is listening to the channel to determine whether its transmission has resulted in a collision. In the latter case, once the station has determined its packet to be involved in a process of collision, the station will immediately abort transmission. In this manner, colliding stations will occupy the channel with their colliding transmissions only for a limited period of time, the collision detection time $T(\text{CD})$. Clearly, if $T(\text{CD}) < T(P)$, where $T(P)$ denotes the transmission time of a packet (MAC frame) across the medium, the CSMA/CD operation leads to improved delay-throughput performance over that of a CSMA operation.

The ethernet LAN developed by Xerox Corporation is a bus-based network operating at a channel data rate of 10 Mb/s and using a 1-persistent CSMA/CD medium access control algorithm. The physical, MAC, and link layers of such a CSMA/CD network are defined by the IEEE 802.3 standard (and a corresponding ISO standard). Ethernet nets can employ different media types: twisted pair, coaxial cable, fiber optic line, as well as radio links (in the case of an ethernet-based wireless LAN system). The configuration of the ethernet LAN is that of a logical bus so that a frame transmission by a station propagates across the bus medium to all other stations. In turn, the physical layout of the medium can assume a bus or a star topology. Under the latter configuration, all stations are connected to a central hub node, at which point the access lines are connected by a reflecting repeater module so that a transmission received from an access line is repeated into all other lines. Typical ethernet layouts are limited in their geographical span to an overall distance of about 500–2000 m.

The delay-throughput efficiency of the CSMA/CD network operation is determined by the acquisition time delay $t(a)$ and index a , as for the CSMA network. In addition, the network efficiency also depends on the CD time $T(\text{CD})$. It is noted that $T(\text{CD})$ can be as long as twice the propagation delay across the overall span of the bus medium, plus the time required by the station to establish the occurrence of a collision. To ensure that a collision is reliably detected, the power levels of received packets must be sufficiently high. This also serves as a factor limiting the length of the bus and of the distance at which repeaters must be placed. As a result, the network stations are attached to several ethernet segments, each assuming a sufficiently short span. The different ethernet segments are interconnected by gateways or routers. The latter act as store-and-forward switches which serve to isolate the CSMA/CD multiaccess operation of each segment.

As for the random-access mechanisms previously discussed, burst loads applied to the CSMA/CD network can cause large delay-throughput degradations. In supporting application streams which require limited packet delay jitters, it is thus required to prevent the bus from being excessively loaded. Many implementations thus plan the net's offered traffic loading levels to be no higher than 40% (or 4 Mb/s). Also note that, as for other random access schemes, large loading variations can induce an unstable behavior. A flow control mechanism must then be employed to regulate the maximum loading level of the network.

When shorter bus spans are used, or when shorter access link distances are employed in a star configuration, it is possible to operate this network at higher channel data rates. Under such conditions, an ethernet operation at a data rate of 100 Mb/s (or higher) has been implemented.

35.6 Multiple-Access Schemes for Wireless Networks

Under a cellular wireless network architecture, the geographical area is divided into cells. Each cell contains a central base station. The mobile terminals communicate with the base station controlling the cell in which they reside. The terminals use the reverse traffic and signalling channel(s) to transmit their messages to the base station. The base station multiplexes the messages it wishes to send to the cell's mobile terminals across the forward traffic and signalling channels.

First-generation cellular wireless networks are designed to carry voice connections employing a circuit switching method. Analog communications signals are used to transport the voice information. The underlying signalling subnetwork is used to carry the connection setup, termination, and handover signalling messages. The voice circuits are allocated through the use of a reservation based demand-assigned/FDMA scheme. A ready mobile uses an allocated signalling channel for its handset to transmit to its cell's base station a request message for the establishment of a voice circuit. If a frequency channel is available for the allocation of such a circuit (traffic channel), the base station will make this allocation by signalling the requesting handset.

Second-generation cellular wireless networks use digital communications channels. A circuit-switching method is still employed, with the primary service providing for the accommodation of voice connections. Circuits are formed across the shared radio medium in each cell by using either a TDMA-access control scheme (through the periodic allocation of time slots to form an established circuit, as performed by the European GSM and the U.S. IS-54 standards) or by employing a CDMA procedure (through the allocation of a code sequence to a connection's circuit, as carried out by the IS-95 standard). A signalling subnetwork is established. Reverse signalling channels (RSCs) are multiple-access channels which are used by the mobile terminals to transmit to their cells' base station their channel-request packets (for a mobile originating call), as well as for the transmission of paging response packets (by those mobiles which terminate calls). Forward signalling channels (FSCs) are multiplexing channels configured for the transmission of packets from the base station to the mobiles. Such packets include channel-allocation messages (which are sent in response to received channel request packets) and paging packets (which are broadcasted in the underlying location area in which the destination mobile may reside).

For the reverse signalling channels, a random access algorithm such as the ALOHA scheme is frequently employed. For TDMA systems, time circuit(s) are allocated for the random access transmission of signalling packets. For CDMA systems, codes are allocated for signalling channels; each code channel is time shared through the use of a random access scheme (employing, for example, a slotted or unslotted ALOHA multiple-access algorithm).

Paging and channel allocation packets are multiplexed (in a time-shared fashion) across the forward signalling channels. To reduce battery consumption at the mobile terminals, a slotted mode operation can be invoked. In this case, the cell mobiles are divided into groups, and paging messages destined to a mobile belonging to a certain group are transmitted within that group's allocated channels (time slots) [Rubin and Choi, 1996]. In this manner, an idle mobile handset needs to be activated for the purpose of listening to its FSC only during its group's allocated slots.

Under the IEEE 802.11 protocol, terminals access the base station by sharing the radio channel through the use of a CSMA/CA (collision avoidance) scheme.

Third-generation cellular wireless networks are planned to provide for the support of both voice and data services. These networks employ packet-switching principles. Many of the multiple-access schemes described in the previous sections can be employed to provide for the sharing of the mobile-to-base-station multiple-access reverse communications channels. In particular, random-access polling (or implicit polling) and reservation protocols can be effectively implemented. For example, the following versions of a reservation method have been investigated. Under the packet reservation multiple access

(PRMA) [Goodman et al., 1989] or random-access burst reservation procedure, a random-access mechanism is used for the mobile to reserve a time circuit for the transmission of a burst (which consists of a number of consecutively generated packets). For voice bursts, a random-access algorithm is used to govern the transmission of the first packet of the burst across the shared channel (by randomly selecting an unused slot, noting that, in each frame, the base station notifies all terminals as to which slots are unoccupied). If this packet's transmission is successful, its terminal keeps the captured slot's position in each subsequent frame until the termination of the burst's activity. Otherwise, the voice packet is discarded and the next voice packet is transmitted in the same manner. In selecting the parameters and capacity levels of such a multiaccess network, it is necessary to ensure that connections receive acceptable throughput levels and that the packet discard probability is not higher than a prescribed level ensuring an acceptable voice quality performance [Rubin and Shambayati, 1995].

For connection-oriented packet-switching network implementations which also provide data packet transport, including wireless ATM networks, it is necessary to avoid frequent occurrences of packet discards to reduce the rate of packet retransmissions and to lower the chances for packet reordering procedures needed to guarantee the ordered delivery of packets. Reverse and forward signalling channels are established to set up the virtual-circuit connection. Channel resources can then be allocated to established connections in accordance with the statistical features of such connections. For example, real-time connections can be accommodated through the periodic allocation of time slots (or frequency/code resources), whereas burst sources can be supported by the allocation of such resources only for the limited duration of a burst activity. A mechanism must then be employed to identify the start and end times of burst activities. For example, the signalling channels can be used by the mobiles to signal the start of burst activity, whereas the in-band channel is used to detect the end of activity (directly and/or through the use of tagging marks).

35.7 Multiple Access Methods for Spatial-Reuse Ultra-High-Speed Optical Communications Networks

As we have seen above, token-ring and FDDI LANs use token-passing methods to access a shared medium. Furthermore, these networks use a source removal procedure so that each station is responsible for removing its own transmitted frames from the ring. In this manner, each transmitted frame circulates the ring and is then removed by its source station. As a result, the throughput capacity of such networks is limited to a value which is not higher than the ring's channel data rate.

In turn, as observed in [Section 35.4](#) (in connection with implicit polling-based multiple-access networks), the bandwidth utilization of shared medium networks, with particular applications to local and metropolitan area networks operating at high speed using generally fiber optic links, can be significantly upgraded through the employment of spatial-reuse methods. For example, consider a ring network which consists of two counter-rotating unidirectional fiber optic ring topologies. Each terminal (station) is connected to both rings through ring interface units. The bandwidth resources of the rings are shared among the active stations. Assume now that a destination removal method is employed. Thus, when a frame reaches its destination node (RIU), it is removed from the ring by the latter. The network communications resources occupied by this frame (such as a time slot) can then be made available to source nodes located downstream to the removing station (as well as to the removing station itself).

A source station which has a frame to transmit selects the ring that offers the shortest path to the destination node. In this manner, the length of a path will be no longer than 1/2 the ring's length. If we assume a uniform traffic matrix (so that traffic flows between the network terminal nodes are symmetrically distributed), the average path length will be equal to 1/4 the ring's length. As a result, using such a destination removal technique, we conclude that an average of four source-destination flows will be carried simultaneously in time by each one of the two rings. Therefore, the throughput capacity of such a spatial reuse network can reach a level which is equal to 400% the ring's channel data rate for each one of the two rings.

Spatial reuse ring networks can be used to carry traffic on a circuit-switched or packet-switched (connectionless or connection-oriented) basis. For packet-switched network implementations, the following two distributed implicit polling multiple-access methods have been used. Under a slotted ring operation, time slots are generated and circulated across the ring. Each time slot contains a header which identifies it as either empty or busy. A station which senses an empty time slot can mark it as busy and insert a segment (a MAC frame which, for example, can carry an ATM cell) into the slot. The destination station will remove the segment from its slot and will designate the slot as idle so that it can be reused by itself or other stations. Under a buffer-insertion ring multiple-access scheme, each station inserts a buffer into the ring. A busy station will defer the transmission of its packet to packets currently being received from an upstream station. In turn, when its buffer is detected to be empty, the station will insert its segment into the ring. The buffer capacity is set equal to a maximum size packet so that a packet received by a station while it is in a process of transmission of its own packet can be stored in the station's inserted buffer. Each packet is removed from the ring by its destination node.

As previously noted, the DQDB MAN is a slotted dual-bus network which employs active station interfaces. To achieve spatial bandwidth reuse gains of the bus' bandwidth resources, frame removal stations can be positioned across the bus. These stations serve to remove frames which have already reached their destinations so that their slots can be reused by downstream stations. Note that such stations must use an inserted buffer of sufficient capacity to permit reading of the frame's destination node(s) so that they can determine whether a received frame has already reached its destination(s).

In designing optical communications networks, it is desirable to avoid the need for executing store-and-forward switching and operations at the network nodes. Such operations are undesirable due to the large differences existing between the optical communications rates across the fiber optic links and the electronic processing speeds at the nodes, as well as due to the difficulty involved in performing intelligent buffering and switching operations in the optical domain. Networks that avoid such operations (at least to a certain extent) are known as *all-optical networks*.

Systems commonly used for the implementation of a shared medium local area all-optical network employ a star topology. At the center of the star, an optical coupler is used. The coupler serves to repeat the frame transmissions received across any of its incoming fiber links to all of its outgoing fiber links. The coupler can be operated in a passive transmissive mode or in an active mode (using optical amplification to compensate for power losses incurred due to the distribution of the received optical signal across all output links). Each station is then connected by a fiber link to the star coupler so that the stations share a multiple-access communications channel. A multiple-access algorithm must then be employed to control the sharing of this channel among all active stations. Typical schemes employed for this purpose use random-access, polling, and reservation methods. Furthermore, multiple wavelengths can be employed so that a WDMA component can be integrated into the multiple-access scheme. The wavelengths can be statically assigned or dynamically allocated. To illustrate the latter case, consider a reservation-based DA/WDMA procedure. Under a connection-oriented operation, wavelengths are assigned to source-destination nodes involved in a connection. Both transmitter and receiver based wavelength assignment configurations can be used: the transmitter's or receiver's (or both) operating wavelengths can be selected dynamically to accommodate a configured connection.

Because of its broadcast feature, the star-configured optical network does not offer any spatial or wavelength reuse advantages. In turn, the meshed-ring scalable multimedia adaptable meshed-ring terabit (SMARTNet) optical network introduced by Rubin [1994] capitalizes on the integrated use of spatial-reuse and wavelength-reuse methods. In the following, we illustrate the architecture of the SMARTNet configuration. Two counter-rotating fibers make up the ring periphery. The stations access the network through their RIUs, which are actively connected to the peripheral fiber rings. The fiber link resources are shared through the use of a wavelength-division scheme. Multiple wavelengths are used, and each station has access to all wavelengths (or to a limited number of them). The rings are divided into segments. Each segment provides access to multiple stations through their connected RIUs. Each segment is connected to its neighboring segments through the use of wavelength cross-connect routers. Such a router switches messages received at multiple wavelengths from its incoming ports to its outgoing ports.

No store-and-forward switching operations are performed. The switching matrix is preset (on a static or adjustable basis) so that messages arriving across an incoming link at a certain wavelength are always immediately switched to a prescribed outgoing link (at the same wavelength, although wavelength translations can also take place). The wavelength routers are also connected (to certain other wavelength routers) by chord links (each consisting of a pair of counterdirectional fiber links). The routers and their chord links form the chord graph topology.

For each configuration of the chord graph, for each assignment of wavelengths, and for each switching table configuration of the routers, the SMARTNet topology can be divided into wavelength graphs. Each wavelength graph represents a subnetwork topology and is associated with a specific wavelength; all stations accessing this subnetwork (which is set here to be a ring or a bus topology) can communicate to each other across this subnetwork by using the associated wavelength. Within each subnetwork, destination-removal spatial-reuse techniques are used. Among the subnetworks, wavelengths can be reused by a number of subnetworks which do not share links.

As previously discussed for the spatial-reuse ring networks, a SMARTNet system can be used to support connection-oriented circuit-switching and packet-switching (including ATM) architectures as well as connectionless packet-switching networking modes. For packet-switching networks, the links (with each wavelength channel) can be time shared by using slotted or buffer-insertion implicit polling schemes or through the use of other multiple-access methods.

As a network which internally employs cross-connect switches, no random delays or packet discards are incurred within the network. Such a performance behavior is advantageous for the effective support of multimedia services, including voice and video streams (which require low network delay jitter levels) and data flows (which prefer no network packet discards, avoiding the need for packet and segment retransmission and reordering operations). An integrated circuit and packet-switched operation is also readily implemented through the allocation of time, wavelength, and subnetwork channels. Such allocations can also be used to support and isolate virtual subnetworks and their associated user communities.

The SMARTNet configuration illustrated in Fig. 35.4 consists of six wavelength routers; each router has a nodal degree of 4, connected to four incoming and outgoing pairs of counterdirectional links. The chord topology is such that every router is connected to its second-neighboring router (rather than to its neighboring router). Analysis shows the network to require the use of a minimum of five wavelengths [Rubin and Hua, 1995]. Five different groups of wavelength graphs are noted. Each group includes three wavelength graph subnetworks (rings) which reuse the same wavelength. Hence, a wavelength reuse factor of 3 is attained. Each ring subnetwork offers a spatial reuse gain of 2.4 (rather than 4, due to the nonuniform

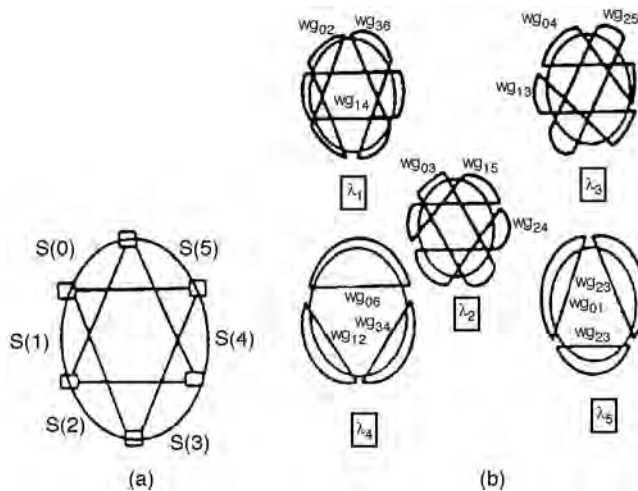

FIGURE 35.4 SMARTNet all-optical network: (a) the network layout; nodes represent wavelength routers; (b) group of wavelength graphs. Five groups are defined, and each group contains three wavelength graphs.

distribution of the traffic across the wavelength graph). Hence, this SMARTNet configuration provides a throughput capacity level of $3 \times 2.4 = 720\%$ of the data rate across each wavelength channel, multiplied by the number of wavelengths used (equal to at least five, and can be selected to be any integral multiple of five to yield the same throughput efficiency factor) and by the number of parallel fiber links employed (two for the basic configuration previously discussed).

It can be shown that an upper bound on the throughput gain achieved by a SMARTNet configuration, which employs wavelength routers of degree four, is equal to 800%. Hence, the illustrated configuration, which requires only six wavelength routers and a minimum of only five wavelengths, yields a throughput gain efficiency which reaches 90% of the theoretical upper bound. Clearly, higher throughput gains can be obtained when the router nodes are permitted to support higher nodal degrees (thus increasing the number of ports sustained by each router). Furthermore, it can be shown that such a network structure offers a throughput performance level which is effectively equal to that obtained when store-and-forward switching nodes are employed for such network configurations.

Defining Terms

Carrier sense multiple access (CSMA): A random access scheme that requires each station to listen to (sense) the shared medium prior to the initiation of a packet transmission; if a station determines the medium to be busy, it will not transmit its packet.

Carrier sense multiple access with collision avoidance (CSMA/CA): A CSMA procedure under which each station uses the sensed channel state and an *a priori* agreed upon scheduling policy to determine whether it is permitted, at the underling instant of time, to transmit its packet across the shared medium; the scheduling function can be selected so that collision events are reduced or avoided.

Carrier sense multiple access with collision detection (CSMA/CD): A CSMA procedure under which each station is also equipped with a mechanism that enables it to determine if its ongoing packet transmission is in the process of colliding with other packets; when a station detects its transmission to collide, it immediately acts to stop the remainder of its transmission.

Code-division multiple access (CDMA): A multiple access procedure under which different messages are encoded by using different (orthogonal) code words while sharing the same time and frequency resources.

Demand assignment multiple access (DAMA): A class of multiple access schemes that allocate dynamically (rather than statically) a resource of the shared medium to an active station; polling and reservation policies are protocols used by DAMA systems; reservation-based TDMA and FDMA systems are also known as demand assigned (DA)/TDMA and DA/FDMA systems.

Fixed assignment multiple access scheme: A multiple access procedure that allocates to each station a resource of the communications medium on a permanent dedicated basis.

Frequency-division multiple access (FDMA): A multiple access method under which different stations are allocated different frequency bands for the transmission of their messages.

Multiple access algorithm: A procedure for sharing a communications resource (such as a communications medium) among distributed end users (stations).

Multiplexing scheme: A system that allows multiple colocated stations (or message streams) to share a communications medium.

Polling scheme: A multiple access method under which the system controller polls the network stations to determine their information transmission (or medium resource) requirements; active stations are then allowed to use the shared medium for a prescribed period of time.

Random access algorithm: A multiple access procedure that allows active stations to transmit their packets across the shared medium without first coordinating their selected access time (or other selected medium's resource) among themselves; this can result in multiple stations contending for access to the medium at overlapping time periods (or other overlapping resource sets), which may lead to destructive collisions.

Reservation scheme: A multiple access method under which a station uses a signalling channel to request a resource of the shared medium when it becomes active; also known as demand assigned scheme.

Time-division multiple access (TDMA): A multiple access scheme under which a station is assigned dedicated distinct time slots within (specified or recurring) time frames for the purpose of transmitting its messages; different stations are allocated different time periods for the transmission of their messages.

Token passing scheme: A polling multiple access procedure that employs a distributed control access mechanism; a token (query) message is passed among the network stations; a station that captures the token is permitted to transmit its messages across the medium for a specified period of time.

36.1 Introduction

There are a large number of issues relating to routing and flow control, and we cannot hope to discuss the subject comprehensively in this short chapter. Instead, we outline generic concepts and highlight some important issues from a high-level perspective. We limit our discussion to the context of **packet switched networks**.

Routing and flow control are concerned with how information packets are transported from their source to their destination. Specifically, routing is concerned with *where* packets travel, that is, the paths traveled by packets through the network. Flow control is concerned with *when* packets travel, that is, the timing and rate of packet transmissions.

The behavior of routing and flow control can be characterized by a number of interrelated performance measures. These performance measures can be categorized into two groups: user metrics and network metrics. User metrics characterize performance from the perspective of a single user. Common user metrics are throughput (rate of information transfer), average delay, maximum delay, delay jitter (variations in delay), and packet loss probability. Network metrics characterize performance from the perspective of the network as a whole and all users of it. Common network metrics are network throughput, number of users that can be supported, average delay (averaged over all users), and buffer requirements. Fairness issues may also arise from the perspective of the network.

The goals of routing and flow control are to balance these different performance measures. Optimization of user metrics is often at the expense of network metrics, and vice versa. For example, if the number of users allowed to access the network is too large, the quality of service seen by some users might fall below acceptable levels.

In reality, it is often even difficult to optimize a single performance measure due to the uncertainty of demand placed on the network. Statistical models can be used, but the appropriate parameters of the models are often unknown. Even with an accurate model of demand, the problem of predicting performance for a given routing or flow control strategy is often intractable. For this reason, routing and flow control algorithms are typically based on several simplifying assumptions, approximations, and heuristics.

Before we discuss routing and flow control in more detail, we begin by classifying different modes of operation common in packet switched networks.

36.2 Connection-Oriented and Connectionless Protocols, Services, and Networks

In a connection-oriented protocol or service between two network terminals, the two terminals interact with one another prior to the transport of data, to set up a connection between them. The interaction prior to the exchange of data is required, for example, to identify the terminals to each other and to define the rules governing the exchange of data. For example, users of the telephone network engage in a connection-oriented protocol in the sense that a phone number must first be dialed, and, typically, the parties involved must identify themselves to each other before the essential conversation can begin. The transport control protocol (TCP) used on the Internet is an example of a connection-oriented protocol. Examples of connection-oriented services are rlogin and telnet, which can be built upon TCP. Connection-oriented protocols and services typically involve the exchange of data in both directions. In addition, connection-oriented protocols are frequently used to provide reliable transport of data packets between network endpoints, whereby the network endpoints continue to interact during the data exchange phase in order to manage retransmission of lost or errored packets.

In connectionless protocols or services between two network terminals, no interaction between the terminals takes place prior to the exchange of data. For example, when a letter is mailed over the postal network, a connectionless protocol is used in the sense that the recipient of the letter need not interact with the sender ahead of time. An example of a connectionless protocol is the current Internet protocol (IP) used to transport packets on the Internet. Electronic mail provides a connectionless service, in the same sense that the postal network provides a connectionless service. Because of the lack of interaction between terminals engaging in a connectionless protocol, retransmission of lost or errored packets is not possible, and, hence, connectionless protocols are not considered intrinsically reliable. On the other hand, connectionless protocols are often appropriate in environments where lost or errored packets are sufficiently rare.

A connection-oriented network is a network specifically designed to support connection-oriented protocols. When a connection request is made to a connection-oriented network, the network establishes a path between the source and destination terminal. The switching nodes are then configured to route packets from the connection along the established path. Each switching node is aware of the connections that pass through it and may reserve resources (e.g., buffers and bandwidth) on a per-connection basis. A packet switched network that is connection oriented is also referred to as a **virtual circuit switched network**. Asynchronous transfer mode (ATM) networks are an example of virtual circuit switched networks.

A connectionless network is a network designed to support connectionless protocols. Each node of a connectionless network typically knows how to route packets to each possible destination since there is no prior coordination between terminals before they communicate. Connectionless networks are sometimes referred to as **datagram networks**.

The terminology as defined is not standard, and indeed there does not appear to be widespread agreement on terminology. We have made a distinction between a connection-oriented protocol and a connection-oriented network, and a distinction connectionless protocol and a connectionless network. The reason for these distinctions is because of the many ways in which protocols and networks can be layered. In particular, connection-oriented protocols can be built upon connectionless networks and protocols, and connectionless protocols can be built upon connection-oriented networks and protocols. For example, TCP is in widespread use on end hosts in the Internet, but the Internet itself is inherently a connectionless network which utilizes IP. Another example that has received attention recently is in using an ATM network (connection oriented) as a lower layer transport mechanism to support the IP protocol between Internet nodes. This may be considered somewhat odd, since IP will, in turn, often support the connection-oriented TCP.

Packet switched networks can be further classified as lossy or lossless according to whether or not network nodes will sometimes be forced to drop (destroy) packets without forwarding them to their

intended destination. Connectionless networks are inherently lossy, since the lack of coordination of data sources creates the possibility that buffers inside the network will overflow. Connection-oriented networks can be designed to be lossless. On the other hand, connection-oriented networks can also be lossy, depending on if and how flow control is exercised.

36.3 Routing in Datagram Networks

We will first confine our discussion on routing to the context of connectionless networks. A common approach to routing in connectionless networks is for each node in the network to have enough intelligence to route packets to every possible destination in the network.

A common approach to route computation is *shortest path routing*. Each link in the network is assigned a weight, and the length of a given path is defined as the sum of the link weights along the path. The weight of a link can reflect the desirability of using that link and might be based on reliability or queuing delay estimates on the link, for example. However, another common choice for link weights is unity, and shortest paths in this case correspond to minimum hop paths.

We now briefly review some popular algorithms for computing shortest paths. Suppose there are n nodes in the network, labeled $1, 2, \dots, n$. The label (i, j) is assigned to a link that connects node i to node j . The links are assumed to be oriented, that is, link (i, j) is distinct from (j, i) . We assume that if there is a link (i, j) in the network, then there is also a link (j, i) in the network. We say that node i is a neighbor of node j if the link (i, j) exists. Let $N(i)$ be the set of nodes for which node i is a neighbor. Let w_{ij} denote the weight assigned to link (i, j) , and define $w_{ij} = +\infty$ if node i is not a neighbor of node j . We assume that $w_{ij} > 0$ for all i and j . Formally, a path from node i_1 to node i_k is a sequence of nodes (i_1, i_2, \dots, i_k) . The length of such a path is the sum of the weights of links between successive nodes, and the path is said to have $k - 1$ hops. We assume that the network is *strongly connected*, that is, there exists a path between all ordered pairs of nodes with finite length.

Consider the problem of finding shortest (i.e., minimum length) paths from each node to a given destination node. Since each node in the network is a potential destination, this problem will be solved separately for each destination. Without loss of generality, assume that the destination node is node 1. The distance from a node i to the destination node is defined to be the length of the shortest path from node i to the destination node and is denoted as D_i . Define $D_1 = 0$.

Consider a shortest path from a node i to the destination: $(i, j, k, \dots, 1)$. Note that the subpath that begins at node j , $(j, k, \dots, 1)$, must be a shortest path from node j to the destination, for otherwise there exists a path from node i to the destination that is shorter than $(i, j, k, \dots, 1)$. Thus, this subpath has length D_j and $D_i = w_{ij} + D_j$. Furthermore, since D_i is the length of a shortest path, we have $D_i \leq w_{ik} + D_k$ for any k . Thus, we have $D_1 = 0$ and

$$D_i = \min\{w_{ij} + D_j : 1 \leq j \leq n\}, \quad 1 < i \leq n$$

This is known as *Bellman's equation* and forms the basis of an optimization technique known as dynamic programming. Let $\mathbf{D} = (D_1, D_2, \dots, D_n)$ denote the vector of shortest path lengths, and let \mathbf{f} denote the vector valued mapping in Bellman's equation. With these definitions, Bellman's equation says that \mathbf{D} is a fixed point of the mapping \mathbf{f} , that is, $\mathbf{D} = \mathbf{f}(\mathbf{D})$. It can be shown that under our assumption of positive link weights, there is only one solution \mathbf{x} to the equation $\mathbf{x} = \mathbf{f}(\mathbf{x})$, that is, \mathbf{D} is the unique solution to Bellman's equation.

The *Bellman-Ford algorithm* for shortest paths finds the solution to Bellman's equation iteratively. Specifically, let $\mathbf{D}^0 = (0, \infty, \infty, \dots, \infty)$. In the first iteration of the Bellman-Ford algorithm, $\mathbf{D}^1 = \mathbf{f}(\mathbf{D}^0)$ is computed. In the m th iteration, $\mathbf{D}^m = \mathbf{f}(\mathbf{D}^{m-1})$ is computed. It can be shown by induction on m that \mathbf{D}^m is the vector of shortest path lengths, where the paths are constrained to have at most m hops. Since link weights are positive, any shortest path visits a node at most once, and, hence, any shortest path has at most $n - 1$ hops. Thus, it follows that the Bellman-Ford algorithm converges within $n - 1$ iterations. In other words, we have $\mathbf{f}(\mathbf{D}^{n-1}) = \mathbf{D}^{n-1} = \mathbf{D}$. The shortest paths can be generated from \mathbf{D} by examining the argument of the minimum in Bellman's equation. Specifically, for each i , let $\text{Next}(i) = j$, where j is an

argument of the minimum in the equation for D_i , that is, $D_i = w_{ij} + D_j$. With this definition, $\text{Next}(i)$ is clearly the first node along a shortest path from node i to the destination. The worst case time complexity of the Bellman–Ford algorithm is easily seen to be $O(n^3)$.

The Bellman–Ford shortest path algorithm is sometimes called a *distance vector* routing algorithm. The algorithm lends itself easily to a distributed, asynchronous implementation that forms the basis for many commonly used routing algorithms. In such an implementation, each node i is responsible for computing the distance from itself to the destination D_i . Each node initially has an estimate of D_i . These initial estimates may be arbitrary, except the destination itself always knows the correct distance from itself to itself, that is, node 1 knows that $D_1 = 0$. Each node i sends, or advertises, to its neighbors the estimate of D_i that it currently has. This advertisement is either done periodically or whenever the estimate changes. Whenever a node receives an estimate from a neighbor, it updates its own estimate in accordance with Bellman’s equation. Specifically, if $D_i(t)$ is the estimate of D_i at time t and if $D_j(t - \tau_j)$ is the estimate of D_j from node j that was most recently advertised to node i , then $D_i(t) = \min\{w_{ij} + D_j(t - \tau_j) : j \in N(i)\}$. Note that this minimum can be taken over only nodes j which are neighbors of node i , since $w_{ij} = \infty$ if node i is not a neighbor of node j . It can be shown that each node’s estimate converges to the actual distance to the destination under essentially arbitrary assumptions regarding propagation delays of advertisements and delays associated with computing estimates [Bertsekas and Gallager, 1992].

In the preceding discussion, we assumed that the link weights were constant. In practice, however, the link weights may change with time. For example, this may be as a result of link failures or changing traffic characteristics on the links. If the link weights change slowly enough, the distributed asynchronous Bellman–Ford algorithm will track the shortest paths correctly as the link weights change. However, if the link weights change fast enough so that the algorithm does not have a chance to converge, problems may arise. For example, if link weights change quickly in response to changing traffic characteristics, it may be possible for packets to travel around in loops indefinitely. In such a scenario, the link weights oscillate as the traffic pattern on the links change due to oscillating estimates of shortest paths [Bertsekas and Gallager, 1992].

Another popular approach to finding shortest paths is for each node to independently compute the shortest paths. Each node i broadcasts the link weight w_{ij} for all outgoing links (i, j) to all other nodes. Each node then has complete information about the network and can compute shortest paths independently. Networks that use this approach are sometimes said to use *link state* routing. Each node could use the Bellman–Ford algorithm as described to compute shortest paths. However, with link state routing, it is common to use *Dijkstra’s algorithm* for shortest paths, described next.

Dijkstra’s algorithm for finding shortest paths first finds the closest node to the destination node (i.e., the node i other than the destination node with the smallest value of D_i), then the second closest node, then the third closest node, and so on. Let us assume again without loss of generality that node 1 is the destination node. Dijkstra’s algorithm is summarized as follows:

```

Initialization:  $m \leftarrow 1, P_m \leftarrow \{1\}, D_1 \leftarrow 0.$ 
For all  $i$  not in  $P_m$ :
 $X_i \leftarrow w_{i1} + D_1$ 
 $\text{Next}(i) \leftarrow 1$ 
Iteration:
 $i^* \leftarrow \operatorname{argmin} \{X_i : i \text{ not in } P_m\}$ 
 $P_{m+1} \leftarrow P_m \cup \{i^*\}$ 
 $D_{i^*} \leftarrow X_{i^*}$ 
For all  $k$  not in  $P_{m+1}$ :
    If  $X_k > w_{ki^*} + D_{i^*}$  then
         $X_k \leftarrow w_{ki^*} + D_{i^*}$ 
         $\text{Next}(k) \leftarrow i^*$ 
 $m \leftarrow m + 1$ 
If  $m = n$ , then terminate, Otherwise, execute iteration again.
```

The set P_m consists of the m closest nodes to the destination, including the destination. In other words, for each m we have $|P_m| = m$, and $D_i \geq D_j$ if j belongs to P_m and i does not belong to P_m . To see why Dijkstra's algorithm works, assume after executing the iteration m times that P_{m+1} is the set of $m + 1$ closest nodes, that $X_k = \min\{w_{kj} + D_j : j \in P_{m+1}\}$, and that D_j has been computed correctly for all $j \in P_{m+1}$. Clearly this is true for $m = 0$, and we now show by induction that it is true for all m . Consider the $(m + 1)$ st iteration. Suppose that node i^* is a node that could be added to P_{m+1} to yield P_{m+2} with the desired property and that node k is an arbitrary node that cannot be added to P_{m+1} to yield P_{m+2} with the desired property. Note that $D_k > D_{i^*}$. By the induction hypothesis and the fact that all link weights are positive, it thus follows from Bellman's equation that $D_{i^*} = X_{i^*}$. Furthermore, we have $X_k \geq D_k > D_{i^*} = X_{i^*}$. Thus, in the $(m + 1)$ st iteration, node i^* is chosen correctly to form P_{m+2} and $D_{i^*} = X_{i^*}$. Furthermore, we see that X_k is updated correctly to preserve the induction hypothesis.

It is seen that the time complexity of Dijkstra's algorithm is $O(n^2)$, which is less than the worst case-time complexity of $O(n^3)$ for the Bellman–Ford algorithm. The description of Dijkstra's algorithm can also easily be adapted to address the computation of shortest paths from a given source node to all possible destinations, which makes it well suited for link state routing.

Deflection routing [Maxemchuk, 1987] has been proposed for high-speed networks. With deflection routing, each node attempts to route packets along a shortest path. If a link becomes congested, however, a node will intentionally send a packet to a node which is *not* along a shortest path. Such a packet is said to be *deflected*. If the number of links incoming to a node is equal to the number of outgoing links, and the capacity of all links is the same, packet buffering can be essentially eliminated with deflection routing. It is possible for packets to circulate in loops with deflection routing. With a suitable priority structure, however, delay can be bounded. Deflection routing has also been proposed within high-speed packet switches [Cruz and Tsai, 1996].

In another approach to routing, sometimes called *optimal routing*, the rate of traffic flow between each possible source–destination pair is estimated. Suppose that $r(w)$ is the estimated rate (bits per second) of traffic flow for a given source–destination pair w . A number of possible paths for routing traffic between each source–destination pair are identified, say path 1 through P_w for source–destination pair w . The total flow $r(w)$ is allocated among all of the P_w paths according to a vector $(f_1, f_2, \dots, f_{P_w})$ such that $r(w) = f_1 + f_2 + \dots + f_{P_w}$, and such that f_p flows on path p . Typically, bifurcation is allowed, so that f_p may be positive for more than one path p . The path flow allocation for all source–destination pairs is determined simultaneously in order to minimize some cost function. Typically, the cost function is of the form $\sum C_e(f_e)$, where the sum is taken over all links e in the network and f_e denotes the total flow over all paths which cross link e . A common choice for $C_e(f_e)$ is $C_e(f_e) = f_e / (C - f_e)$, where C is the capacity in bits per second of link e . This would correspond to the average delay on link e if the output queue for link e were an M/M/1 queue. Nonlinear optimization techniques can be used to optimize the path flow allocations with respect to the cost function. The disadvantage of the optimal routing approach is that it is difficult to estimate the rates $r(w)$ *a priori*. In addition, the choice of the cost function to minimize is somewhat arbitrary.

Typically, in connectionless networks, the network nodes will determine where to route a packet so that it gets forwarded to its destination. In such an environment, the source places the address of the destination in a **header field** of each packet. Upon receiving a packet, a network node examines the destination address and uses this to index into a lookup table to determine the outgoing link that the packet should be forwarded on.

In contrast, *source routing* describes the situation where the route that a packet travels is determined by the source. In this case, the source explicitly specifies what route the packet should take within a header field of the packet. Typically, this specification consists of the list of node addresses along the path that the packet should travel. This eliminates the need for large lookup tables within each network node. For example, link state routing can be used, where the sources compute shortest paths.

36.4 Routing in Virtual Circuit Switched Networks

In connection-oriented networks, sources make connection requests to the network, transmit data to the destinations through the connection, and then terminate the connection. Since connection requests are distributed in time, a routing decision is typically made for each connection request as it is made.

In other words, the sequence of connection requests that will be made is unknown, and a routing decision for a connection is not made until the connection request occurs.

Shortest path routing is still a viable approach in connection-oriented networks. The network nodes calculate shortest paths to all possible destinations. When a connection request is made, the connection request is forwarded along a shortest path to the destination, and the switching nodes along the path can determine if they have the resources (e.g., bandwidth, buffers) to support the connection request. If all network nodes determine that they can support the request, the network accepts the connection, link weights are updated to reflect the newly formed connection, and data for the connection is forwarded along the established path. If a network node along the shortest path is not able to support the connection request, the network would then reject the connection request.

It is possible for the network to attempt to route a connection request along another path if the first attempted path fails. However, this should be done carefully, since routing a connection on a path with many hops may use up bandwidth that could be better used to support other connection requests. **Trunk reservation** techniques may be used to advantage in this regard.

Alternatively, the sources might be responsible for specifying a desired path in a connection request, which would be a form of source routing. Obviously in this case, the sources would need knowledge of the network topology in order to make intelligent choices for the routes they request.

In connection-oriented networks, the source need not place the destination address into each packet. Rather, it could put a *virtual circuit identifier* (VCI) in each packet, which labels the connection that the packet belongs to. This can result in a savings of bandwidth if there are a large number of potential destinations and a comparatively smaller number of connections passing through each link. A given connection can have a different VCI assigned on every link along the path assigned to it. When a connection is set up through a node, the node assigns a VCI to the connection to be used on the outgoing link, which may be different from the VCI used for the connection on the incoming link. The node then establishes a binding between the VCI used on the incoming link, the VCI assigned on the outgoing link, as well as the appropriate output link itself. Upon receiving a packet, the network node reads the VCI used on the incoming link and uses this as an index into a lookup table. In the lookup table, the node determines the appropriate outgoing link to forward the packet on, as well as the new VCI to use. This is sometimes referred to as VCI translation.

36.5 Hierarchical Routing

In a network with a very large number of nodes, lookup tables for routing can get very large. It is possible to reduce the size of the lookup tables, as well as the complexity of route computation, by using a hierarchical routing strategy. One approach to a hierarchical routing strategy is as follows. A subset of the network nodes are identified as *backbone* nodes. A link connecting two backbones is called a backbone link. The set of backbone nodes and backbone links is called the backbone network. The nonbackbone nodes are partitioned into clusters of nodes called domains. Each backbone node belongs to a distinct domain and is called the *parent* of all nodes in the domain. The nodes within a domain are typically geographically close to one another. Routes between pairs of nodes in the same domain are constrained not to go outside the domain. Routes between pairs of nodes in different domains are constrained to be a concatenation of a path completely within the source domain, a path completely within the backbone network, and a path completely within the destination domain. Routes are computed at two levels, the backbone level and the domain level. Route computations at the backbone level need only information about the backbone network and can proceed independently of route computations at the domain level. Conversely, route computations at the domain level need only information about the specific domain for which routes are computed. Because of this decoupling, the problem of route computation and packet forwarding can be considerably simplified in large networks.

With a hierarchical routing approach it is often convenient to have a hierarchical addressing strategy as well. For example, for the hierarchical routing strategy just described, a node address could be grouped

into two parts, the domain address and the address of the node within the domain. Packet forwarding mechanisms at the backbone level need only look at the domain part of the node address, and packet forwarding mechanisms at the domain level can ignore the domain part of the node address. Of course, it is possible to have hierarchical routing strategies with more than two levels as described.

36.6 Flow Control in Datagram Networks

Since sources in a connectionless network do not interact with the network prior to the transmission of data, it is possible that the sources may overload the network, causing buffers to overflow and packets to be lost. The sources may become aware that their packets have been lost and, as a result, retransmit the lost packets. In turn, it is possible that the retransmission of packets will cause more buffers to overflow, causing more retransmissions, and so on; the network may be caught in a traffic jam where the network throughput decreases to an unacceptable level. It is also possible that buffers may overflow at the destinations if the sources send data too fast. The objective of flow control in connectionless networks is to throttle the sources, but only as necessary, so that rate of packet loss due to buffer overflow is at an acceptably low level.

A number of schemes have been proposed for flow control in connectionless networks. One technique that has been proposed is that network nodes that experience congestion (e.g., buffer overflow) should send the network nodes causing the congestion special control packets, which, in effect, request that the offending nodes decrease the rate at which packets are injected into the network. This has been implemented in the Internet, and the control packets are called *source quench* packets. A practical problem with this approach is the lack of accepted standards that specify under what conditions source quench packets are sent and exactly how network nodes should react to receiving a source quench packet.

We now focus our discussion on a common flow control technique used on connectionless networks, whereby the network carries traffic predominately from connection-oriented protocols, and *window flow control* is exercised within the connection-oriented protocols.

Window flow control is a technique where a source may have to wait for acknowledgements of packets previously sent before sending new packets. Specifically, a *window size* W is assigned to a source, and the source can have at most W unacknowledged packets outstanding. Typically, window flow control is exercised end-to-end, and the acknowledgements are sent back to the source by the destination as soon as it is ready to receive another packet. By delaying acknowledgements, the destination can slow down the source to prevent buffer overflow within the destination.

Another motivation behind window flow control is that if the network becomes congested, packet delays will increase. This will slow down the delivery of acknowledgements back to the source, which will cause the source to decrease its rate of transmissions. The window size W is typically chosen large enough so that in the absence of congestion, the source will not be slowed down by waiting for acknowledgements to arrive.

Although it is possible to prevent buffer overflow by choosing the window sizes small enough and appropriately managing the creation of connections, this is typically not how datagram networks operate. In many cases, packet loss due to buffer overflow is possible, and window flow control is combined with an **automatic repeat request (ARQ) protocol** to manage the retransmission of lost packets. In particular, the source will wait only a limited time for an acknowledgement to arrive. After this amount of time passes without an acknowledgement arriving, the source will timeout and assume that the packet has been lost, causing one or more packets to be retransmitted. The amount of time that the source waits is called the *timeout value*.

As already mentioned, retransmissions should be carefully controlled to prevent the network throughput from becoming unacceptably low. We now provide an explanation of how this is commonly handled within the current Internet, specifically within the TCP protocol. The explanation is oversimplified, but it should give a rough idea of how congestion control mechanisms have been built into the TCP protocol. This is the primary method of flow control within the current Internet.

The first idea [Jain, 1986] is that a timeout indicates congestion, and sources should wait for the congestion to clear and not add to it. In the TCP protocol [Jacobson, 1988], each timeout causes the timeout value to be doubled. This is called *exponential backoff*, and is similar to what happens on ethernet networks. In practice, so that the timeout values do not get unacceptably large, exponential backoff is stopped when the timeout value reaches a suitable threshold. After acknowledgements begin to arrive at the source again, the source can reset the timeout value appropriately.

In addition to exponential backoff, the TCP protocol dynamically adjusts the window size in response to congestion. In particular, a congestion window W' is defined. Initially, W' is set to the nominal window size W , which is appropriate for noncongestion conditions. After each timeout, W' is reduced by a factor of two, until $W' = 1$. This is called *multiplicative decrease*.

The window size used by the TCP protocol is at most W' , and could be less. The idea is that after a period of congestion, a large number of sources could still retransmit a large number of packets and cause another period of congestion. To prevent this, each time a timeout occurs, the window size is reset to one. Hence, a source is then allowed to send one packet. If the source receives an acknowledgement of this packet, it increases the window size by one, and, hence, is then allowed to send two packets. In general, the source will increase the window size by one for each acknowledgement it receives, until the window size reaches the congestion window size W' . This is called *slow start* and is also used for new connections. After the window size reaches W' , the window size is increased by one for every roundtrip delay, assuming no timeouts occur, until the original window size appropriate for noncongestion conditions is reached. This has been called *slower start*.

36.7 Flow Control in Virtual Circuit Switched Networks

In connection-oriented networks, flow control, in a broad sense, can be exercised at two different levels. At a coarse level, when a connection request is made, the network may assess whether it has the resources to support the requested connection. If the network decides that it cannot support the requested connection, the request is blocked (rejected). This is commonly called *admission control*. A connection request may carry information such as the bandwidth of the connection that is required, which the network can use to assess its ability to carry the connection. Some sources do not formally require any specified bandwidth from the network, but would like as high a bandwidth as possible. Such sources are not acutely sensitive to delay; as an example, a file transfer might be associated with such a source. These types of sources have been recently named *available bit rate* (ABR) sources. If all sources are ABR, it may be unnecessary for the network to employ admission control.

At a finer level, when a connection is made, flow control may be exercised at the packet level. In particular, the rate as well as the burstiness of sources may be controlled by the network. We focus our discussion on flow control entirely at the packet level. Proposals have also been made to exercise flow control at an intermediate level, on groups of packets called bursts, but we do not discuss that here.

We first discuss flow control for ABR sources. Given that the bandwidth allocated to an ABR source is variable, the issue of fairness arises. There are many possible ways to define fairness. One popular definition of fairness is *max-min fairness*, which is defined as follows. Each link in the network has a given maximum total bandwidth that is allocated to ABR sources using that link. Each ABR source has an associated path through the network that is used to deliver data from the source to the associated destination. An allocation of bandwidths to the ABR sources is called max-min fair if the minimum bandwidth that is allocated is as large as possible. Given that constraint, the next lowest bandwidth that is allocated is as large as possible, and so on.

A simple algorithm to compute the max-min fair allocation of bandwidths to the ABR sources is as follows. A link is said to be saturated if the sum of the bandwidths of all ABR sources using that link equals the total bandwidth available to ABR sources on that link. Each ABR source is initially assigned a bandwidth of zero. The bandwidth of all ABR sources is increased equally until a link becomes saturated. The bandwidth allocated to each ABR source that crosses a saturated link is then frozen. The bandwidth of all remaining ABR sources are then increased equally until another link becomes saturated, and the

bandwidth of each ABR source that crosses a newly saturated link is then frozen. The algorithm repeats this process until the bandwidth of each ABR source is frozen.

One proposed way to impose flow control on ABR sources is to use window flow control for each ABR connection at the hop level. That is, each ABR connection is subject to a window flow control algorithm for each hop along the path of the connection. Thus, each ABR connection is assigned a sequence of window sizes which specify the window size to be used at each hop along the path for the connection. Each node along the path of a connection reserves buffer space to hold a number of packets equal to the window size for the link incoming to that node. Packet loss is avoided by sending acknowledgements only after a packet has been forwarded to the next node along the path. This scheme results in backpressure that propagates toward the source in case of congestion. For example, if congestion occurs on a link, it inhibits acknowledgements from being sent back on the upstream link, causing the buffer space allocated to the connection at the node feeding the upstream link to fill. This will cause that node to delay sending acknowledgements to the node upstream to that node, and so forth. If congestion persists long enough, the source will eventually be inhibited from transmitting packets. It has been shown that if each node transmits buffered packets from ABR connections that pass through it on a round robin basis, that if window sizes are sufficiently large, and that if each source always has data to send, then the resulting bandwidths that the ABR sources receive are max–min fair [Hahne, 1991]. This scheme is also known as *credit-based flow control* [Kung and Morris, 1995], and algorithms have been proposed for adaptively changing the window sizes in response to demand.

Another way to achieve max–min fairness (or fairness with respect to any criterion for allocated bandwidths) is to explicitly compute the bandwidth allocations and enforce the allocations at the entry points of the network. Explicit enforcement of bandwidth allocations is known as *rate-based flow control*.

Bandwidth is defined in a time-average sense, and this needs to be specified precisely in order to enforce a bandwidth allocation. Suppose packet sizes are fixed. One way to precisely define conformance to a bandwidth allocation of ρ packets per unit time is as follows. In any interval of time of duration x , a source can transmit at most $\rho x + \sigma$ packets. The packet stream departing the source is then said to be (σ, ρ) *smooth*. The parameter σ is a constant positive integer and is a measure of the potential burstiness of the source. Over short intervals of time, the bandwidth of the source can be larger than ρ , but over sufficiently large (depending on the value σ) intervals of time, the bandwidth is, essentially, at most ρ . The source or network can ensure conformance to this by using *leaky bucket flow control* [Turner, 1986], defined as follows.

A source is not allowed to transmit a packet unless it has a permit, and each transmitted packet by the source consumes one permit. As long as the number of permits is less than σ , the source receives new permits once every $(1/\rho)$ units of time. Thus, a source can accumulate up to σ permits. A packet that arrives when there are no permits can either be buffered by the source or discarded. Each ABR source could be assigned the parameters (σ, ρ) , where ρ is the allocated bandwidth of the source, and σ represents the allocated burstiness of the source, in some sense.

Non-ABR sources require a certain minimum bandwidth from the network for satisfactory operation and may also require that latency be bounded. Examples are multimedia sources, interactive database sources, distributed computing applications, and real-time applications. Leaky bucket flow control can also be applied to non-ABR sources. The parameter ρ specifies the maximum average bandwidth of the source, and the parameter σ measures the potential burstiness of the source, in some sense. If leaky bucket rate control is applied to all of the sources in the network, delay and buffering requirements can be controlled, and packet loss can be reduced or eliminated. Some recent analyses of this issue are presented in Cruz [1995, 1991a, 1991b]. We now briefly describe one important idea in these analyses.

A packet stream may become more bursty as it passes through network nodes. For example, suppose a packet stream arriving to a node is (σ, ρ) smooth, and that each packet has a delay in the node of at most d seconds. Consider the packet stream as it departs the node. Over any interval of length x , say, $[t, t + x]$, the packets that depart must have arrived to the switch in the interval $[t - d, t + x]$ since the delay is bounded by d . The number of these packets is bounded by $\rho(x + d) + \sigma = \rho x + (\sigma + \rho d)$, since the packet stream is (σ, ρ) smooth as it enters the node. Hence, the packet stream as it departs the node is

$(\sigma + \rho d, \rho)$ smooth and is potentially more bursty than the packet stream as it entered the node. Thus, as a packet stream passes through network nodes, it can get more bursty at each hop, and the buffering requirements will increase at each hop.

We note that buffer requirements at intermediate nodes can be reduced by using rate control (with buffering) to govern the transmission of packets *within* the network [Cruz, 1991b; Golestani, 1991]. This limits the burstiness of packet flow within the network, at the expense of some increase in average delay. It is also possible to reduce delay jitter by using this approach.

Defining Terms

ARQ protocol: An automatic repeat request (ARQ) protocol ensures reliable transport of packets between two points in a network. It involves labeling packets with sequence numbers and management of retransmission of lost or errored packets. It can be exercised on a link or an end-to-end basis.

Datagram network: A packet switched network that treats each packet as a separate entity. Each packet, or datagram, is forwarded to its destination independently. The data sources do not coordinate with the network or the destinations prior to sending a datagram. Datagrams may be lost in the network, without notification of the source.

Header field: A packet is generally divided into a header and a payload. The payload carries the data being transported, whereas the header contains control information for routing, sequence numbers for ARQ, flow control, error detection, etc. The header is generally divided into fields, and a header field contains information specific to a type of control function.

Packet switched network: A network where the fundamental unit of information is a packet. To achieve economy, the communication links of a packet switched network are statistically shared. Buffering is required at network nodes to resolve packet contentions for communication links.

Trunk reservation: A technique used in telephone networks whereby some portion of a communications link is reserved for circuits (trunks) that make most efficient use of the link. A link may reject a circuit request because of trunk reservation so that other circuits, which make better use of the link, may later be accepted.

Virtual circuit switched network: A packet switched network that organizes data packets according to the virtual circuit that they belong to. Packets from a given virtual circuit are routed along a fixed path, and each node along the path may reserve resources for the virtual circuit. A virtual circuit must be established before data can be forwarded along it.

37.1	Introduction
37.2	Transport Service
37.3	Data-Transfer Protocol
37.4	Connection-Management Protocol
37.5	Transport Protocols.
37.6	Conclusions

37.1 Introduction

The transport layer of a computer network is situated above the network layer and provides reliable communication service between any two users on the network. The users of the **transport service** are e-mail, remote login, file transfer, Web browsers, etc. Within the transport layer are **transport entities**, one for each user. The entities execute distributed algorithms, referred to as **transport protocols**, that make use of the message-passing service of the network layer to offer the transport service. The most well-known transport protocols today are the Internet Transmission Control Protocol (TCP), the original transport protocol, and the ISO TP4.

Historically, transport protocol design has been driven by the need to operate correctly in spite of unreliable network service and failure-prone networks and hosts. The channels provided by the network layer between any two entities can lose, duplicate, and reorder messages in transit. Entities and channels can fail and recover. An entity failure is fail-stop, that is, a failed entity performs no actions and retains no state information except for stable storage. A channel failure means that the probability of message delivery becomes negligible; that is, even with retransmissions, a message is not delivered within a specified time. These fault-tolerance considerations are still valid in today's internetworks.

To a first approximation, we can equate transport service to reliable data transfer between any two users. But reliable data transfer requires resources at the entities, such as buffers and processes for retransmitting data, reassembling data, etc. These resources typically cannot be maintained across failures. Furthermore, maintaining the resources continuously for every pair of users would be prohibitively inefficient because only a very small fraction of user pairs in a network exchange data with any regularity, especially in a large network such as the Internet.

Therefore, a transport service has two parts: **connection management** and **data transfer**. Data transfer provides for the reliable exchange of data between connected users. Connection management provides for the establishment and termination of connections between users. Users can open and close connections to other users and can accept or reject incoming connection requests. Resources are acquired when a user enters a connection and released when the user leaves the connection. An incoming connection request is rejected if the user has failed or its entity does not have adequate resources for new connections.

A key concern of transport protocols is to ensure that a connection is not infiltrated by old messages that may remain in the network from previous terminated connections. The standard techniques are to use the **3-way handshake** mechanism for connection management and the **sliding window** mechanism

for data transfer within a connection. These mechanisms use **cyclic sequence numbers** to identify the connection attempts of a user and the data blocks within a connection. The protocol must ensure that received cyclic sequence numbers are correctly interpreted, and this invariably requires the network to enforce a **maximum message lifetime**.

In the following section, we describe the desired transport service. We then describe a simplified transport protocol that illustrates the core of TCP and ISO TP4. We conclude with a brief mention of performance issues and *minimum-latency* transport protocols.

Unless explicitly mentioned, we consider a **client-server** architecture. That is, the users of the transport layer are partitioned into clients and servers, and clients initiate connections to servers. Every user has a unique identity (*id*).

37.2 Transport Service

This section explains the correctness properties desired of the transport layer. We first define the notion of **incarnations**. An incarnation of a client is started whenever the client requests a connection to any server. An incarnation of a server is started whenever the server accepts a (potentially new) connection request from any client. Every incarnation is assigned an **incarnation number** when it starts; the incarnation is uniquely distinguished by its incarnation number and entity *id*.

Once an incarnation x of an entity c is started in an attempt to connect to an entity s , it has one of two possible futures. The first possibility is that at some point x becomes open and acquires an incarnation number y of some incarnation of s —we refer to this as “ x becomes open to incarnation y of s ”; at some later point, x becomes closed. The second possibility is that x becomes closed without ever becoming open. This can happen to a client incarnation either because its connection request was rejected by the server or because of failure (in the server, the client, or the channels). It can happen to a server incarnation either because of failure or because it was started in response to a connection request that later turns out to be a duplicate request from some old, now closed, incarnation.

Because of failures, it is also possible that an incarnation x of c becomes open to incarnation y of s but y becomes closed without becoming open. This is referred to as a *half-open* connection.

A **connection** is an association between two open incarnations. Formally, a connection exists between incarnation x of entity c and incarnation y of entity s if y has become open to x and x has become open to y . The following properties are desired of connection management:

- **Consistent connections:** If an incarnation x of entity c becomes open to an incarnation y of entity s , then incarnation y is either open to x or will become open to x unless there are failures.
- **Consistent data transfer:** If an incarnation x of entity c becomes open to an incarnation y of entity s , then x accepts received data only if sent by y .
- **Progress:** If an incarnation x of a client requests a connection to a server, then a connection is established between x and an incarnation of the server within some specified time, provided the server does not reject x 's request and neither client, server, nor channels fail within that time.
- **Terminating handshakes:** An entity cannot stay indefinitely in a state (or set of states) where it is repeatedly sending messages expecting a response that never arrives. (Such *infinite chatter* is worse than deadlock because in addition to not making progress, the protocol is consuming precious network resources.)

Given a connection between incarnations x and y , the following properties are desired of the data transfer between x and y :

- **In-sequence delivery:** Data blocks are received at entity $y(x)$ in the same order as they were sent by $x(y)$.
- **Progress:** A data block sent by $x(y)$ is received at $y(x)$ within some specified time, provided the connection is not terminated (either intentionally or due to failures) within that time.

37.3 Data-Transfer Protocol

This section describes the sliding-window method for achieving reliable flow controlled data transfer, assuming that users are always connected and correctly initialized. Later we add connection management to this protocol.

Consider two entities c and s connected by unreliable network channels. The user at c produces data blocks to be delivered to the user at s . Because the channels can lose messages, every data block has to be retransmitted until it is acknowledged. For throughput reasons, entity c should be able to have several data blocks outstanding, that is, sent but not acknowledged. Similarly, entity s should be able to buffer data blocks received out-of-sequence (due to retransmissions or network reordering).

Let us number the data blocks produced by user c with successively increasing sequence numbers, starting from 0. The sliding window mechanism maintains two windows of sequence numbers, one at each entity.

Entity c maintains the following variables:

- na : $\{0, 1, \dots\}$; initially 0. This is the number of data blocks sent and acknowledged.
- ns : $\{0, 1, \dots\}$; initially 0. This is the number of data blocks produced by the local user.
- sw : $\{0, 1, \dots, SW\}$; initially 0. This is the maximum number of outstanding data blocks that the entity can buffer.

Data blocks na to $ns - 1$ are outstanding and must be buffered. The entity can accept an additional $sw - ns + na$ data blocks from its user, that is, data blocks ns to $na + sw - 1$. The sequence numbers na to $na + sw - 1$ constitute the **send window**, and sw is its size.

Entity s maintains the following variables:

- nr : $\{0, 1, \dots\}$; initially 0. This is the number of data blocks delivered to the user.
- rw : $\{0, 1, \dots, RW\}$; initially 0. This is the maximum number of data blocks that the entity can buffer.

Data blocks 0 to $nr - 1$ have been delivered to the user in sequence. A subset, perhaps empty, of the data blocks nr to $nr + rw - 1$ has been received and the blocks are buffered. The sequence numbers nr to $nr + rw - 1$ constitute the **receive window**, and rw is its size.

The easiest way for an entity to identify a received data block or acknowledgement is for the message to include the sequence number of the concerned data block. But such a sequence number field would grow without bound. Instead, the protocol uses cyclic sequence numbers; that is, $j \bmod N$, for some N , instead of the *unbounded* sequence number j .

To ensure that a received cyclic sequence number is correctly interpreted, it is necessary for the network to enforce a maximum message lifetime, that is, no message older than the lifetime remains in the network. It then suffices if N satisfies

$$N \geq SW + RW + \frac{L}{\delta}$$

where SW and RW are the maximum sizes of the send and receive windows, L is the maximum message lifetime, and δ is the minimum time between successive data block productions.

Flow control is another issue in data transfer, that is, entity c should not send data faster than the network or entity s can handle. By dynamically varying the send window size, the sliding window mechanism can also achieve flow control. In particular, consumer-directed flow control works as follows: entity s dynamically varies its receive window size to reflect local resource constraints and regularly requests entity c to set its send window size to the receive window size. Note that in this case, the previous condition on N reduces to $N \geq 2RW + L/\delta$.

We finish this section with a specification of the sliding window protocol. The data messages of the protocol have the form $(D, sid, rid, data, cj)$, where sid is the sender's id, rid is the intended receiver's id, $data$ is a data block, and cj is its cyclic sequence number.

Entity c

```
Accept datablock from user (data)
  ec: ns-na < sw
  ac: buffer data as datablock ns;
      ns := ns+1

Send datablock (j)           //also resends
  ec: 0 ≤ j ≤ ns-na-1
  ac: Send (D, c, s, datablock j, j mod N)

Reception of (ACK, s, c, cj, w)
  ac: tmp := (cj-na) mod N;
      if 1 ≤ tmp ≤ ns-na then
          delete datablocks na to na+tmp
              from send window;
          na := na+tmp;
          sw := w
      else if tmp = 0 then sw := max(sw, w)
      // else tmp > ns-na; do nothing
```

Entity s

```
Expand receive window
  ec: rw < RW
  ac: rw := rw+1

Deliver datablock to user (data)
  ec: datablock nr in receive window
  ac: data := datablock nr;
      nr := nr+1;
      rw := rw-1

Send acknowledgement
  ec: true           // also resends
  ac: Send (ACK, s, c, nr mod N, rw)

Reception of (D, c, s, data, cj)
  ac: tmp := (cj-nr) mod N;
      if 0 ≤ tmp < rw then
          buffer data as datablock nr+tmp;
      // else tmp ≥ rw; do nothing
```

FIGURE 37.1 Events of sliding window protocol.

The acknowledgment (ack) messages of the protocol have the form (ACK, *sid*, *rid*, *cj*, *w*), where *sid* and *rid* are as defined previously, *cj* is a cyclic sequence number, and *w* is a window size. When the message is sent, *cj* and *w* are set to the values of $nr \bmod N$ and *rw*, respectively. Thus, the message indicates the data block next expected in sequence. Because it acknowledges all earlier data blocks, it is referred to as a *cumulative ack*.

The events of the producer and consumer entities are shown in Fig. 37.1. There are two types of events. A *nonreceive* event has an enabling condition, denoted *ec*, and an action, denoted *ac*; the action can be executed whenever the event is enabled. A receive event for a message has only an action; it is executed whenever the message is received.

37.4 Connection-Management Protocol

This section describes a connection-management protocol. Traditional transport protocols, including TCP and TP4, identify successive incarnations by increasing, though not necessarily successively, incarnation numbers from some modulo-*N* space. Every entity uses a counter or a real-time clock to generate incarnation numbers for local incarnations.

Another feature of traditional transport protocols is that an entity stores a remote incarnation's number only while it is connected to the remote incarnation. This necessitates a 3-way handshake for connection establishment. A client that wants to connect to a server sends a connection request with its incarnation number, say, *x*. When the server receives this, it responds by sending a response containing *x* and a server incarnation number, say, *y*. When the client receives the response, it becomes open to *y* and responds by sending an ack containing *x* and *y*. The server becomes open when it receives the ack. The server could not become open when it received the connection request containing only *x* because it may have been a duplicate from a previous, now terminated, connection.

A 2-way handshake suffices for connection closing. An open entity sends a disconnect request that is acknowledged by the other entity. A 2-way handshake also suffices for connection rejection. It is obvious that a server may have to reject a connection request of a client. What is not so obvious is that a client may have to reject a "connection request" of a server. Specifically, if a server receives an old connection request from a terminated incarnation of the client, the server attempts to complete the second stage of the 3-way handshake. In this case, the client has to reject the server.

The unreliable channels imply that a k -way handshake has the following structure: In every stage except the last, a message is sent repeatedly until the message of the next stage is received. The message of the last stage is sent only in response, otherwise the handshake would never terminate.

It is convenient to think of the protocol as a distributed system that is driven by user requests. Each user request causes the associated entity to initiate a 2- or 3-way handshake with the other entity. At each stage of the handshake, one entity learns something about the other entity and may issue an appropriate indication to its local user. At the end of the handshake, the protocol has served the user request. The protocol's behavior can be complex because two handshakes can be executing concurrently, with one of them conveying information that is relevant to the other.

There is an intricate relationship between the modulo- N space of the incarnation numbers and the handshaking algorithms, much more so than in the case of data transfer, since the latter assumes correctly initialized users. To achieve correct interpretation of received cyclic incarnation numbers, it is necessary to have bounds on message lifetime, incarnation lifetime, wait duration, and recovery duration. Under the reasonable assumption that the incarnation lifetime dominates the wait and recovery durations, it is sufficient and necessary to have

$$N \geq \frac{4L + I}{\alpha}$$

where L is the maximum message lifetime, I is the maximum incarnation lifetime, and α is the minimum time between successive incarnation creations at an entity. Most references in the literature incorrectly assume that $N \geq 2L/\alpha$ is sufficient.

This bound may not be satisfiable for exceedingly long-lived incarnations, say, of the order of days. In that case, if we assume that the probability of two successive connections having identical modulo- N client and server incarnation numbers is negligible (it is approximately $1/N^2$ under reasonable assumptions of incarnation lifetimes), then the following bound, which does not depend on I , suffices:

$$N \geq \frac{4L}{\alpha}$$

We now give a specification of the connection-management protocol. A client entity maintains the following variables for each server s :

- $status[s]$: {CLOSED, OPENING, OPEN, CLOSING}; initially CLOSED. This is the status of the client's relationship with server s : CLOSED if client has no incarnation involved with s . OPENING means client has an incarnation requesting a connection with s . OPEN means client has an incarnation open to s . CLOSING means client has an incarnation closing a connection with s .
- $lin[s]$: {NIL, 0, 1, ...}; initially NIL. This is the local incarnation number: NIL if $status[s]$ equals CLOSED; otherwise identifies client incarnation involved with server s .
- $din[s]$: {NIL, 0, 1, ...}; initially NIL. This is the distant incarnation number: NIL if $status[s]$ equals CLOSED or OPENING; otherwise identifies the incarnation of server s with which the client incarnation is involved.

A server entity maintains the following state variables for each client c :

- $status[c]$: {CLOSED, OPENING, OPEN}; initially CLOSED. This is status of server's relationship with client c : CLOSED iff server has no incarnation involved with c . OPENING means server has an incarnation accepting a connection request from c . OPEN means server has an incarnation open to c .
- $lin[c]$: {NIL, 0, 1, ...}; initially NIL. This is local incarnation number: NIL if $status[c]$ equals CLOSED; otherwise identifies server incarnation involved with client c .
- $din[c]$: {NIL, 0, 1, ...}; initially NIL. This is the distant incarnation number. NIL if $status[c]$ equals CLOSED; otherwise identifies the incarnation of client c with which the server incarnation is involved.

The messages of the protocol have the form (M, sid, rid, sin, rin) , where M is the type of the message, sid is the sender's id, rid is the intended receiver's id, sin is the sender's incarnation number, and rin is the intended receiver's incarnation number. In some messages, sin or rin may be absent.

Each message is either a *primary* message or a *secondary* message. A primary message is sent repeatedly until a response is received or the maximum wait duration has elapsed. A secondary message is sent only in response to the reception of a primary message. Note that the response to a primary message may be another primary message, as in a 3-way handshake.

The messages sent by clients are as follows:

- (CR, sid, rid, sin) : Connection request; sent when opening; primary message.
- $(CRRACK, sid, rid, sin, rin)$: Acknowledgement to connection request reply (CRR); secondary message.
- (DR, sid, rid, sin, rin) : Disconnect request; sent when closing; primary message.
- (REJ, sid, rid, rin) : Reject response to a connection request reply that is received when closed. The sin of the received CRR is used as the value of rin ; secondary message.

The messages sent by servers are as follows:

- $(CRR, sid, rid, sin, rin)$: Reply to connection request in 3-way handshake; sent when opening; primary message.
- $(DRACK, sid, rid, sin, rin)$: Response to disconnect request; secondary message.
- (REJ, sid, rid, rin) : Reject response to a CR received when closed. The sin of the received message is used as the value of rin , secondary message.

The events of the client and server entities are shown in [Figs. 37.2](#) and [37.3](#), assuming unbounded incarnation numbers.

37.5 Transport Protocols

A transport protocol between a client entity c and a server entity s consists of a connection-management protocol augmented with two data-transfer protocols, one for data transfer from c to s and another for data transfer from s to c . At each entity, the data-transfer protocol is initialized each time the entity becomes open and its events are executed only while open. The data-transfer messages are augmented by incarnation number fields, which are used by receiving entities to filter out data-transfer messages of old connections.

We illustrate with the protocols of the previous sections. Start with the connection-management protocol of [Section 37.4](#) between c and s . Add two sliding window protocols, one from c to s and one from s to c , as follows:

- At each entity, introduce variables ns , na , sw , and the send window buffers for the outgoing data transfer and nr , rw , and the receive window buffers for the incoming data transfer. These data-transfer variables are initialized whenever the entity becomes open. Whenever the entity becomes closed, these variables are deallocated.
- Modify the client as follows. Add $status[s] = OPEN$ to the enabling condition of every data-transfer event. Add sin and rin fields to the sliding window protocol messages. When a data-transfer message is sent, sin is set to the local incarnation number $lin[s]$ and rin is set to the remote incarnation number $din[s]$. When a data-transfer message is received, first test for $status[s] = OPEN$, $sin = din[s]$ and $rin = lin[s]$. If the test fails, ignore the message, otherwise, process the message as in the sliding window protocol specification.
- Modify the server similarly.

There are various ways to extend and integrate the data-transfer protocols. The messages of the two data-transfer protocols can be combined. For example, the data messages sent by an entity can have

Client entity c: events concerning server s

```
Connect Request(s)
  ec: status[s] := CLOSED
  ac: status[s] := OPENING ; lin[s] := new incarnation number

Disconnect Request(s)
  ec: status[s] = OPEN
  ac: status[s] := CLOSING

Abort(s)
  ec: status[s] ≠ CLOSED & "response timeout"
  ac: status[s] := CLOSED ; lin[s] := NIL ; din[s] := NIL

SendCR(s)
  ec: status[s] = OPENING
  ac: Send ( CR, c, s, lin[s] )

SendDR(s)
  ec: status[s] = CLOSING
  ac: Send ( DR, c, s, lin[s], din[s] )

Receive (CRR, s, c, sin, rin)
  ac: if status[s] = OPENING & rin = lin[s] then
    status[s] := OPEN ; din[s] := sin ;
    Send (CRRACK, c, s, lin[s], din[s])

    else if status[s] = OPEN & rin = lin[s] & sin = din[s] then
      // duplicate CRR
      Send (CRRACK, c, s, lin[s], din[s])

    else if status[s] = OPEN & rin = lin[s] & sin > din[s] then
      // server crashed, recovered, responding to old CR
      Send ( REJ, c, s, sin ) ; status[s] := CLOSED ;
      din[s] := NIL ; lin[s] := NIL

    else if status[s] is CLOSED or CLOSING then Send ( REJ, c, s, sin )

Receive ( REJ, s, c, rin )
  ac: if status[s] is OPENING or CLOSING & rin = lin[s] then
    status[s] := CLOSED ; din[s] := NIL ; lin[s] := NIL
  //else status[s] is OPEN or CLOSED; do nothing

Receive ( DRACK, s, c, sin, rin )
  ac: if status[s] = CLOSING & rin = lin[s] & sin = din[s] then
    status[s] := CLOSED ; din[s] := NIL ; lin[s] := NIL
  // else status[s] is OPENING or OPEN or CLOSED; do nothing
```

FIGURE 37.2 Client events of connection management protocol.

additional fields to *piggy-back* acknowledgement information for incoming data, that is, fields for *nr* and *rw*. This is done in TCP and ISO TP4.

The preceding protocol uses cumulative acknowledgments. We can also use *reject* messages to indicate a gap in the received data. Rejects allow the data source to retransmit missing data sooner than cumulative acks. The protocol can also use *selective* acknowledgments to indicate correctly received out-of-sequence data. This allows the data source to retransmit only what is needed, rather than everything outstanding. Selective acks and rejects are not used in TCP and ISO TP4, although there are studies indicating that they can improve performance significantly.

Server entity s: events concerning client c

```
Abort(c)
  ec: status[c] ≠ CLOSED & "response timeout"
  ac: status[c] := CLOSED ; lin[c] := NIL ; din[c] := NIL

Send CRR(c)
  ec: status[s] = OPENING
  ac: Send ( CRR, s, c, lin[c], din[c] )

Receive ( CR, c, s, sin )
  ac: if status[c] = CLOSED & "rejecting connections" then
    Send ( REJ, s, c, sin ) ;
  else if status[c] = CLOSED & "accepting connections" then
    lin[c] := new incarnation number ;
    status[c] := OPENING ; din[c] := sin

  else if status[c] = OPENING & sin > din[c] then
    // previous din[c] value was from some old CR
    din[c] := sin

  else if status[c] = OPEN & sin > din[c] then
    // client crashed, reconnecting
    if "willing to reopen" then
      lin[c] := new incarnation number ;
      din[c] := sin ; status[c] := OPENING
    else status[c] := CLOSED ; lin[c] := NIL ; din[c] := NIL
    // else status[c] = OPEN & sin ≤ din[c]; do nothing

Receive ( CRRACK, c, s, sin, , rin, )
  ac: if status[c] = OPENING & sin = din[c] & rin = lin[c] then
    status[c] := OPEN
    // else status[c] is OPEN or CLOSED; do nothing

Receive ( DR, c, s, sin, rin )
  ac: if status[c] = OPEN & sin = din[c] & rin = lin[c] then
    Send ( DRACK, s, c, lin[c], din[c] );
    status[c] := CLOSED ; lin[c] := NIL ; din[c] := NIL

  else if status[c] = CLOSED then Send ( DRACK, s, c, rin, sin ) ;
  // else status[c] = OPENING; do nothing

Receive ( REJ, c, s, rin )
  ac: if status[c] = OPENING & rin = lin[c] then
    status[c] := CLOSED ; lin[c] := NIL ; din[c] := NIL
  // else status[c] is OPEN or CLOSED; do nothing
```

FIGURE 37.3 Server events of connection management protocol.

The preceding protocol uses fixed-size data blocks. An alternative is to send variable-sized data blocks. This can be done by augmenting the data messages with a field indicating the size of the data block. TCP does this with an octet, or byte, as the basic unit. A similar modification would be needed for selective acks.

The connection-management protocol can be extended and integrated in several ways.

The preceding protocol allows either user to close a connection at any point, without waiting for data transfer to be completed. An alternative is so-called *graceful closing*, where a user can close only its outgoing data transfer. The user must continue to handle incoming data until the remote user issues a close also. TCP has graceful closing, whereas ISO TP4 does not. It is a simple matter to add graceful closing to a protocol that does not have it.

It is possible to merge connection establishment, data transfer, and connection termination. The connection request can contain data, which would be delivered after the server becomes open. The connection request can also indicate that after the data is delivered, the connection is to be closed. TCP allows this.

TCP uses a single 32-b cyclic sequence number space to identify both incarnations and data blocks. When an incarnation is created at an entity, an **initial sequence number** is chosen and assigned to the incarnation. Successive new messages sent by the incarnation, whether of connection management or data transfer, occupy increasing sequence numbers starting from this initial sequence number.

TCP messages integrate both data transfer and connection management. Every TCP message has fields indicating the sequence number of the message, the next sequence number expected, the data segment (if any), the segment length, and receive window size. A connection-management message that requires an acknowledgement is considered to use up a sequence number, say, n . This means that the next new connection-management message sent by the entity, whether or not it requires an acknowledgement, would have the sequence number $n + 1$. The remote entity can acknowledge a connection-management message by sending a message of any type with its next expected sequence number field equal to $n + 1$.

The TCP messages SYN, SYN-ACK, ACK, FIN, FIN-ACK, and RST correspond, respectively, to the messages CR, CRR, CRRACK, DR, DRACK, and REJ of our protocol.

TCP provides **balanced opening**, a service that is outside the client-server paradigm. Here, if two entities request connections to each other at the same time, a *single* connection is established. In the client-server architecture, each entity would be considered to have a client-half and a server-half, and two connections would be established. In fact, TCP's algorithm for balanced opening is flawed: it may result in valid connection requests being rejected and invalid connection requests leading to connections. Fortunately, no application seems to use TCP's balanced-opening service. ISO TP4 does not have balanced opening.

37.6 Conclusions

This chapter has described the service expected of a transport layer and a distributed algorithm, or protocol, that achieves this service. The protocol faithfully illustrates the inner workings of TCP and ISO TP4. We conclude by outlining two currently active research areas in transport protocols.

One area is that of minimum-latency transport protocols. The delay in connection establishment incurred by the 3-way handshake is unacceptable for many transaction-oriented applications such as remote procedure calls (RPCs). Note that although transaction data can be sent with a connection request, the server cannot process the transaction until it confirms that this is a new request. This has motivated the development of transport protocols where the server can determine the *newness* of a connection request as soon as it is received, thereby achieving connection establishment with a 2-way handshake.

To achieve this, the server has to retain information about clients even when it is not connected to them. Consider a 3-way handshake between client incarnation x and server incarnation y . If the server had remembered the incarnation number, say, z , that the client had previously used when it connected to the server, then the server could determine that the connection request with x was new (because x would be greater than z). In that case, the server could have become open at once, resulting in a 2-way handshake connection establishment. A server cannot be expected to indefinitely remember the last incarnation number of every client to which it was connected, due to the enormous number of clients in a typical internetwork. However, a caching scheme is feasible, and several have been proposed, culminating recently in a proposed modification to TCP.

An alternative to caching is to use timer-based mechanisms. Here also, a server is required to maintain information on each client it has served for a duration comparable to that in cache-based mechanisms (the major component in both is the message lifetime). In most timer-based protocols, if a client's entry is removed before the specified duration, for example, due to a crash or memory limitation, then the server can incorrectly accept old connection requests of that client. Simple connection management protocol (SCMP) is an exception: assuming synchronized clocks maintains correctness, but it may reject

new connections for a period of time depending on clock skews and other parameters. In any case, timer-based approaches do not have a backup 3-way handshake.

Another area of current research concerns the performance of transport protocols. As mentioned earlier, transport protocol design has been historically driven by the need to operate correctly in spite of unreliable network service and failure-prone networks and hosts. This has resulted in the premise that transport protocols should have minimal knowledge of the network state. For example, message roundtrip times are the only knowledge that TCP has of the current network state.

In recent years, Internet traffic has grown both in quantity and variety, resulting in increasing utilization, delays, and often congestion. This has prompted the development of retransmission and windowing policies to reduce network congestion, mechanisms to reduce processing time for transport protocol messages, etc. However, this performance work is still governed by the premise, motivated by fault tolerance, that a transport protocol should have minimal knowledge of the network state.

It is not clear whether this premise would be valid for the high-speed networks of the near and far future. Current implementations of TCP use a very conservative flow control scheme: the source reduces its send window by a multiplicative factor whenever roundtrip times indicate network congestion, and increases the send window by an additive factor in the absence of such indication. Although this is very robust, it tends to underutilize the network resources. It should be noted that most protocol proposals for high-speed networks make use of some form of resource reservation to offer varying quality-of-service guarantees. It is not clear how this can be incorporated within the current TCP framework, or even whether it should be.

Defining Terms

3-way handshake: A handshake between two entities involving three messages, say m_1 , m_2 , m_3 . The initiating entity repeatedly sends m_1 . The other entity responds by repeatedly sending m_2 . The initiating entity responds by sending a single m_3 for each m_2 received.

Balanced-opening: Where two entities requesting connections to each other at the same time establish a single connection.

Client-server architecture: A paradigm where the users of the transport layer consist of clients and servers, connections are always between clients and servers, and connections are always initiated by clients.

Connection: An association between two open incarnations.

Connection management: That portion of the transport service and protocol responsible for the establishment and termination of connections between users.

Cyclic sequence numbers: The modulo- N sequence numbers used for identifying incarnations and data blocks.

Data transfer: That portion of the transport service and protocol responsible for the reliable exchange of data between connected users.

Incarnation: An instance of an entity created for a connection attempt.

Incarnation numbers: Sequence numbers for identifying incarnations.

Initial sequence numbers: The incarnation numbers of TCP.

Maximum message lifetime: The maximum duration for which a message can reside in the network.

Receive window: The data blocks that can be buffered at the consuming entity.

Send window: The data blocks that can be outstanding at the producing entity.

Sliding-window mechanism: A method for sending data reliably over unreliable channels, using cyclic sequence numbers to identify data, a send window at the data producer, and a receive window at the data consumer.

Transport entities: The processes within the transport layer.

Transport protocols: The distributed algorithm executed by the transport entities communicating over the network service.

Transport service: The service expected of the transport layer.

Further Information

The specification of TCP can be found in:

Postel, J. 1981. *Transmission Control Protocol: DARPA Internet Program Protocol Specification*. Request for Comment RFC-793, STD-007, Network Information Center, Sept.

The specification of ISO TP4 can be found in:

38.1 Introduction

This chapter summarizes what we have learned in the past decade of research into extremely high throughput networks. Such networks are colloquially referred to as *gigabit networks* in reference to the billion bit per second throughput regime they now operate in. The engineering challenges are in delivering this bandwidth *end-to-end* from hosts, through access networks and fast transmission systems, to receiving hosts. Hosts range through PCs, high-performance engineering workstations, to parallel supercomputing systems.

First, some history: high-throughput fiber optic networks, prototype high-speed packet switches, and high-performance workstations were all available in the late 1980s. A major engineering challenge was integrating these elements into a computer networking system capable of high application-to-application throughput. As a result of a proposal from D. Farber and R. Kahn (the Kahn/Farber Initiative) the U.S. Government [National Science Foundation (NSF) and DARPA] funded sets of collaborators in five gigabit testbeds. [Computer Staff, 1990]. These testbeds were responsible for investigating different issues, such as applications, metropolitan-area networks (MANs) vs. local-area networks (LANs), and technologies such as high performance parallel interface (HIPPI), asynchronous transfer mode (ATM), and synchronous optical network (SONET) [Partridge, 1993]. The Aurora gigabit testbed linked University of Pennsylvania (Penn), Bellcore, IBM, and MIT, with gigabit transmission facilities provided by collaborators Bell Atlantic, MCI, and Nynex (both Bell Atlantic and Nynex are part of Verizon), and was charged with exploring technologies for gigabit networking, whereas the other four testbeds were applications-focused and, hence, used off-the-shelf technologies. The results of Aurora work underpin most of today's high-speed network infrastructures.

Clark et al. [1993] set out the research goals and plans for the testbed and outlined major research directions addressed by the testbed. Aurora uniquely addressed the issues of providing switched infrastructure and high end-to-end throughput between workstation class machines. In contrast to supercomputers, these machines were, and are, the basis for most computing today.

Figures 38.1 and 38.2 provide illustrations of the Aurora geography and logical topologies, respectively. Sections 38.2–38.4 describe network host interface architectures that can operate in gigabit ranges,

^{*}Support for research reported by University of Pennsylvania came from Bellcore (which is now called Telcordia Technologies) (through Project Dawn), IBM, Hewlett-Packard, National Science Foundation and Defense Advanced Research Projects Agency (DARPA) through Corporation for National Research Initiative (CNRI) under cooperative agreement NCR-89-19038, and the National Science Foundation under CDA-92-14924.

multimedia aspects of gigabit networks, and the World Wide Web as an applications programming interface for gigabit (and beyond) networks. [Section 38.5](#) summarizes our state of knowledge. [Table 38.1](#) provides a compact summary of some major Aurora milestones.

38.2 Host Interfacing

Asynchronous transfer mode (ATM) networks were an attempt to use the same data units end-to-end, from host to host through the network. These units were small packets called *cells*, which were fixed in size (48 byte payloads and 5 byte headers). Aurora work showed that efficient, low-cost host/computer interfaces to ATM networks could be built and incorporated into a hardware/software architecture for workstation-class machines. This was believed to be problematic due to the nature of small, fixed-size ATM cells and their mismatch with workstation memory architectures. Penn designed [Traw and Smith, 1991] and implemented an ATM host interface for the IBM RISC System/6000 workstation, which connects to the machine's micro channel bus. It translated variable-size application data units into streams of fixed-size ATM cells using dedicated segmentation-and-reassembly logic. The novel application of a content-addressable memory, hardware-implemented linked-list manager, and the reassembly pipeline structure allowed use of a low clock speed and, hence, low-cost technologies. The cellification and decellification logic have measured performance which could support data rates of 600–700 Mb/s [Traw, 1995].

What this research illustrated was that hosts could achieve substantial throughputs by appropriate choice of protocol parameters (for example, by using large TCP/IP window sizes) over high performance wide-area networks. The ATM adapters carried out the job of converting between the variable-sized packet

TABLE 38.1 Aurora Gigabit Testbed: Selected Milestones

Date	Milestone
5/6/93	2.4 Gb/s OC-48 SONET backbone operational Penn <=> Bellcore
5/7/93	End-to-end data between workstations at Penn and Bellcore, interoperating Penn and Bellcore ATM host interfaces
5/19/93	Sunshine switches ATM cells between IBM RS/6000 at Penn and IBM RS/6000 at Bellcore
6/7/93	Penn and Bellcore ATM interfaces interoperate through Sunshine
6/8/93	End-to-end video over ATM from Penn workstation w/Penn video card to Bellcore workstation display
10/26/93	2nd Sunshine operational, at Penn
11/12/93	Full-motion A/V teleconference over packet transfer mode (PTM)/SONET, Penn <=> IBM
12/31/93	25 Mb/s TCP/IP over Aurora switched loopback
2/25/94	Cheap Video ATM appliance running over Aurora
3/15/94	Telementoring interactive distance learning over Aurora Penn <=> Bellcore using Cheap Video NTSC/ATM
3/30/94	70 Mb/s TCP/IP over Aurora between RS/6000s
4/17/94	MNFS/AIX solving differential heat equations over Aurora
4/21/94	Avatar, w/audio VC operational Penn <=> Bellcore, and IBM PVS IBM <=> over PlaNET, and VuNet Penn <=> MIT
5/6/94	Avatar in operation Penn <=> MIT
12/31/94	Link to IBM and MIT taken out of operation
7/5/95	HP PA-RISC/Afterburner ATM Link Adapter achieves 144 Mb/s TCP/IP
8/22/95	ATM Link Adapter achieves 215 + Mb/s TCP/IP

abstraction used by the hosts and applications and the cell abstraction used by the network infrastructure. Today's deployed infrastructures use 100 megabit or gigabit ethernet [Seifert, 1999] local area networks as interconnects rather than ATM switches, and, thus, the size conversions that take place are between the application's preferred data unit size and the approximately 1500 byte MTU resulting from limitations on the size of ethernet frames. Such conversions, as they are on larger data units, are less frequent than with ATM networks and so can be performed by host software.

A continuing concern with advanced applications such as medical imaging, e-commerce and commercial teleconferencing is privacy. Privacy transformations have traditionally been rather slow due to the *bit-complexity* of the substitution—and confusion—introducing operations. Augmentation of network host interfaces with cryptographic hardware to achieve high performance [Smith, Traw, and Farber, 1992] has been designed; this work was based on earlier observations by Broscius and Smith [1991] describing the use of parallelism to achieve high performance in an implementation of the National Bureau of Standards (NBS)

data encryption standard. Smith, Traw, and Farber [1992] describe the history and motivation for the architecture and explain how to insert a high-performance cryptographic chip (for example, the VLSI Technologies VM007 data encryption standard (DES) chip, which operates at 192 Mb/s) into the ATM host interface architecture. The resulting system is able to operate at full network speed while providing a per-cell (agile) per virtual channel identifier (VCI) rekeying; both the performance and the operation are transparent to the host computer while providing much greater key control than possible with link encryption approaches. A current implementation using the new Advanced Encryption Standard (AES) based on the Rijndael cipher may be able to operate up to 10 Gb/s. The difficulty of getting data to and from the encrypting hardware through a bus remains—one attractive solution (which may or may not be economically feasible) is the use of a *cryptographic coprocessor* attached directly to the CPU.

A key principle in interface design is to leave all but the most bit-intensive tasks to software. This is one of the virtues of the ethernet design and is among the many reasons for its longevity. A number of researchers in the early 1990s (in particular Van Jacobson) characterized this approach as WITLESS, for *workstation interface that's low-cost efficient and stupid*. This approach was adopted by Traw and Smith [1991] and used no microcontrollers in a simple all-hardware adapter, with careful separation of functions between hardware and software implementation. Traw and Smith [1993] report on the implementation of the ATM host interface and its support software. The architecture is presented in detail, and design decisions are evaluated. Later work [Smith and Traw, 1993] focused attention on the adapter to application path through software, and some of the key design decisions embedded in the software are examined. Of particular interest are the system performance measures where the adaptor operates with a significant application workload present.

The initial software subsystem provided an application programmer interface roughly equivalent to a raw Internet protocol (IP) socket and was able to achieve more than 90% of the hardware subsystem's performance, thus driving an optical carrier level 3 (OC-3) at its full 155 Mb/s rate. Key innovations were the reduction of data copying (through use of virtual memory (VM) support; this direction was later followed by others, including the University of Arizona team [Druschel, Peterson, and Davie, 1994] designing software for the Osiris [Davie, 1993] interface developed at Bellcore by Bruce Davie) and the partitioning of functions between hardware and software. As can be seen from Table 38.2 [Druschel et al., 1993] this reduction in data copying was necessitated by the memory bandwidth limitations of early-1990s workstations. The bottleneck on the IBM RS/6000 was initially the workstation's system bus to I/O bus interconnect [Traw and Smith, 1993], however, improvements to the I/O subsystem architecture moved the bottleneck to the physical link. For the Hewlett-Packard (HP) PA-RISC implementation [Traw, 1995] designed to demonstrate scaling of the host interface architecture to higher speeds, the bottleneck was the bus attachment (for this environment, the SGC graphics bus served as the attachment point).

The HP PA-RISC/afterburner ATM link adapter held a record for highest reported transport control protocol (TCP)/IP/ATM performance of 215 + Mb/s for almost one year. This performance was measured between two HP PA-RISC 755s, connected by a 320 Mb/s SONET-compliant null modem, using the *netperf* test program. The best performance was achieved using a 32-kilobyte socket buffer size and 256-kilobyte packets.

The lessons from this research have made their way into common use in all modern systems software. As Table 38.2 illustrates, the memory bandwidths of the second generation of RISC workstations, with

TABLE 38.2 Workstation Memory Bandwidths, Early 1990s

	Memory (Mb/s, peak)	CPU/Memory (Mb/s, sustained)		
		Copy	Read	Write
IBM RS/6000 340	2133	405(0.19)	605(0.30)	590(0.28)
Sun SS 10/30	2300	220(0.10)	350(0.15)	330(0.14)
HP 9000/720	1600	160(0.10)	450(0.28)	315(0.20)
Dec 5000/200	800	100(0.13)	100(0.13)	570(0.71)

the exception of the RS/6000, were poor. The designers relied on effective caches to maintain high instruction processing rates. While the architectures were effective on scientific workloads, they were far less effective when the data was moved to and from memory as they are in moving to and from the network. If anything, in the first decade of the 21st century, the ratio between CPU performance and memory throughput has gotten worse rather than better, and thus the need for reducing memory copies has increased. Pragmatically, if a modern host is achieving any approximation to a gigabit of throughput through a Gb/s ethernet adapter, it is copying the data only once.

38.3 Multimedia Services

Multimedia services for a networking infrastructure capable of gigabit throughputs must be designed with scale, endpoint heterogeneity, and application requirements as the key driving elements. For example, an integrated multimedia architecture with which applications define which data are to be bundled together for transport and select which data are unbundled from received packages can be far more receiver-driven in nature. Later work in the Internet community took this approach by “layering” different qualities of media delivery, so that receivers can select the quality of video which they choose to reproduce. This allows sources to choose the degree of resource allocation they wish to provide; receivers choose which elements of the package they wish to produce. Although potentially wasteful of bandwidth, the massive reduction in the multiplicity of customized channels allows sources to service a far greater number of endpoints and receivers to accommodate endpoint resources by reproducing what they are capable of. The scaling advantage of this approach is that much of the complexity of customization is moved closest to the point where customization is required, namely, the endpoint.

Multimedia appliances [Udani, 1992] were developed in anticipation of readily available bandwidth, an approach which is now again revived with the model of “always-on” Webcams. For example, this led to the all-hardware National Television Systems Committee (NTSC)/ATM Avatar ATM [Marcus and Traw, 1995] card, which supports NTSC video and CD-quality audio, and is the first example of an ATM appliance, with a parts cost (in 1993) of under \$300. Many of these cards were fabricated. They were used for distance teaching when connecting experimental “Video Windows,” for collaborative work between researchers at Penn and Bellcore, and for teleconferencing between Penn and Massachusetts Institute of Technology (which had its own extensive research effort in ubiquitous ATM hardware, the ViewStation, modeled after the Desk Area Network at Cambridge University).

Multimedia provision relies on the development of operating system abstractions which can support high-speed applications. These abstractions use the hardware and low-level operating system support of the operating system to provide an application-centered model of quality of service (QoS) requirements. Novel technical means had to be developed for bandwidth allocation implementations, e.g., support from the operating system scheduling mechanism for true end-to-end service delivery. Nahrstedt [1995] identified the software support services needed to provide QoS guarantees to advanced applications that control the characteristics of their networking system and adapt within parameterized limits. These services form a kernel, or a least common subset of services, required to support advanced applications.

A logical relationship between applications-specified QoS [Nahrstedt and Smith, 1996], as well as operating system policy and mechanism, and network-provided QoS was developed. An example challenge is the kinematic data stream directing a robotic arm, which can tolerate neither packet drops nor packet delays—unlike video or audio, which can tolerate drops but not delays. The approach used is a bidirectional translator (like a compiler/uncompiler pair for a computer language) which resides between the network service interface and the applications’ service primitives. This can dynamically change QoS as application requirements or network capabilities change, allowing better use of network capacity, which can be mapped more closely to application’s current needs than if a worst-case requirement is maintained. The implementation [Nahrstedt, 1995] outlined the complete requirements for such a strategy, including communication primitives and data necessary for translation between network and application. For example, an application request to zoom and refocus a camera on the busiest part of a scene will certainly require peer-to-peer communication between the application and the

camera management entity. The network may need to understand the implications for interframe compression schemes and required bandwidth allocations. The translation method renegotiates QoS as necessary.

These ideas were described in Nahrstedt and Smith [1995], which describes a mechanism to provide bidirectional negotiation of quality-of-service parameters between applications and the other elements of a workstation participant in advanced network applications. The scheme is modeled on a *broker*, a traditional mechanism for carrying on back-and-forth negotiations while filtering implementation details irrelevant to the negotiation. The QoS broker reflects both the dynamics of service demands for complex applications and the treatment of both applications and service kernels as first-class participants in the negotiation process. The QoS broker was implemented in the context of a system for robotic teleoperation. The broker was implemented and evaluated as part of a complete end-to-end architecture Nahrstedt [1995].

Gigabit multimedia is much desired by the applications community. Applications include high-quality (e.g., HDTV) movies, interactive games, and ultra-high-quality conferencing.

38.4 The World-Wide Web

One of the major questions addressed in the gigabit testbeds was what application programming interface would be used. The connection-oriented model of telephony and TCP/IP was looking limited, especially in the face of long latencies and clashes between the connection-oriented model and the object-access paradigm (memory and files) used in computer systems. Farber [1995] had proposed distributed shared memory (DSM) as a technology solution for integrating computation and communications more closely. At about the same time that the gigabit testbed research was underway, a new paradigm for network resource access was being developed, the World Wide Web. This model relied on a hypertext model—one where documents are named and may link to other named documents. The naming paradigm, such as <http://my.location.edu/~me/myfile>, incorporates both the object name and its location in its name, allowing non-local objects to be referenced and fetched. In this sense, then, the Web can be seen as a very loosely coupled distributed shared memory. Thus, the Web satisfies some interesting properties when viewed as a memory. First, it can be searched—this is exemplified by various Web-crawling programs, such as <http://www.google.com>, which make the Web into the equivalent of a large-scale content addressable memory. Second, the objects referenced are often visual. As Shaffer's thesis [Shaffer 1996] showed, the benefits of high bandwidth accrue directly to applications requiring high throughput by reducing the perceived latency to the application (such as a web browser) for remotely referencing the object. This advantage will continue to accrue as Web caches are used to reduce the effects of other latencies such as disk accesses and round-trip delays and will be amplified as protocols such as parallel HTTP and persistent HTTP are used to overcome some of the delay inherent in TCP/IP's slow-start behavior.

The Web is a superb application for end-to-end gigabit networks, as the availability of bandwidth makes more complex content and even the multimedia services of the previous section available to users. Fortunately, the workstations, LANs, and core networks have been evolving rapidly. Less fortunately, deployment of broadband to the home, where most people access the Web, has been far too slow.

38.5 Conclusions

There is an old network saying: Bandwidth problems can be cured with money. Latency problems are harder because the speed of light is fixed—you can't bribe God.

—D. Clark [Patterson and Hennessy, 1996]

The Aurora gigabit testbed research had a fundamental influence on the design and development of network technology. The host interface work answered concerns about the viability of ATM segmentation and reassembly (SAR) and made the performance concerns expressed when the testbeds were begun nonissues. Host interface work from Aurora has influenced all of today's commercial products, both ATM and ethernet [Chu, 1996].

Operating systems research at Penn and later work at the University of Arizona showed how to reduce copying between host interfaces and applications through careful management of DMA, buffer pools, and process data access [Chu, 1996]. Operating systems can deliver gigabit range throughputs to applications with appropriate restructuring and rethinking of copying and protection boundary crossing.

The still unanswered questions revolve around the discovery and evaluation of mechanisms that deliver a practical reduction in latency to applications. These include better cache management algorithms for shared objects as well as techniques for look-ahead referencing, or prefetching. Another important area is the reduction in operating system induced costs in network latency. The multimedia work in the gigabit networking research community [Steinmetz and Nahrstedt, 1995] has had impact on the operating systems and robotics communities. It also pointed out some issues to be avoided in adapter design, such as head-of-line blocking observed in serial DMA of large media objects.

The Web remains the most exciting frontier for high-speed networking, as user demand for bandwidth appears insatiable. The increasing availability of home broadband, in the form of digital subscriber line and ever-faster cable modem bandwidths, and eventually fiber-to-the-home, will make gigabit networking for all a reality, a path illuminated by the early work in the Aurora gigabit testbed.

39.1 Introduction

Local area networks (LANs) are computer networks operating over a small area such as a single department in a company. Typically, a single LAN will support a small number of users (say, less than 25). Most LANs provide communications between terminals, PCs, workstations, and computers. Local area networks were first created in the late 1970s and early 1980s. Today, LANs may carry a variety of traffic, such as voice, video, and data.

In general, the elements of a computer or local area network must follow compatible rules of operation together to function effectively. These rules of operation are known as protocols. A variety of LANs, operating under different protocols, are available today. These are described below.

39.2 Local Area Networks (LANs)

There are a variety of local network architectures that have been commercially produced to date including ethernets, token rings, wireless LANs, and others. A number of these have been standardized in the IEEE 802 series standards.

Ethernet

Ethernet is a very popular LAN technology that has several versions. The original IEEE 802.3 standard deals with a network architecture and protocol first constructed at Xerox in the 1970s and termed “ethernet.” All stations in the original ethernet protocol are connected, through interfaces, to a coaxial cable that is run through the ceiling or floor near each user’s computer equipment.

The coaxial cable essentially acts as a private radio channel for the users. An interesting protocol called Carrier Sense Multiple Access with Collision Detection (CSMA/CD) is used in such a network. Each station constantly monitors the cable and can detect when it is idle (no user transmitting), when one user is transmitting (successfully), or when more than one user is simultaneously transmitting (resulting in an unsuccessful collision on the channel). The cable basically acts as a broadcast bus. Any station can transmit on the cable if the station detects it to be idle. Once a station transmits, other stations will not interrupt the transmission. As there is no central control in the network, occasionally two or more stations may attempt to transmit at about the same time. The transmissions will overlap and be unintelligible (collision).

The transmitting stations will detect such a situation and each will retransmit at a randomly chosen later time. Ethernet operates at 10 Mbps.

Computer capabilities have increased significantly since the introduction of standard 802.3. To keep pace, a 100 Mbps version of Ethernet was standardized in 1995. Furthermore, gigabit ethernet became available in the late 1990s. All versions of ethernet today are generally wired together using a star type-wiring pattern with hubs at the center. Hubs are boxes that provide media sharing or switching capabilities for interconnecting local computers. Moreover, all versions of ethernet today support the use of twisted pair or fiber optics for wiring.

The 100 Mbps version of ethernet is known as fast ethernet (IEEE 802.3u). To maintain channel utilization at a similar rate as 802.3, in spite of the ten-fold speed increase, the maximum segment length is ten times smaller for 802.3u compared to 802.3. A combination of ternary signaling (i.e., three logic levels) and parallel wiring is used to achieve a fast ethernet version 100 Base-T4 signaling speed only 25% higher (at 25 MHz) than that for 802.3. The 100-Base-TX version uses twisted pair wires and handles full duplex 100 Mbps transmission with the use of 4B5B coding. The 4B5B coding provides sufficient logic transitions, in spite of long message runs of 1s or 0s, for digital receivers to lock on to for synchronization.

The gigabit (1000 Mbps) version of ethernet is known as gigabit ethernet. To maintain channel utilization at a similar value as 802.3 and 802.3u in spite of the speed increase, the minimum frame length has been increased to 512 bytes from 512 bits. Gigabit standard IEEE 802.3z allows the use of fiber optic transmission while IEEE 802.ab allows the use of twisted pair wiring. Older PCs may not be able to keep up with gigabit ethernet, and performance may actually degrade.

There is work on developing a 10 Gbps version of ethernet. This is a more difficult task than creating some of the previous variants as it is not possible to reuse certain technology from other networks, as was done in creating fast ethernet and gigabit ethernet. The forthcoming 10 Gbps ethernet standard is IEEE 802.3ae and should be finalized in 2002. Pre-standards products appeared in the market in late 2000/early 2001 and standards compliant products after the standards ratification. One version of the standard allows single mode fiber optic transport for 40+ km. Another means of 10 Gbps ethernet transport is on SONET OC-192 links.

There have been efforts to create a multimedia ethernet known as Iso-ethernet (IEEE 802.9). By using 4B5B (80% efficiency) instead of 802.3s Manchester encoding (50% efficiency), one can use 802.3 wiring with a 60% boost in speed. Specifically, an Iso-ethernet has a speed of 16.384 Mbps. This can be allocated either mostly to multimedia traffic (all isochronous mode) or split between 10 Mbps of regular ethernet packet service and 6.144 Mbps of multimedia traffic (multiservice mode).

Ethernet, in all its variety, is the most popular LAN to date. For instance, a 1999 Sage Research survey of 700 US organizations indicated that half the organizations planned to buy fast ethernet by the end of 1999.

Token Ring

Token rings are covered by the IEEE 802.5 standard. Token ring LANs were developed by IBM in the early 1980s. Logically, stations are arranged in a circle with point-to-point links between neighbors. Transmissions flow in only one direction (clockwise or counter-clockwise). A message transmitted is relayed over the point-to-point links to the receiving station and then forwarded around the rest of the ring and back to the sender to serve as an acknowledgement.

Only a station possessing a single digital codeword known as a “token” may transmit. When a station is finished transmitting, it passes the token to its downstream neighbor. Thus, there are no collisions in a token ring and utilization can approach 100% under heavy loads.

Because of the use of point-to-point links, token rings can use various transmission media such as twisted pair wire or fiber optic cables. The transmission speed of an 802.5 token ring is generally 4 or 16 Mbps. A standard for a 100 Mbps variant of token ring is 802.5t and a standard for a gigabit variant is 802.5v. Token rings are often wired in star configurations for ease of installation.

Token Bus

Token bus operation is standardized in the IEEE 802.4 standard. A token bus uses a coaxial cable along with the token concept to produce a LAN with improved throughput compared to the 802.3 protocol. That is, stations pass a token from one to another to determine which station currently has permission to transmit. Also, in a token bus (and in a token ring), response times can be deterministically bounded. This is important in factory automation where commands to machines must be received by set times. By way of comparison, response times in an ethernet-like network can only be probabilistically defined. This is one reason General Motor's Manufacturing Automation Protocol made use of the token bus. Token buses can operate at 1,5, and 10 Mbps.

Wireless LANs

Wireless LANs use a common radio channel to provide LAN connectivity without any physical wiring. Protocols for wireless LANs include the IEEE 802.11 standard. One might consider the use of a CSMA/CD protocol in this environment. However, it is not possible to implement the collision detection (CD) part of CSMA/CD in a radio environment. Therefore, a modified protocol known as CSMA/CA is used. CSMA/CA stands for Carrier Sense Multiple Access with Collision Avoidance. In this variant on CSMA, a station requests permission from a station it wishes to transmit to.

An industrial, science, and medical (ISM) band (at 2.4 GHz) is used for 802.11 transmission. The two architectures envisioned are tying stations to a local access point (i.e., base station) connected to a backbone or direct "ad hoc" station to station communication. Spread spectrum technology is used in 802.11. Transmission speed is in the low megabit range. The 802.11 standard was finalized in 1997.

A newer standard, IEEE 802.11b, allows data transfer at up to 11Mbps. It uses WEP (wired equivalency privacy) encryption for security.

There are also other wireless products such as bluetooth (802.15). Bluetooth establishes a wireless link between devices such as laptops and printers.

An alternative wireless LAN technology uses infrared light as the transmission medium. There are both direct infrared systems (range: 1-3 miles) and non-direct systems (bounced off walls or ceilings). For small areas, data rates are consistent with those of existing ethernet and token ring networks with 100 Mbps systems possible.

IEEE 802.12

As mentioned, in going from a speed of 10 Mbps to 100 Mbps in creating fast ethernet, it was necessary to reduce the maximum LAN segment size by a factor of ten in order to maintain channel utilization at a reasonable level. Some people considered this an undesirable compromise. A group of parties split off from the 802.3 standardization effort and sought to develop a completely new protocol, known as 802.12. This protocol operates at 100 Mbps. The standard makes use of hubs called repeaters. A station wishing to transmit sends a request to a hub. The repeater arbitrates among requests using a round robin algorithm. That is, each station requesting access is given some access in turn. Trees of repeaters are possible. Either twisted pair or fiber optics can be used. There is a priority structure in 802.12. This protocol can also be adapted to higher speeds.

ATM LANs and Backbones

ATM stands for asynchronous transfer mode. This is a packet switching technology utilizing relatively short, fixed length packets to provide networking services. ATM was originally seen as a way to develop the next generation wide area telephone network using packet switching, rather than the more conventional circuit switching technology. It was envisioned as a way to transport video, voice, and data in an integrated network. A short packet size was chosen to meet several requirements including minimizing real time queueing delay.

While progress on the original goal of using ATM technology in wide area telephone networks proceeded slowly because of the complexity of the challenge and the large investments involved, a number of smaller companies introduced ATM local area network and backbone products using much the same technology. Backbones are high speed networks used to interconnect LANs.

An ATM network consists of one or more switches. There are several possibilities for the internal architecture of the switch. A low cost switch may essentially be a computer bus in a box. More sophisticated switches may use switching fabrics. These are VLSI implementations of patterned networks of simple switching elements, sometimes referred to as space division switching. A great deal of effort has gone into producing cost-effective ATM switches. It should be pointed out that many of the issues that are difficult for wide area network ATM (i.e. traffic policing, billing) are more tractable in the private ATM LAN/backbone environment.

39.3 The Future

The future is likely to see an increase in data rates. This will spur the development of faster switching nodes through the use of parallel processing and VLSI implementation. Protocols will have to be simplified to increase processor throughput. Higher speed computer networks in general, and LANs in particular, will continue to proliferate throughout the world, making possible ubiquitous communications between any two points on the globe.

Defining Terms

Area networks: LAN, within single building; MAN, metropolitan sized region; WAN, national/international region.

Coaxial cable: A shielded cable that conducts electrical signals and is used in older bus type local area networks.

Fiber-optic cable: A glass fiber cable that conducts light signals. Fiber optic cables can carry data at very high speeds and are immune to electrical interference.

SONET: Synchronous optical network. A widely used fiber optic standard.

Twisted pair wire: Two thin wires that are twisted together. Wires with different numbers of twists per unit length are available that provide different amounts of rejection to electromagnetic interference.

The following are the IEEE 802 series of standards related to local area networks.

IEEE 802.3: Ethernet (CSMA/CD bus) protocol standard.

IEEE 802.3u: Fast ethernet (100 Mbps).

IEEE 802.3z: Gigabit ethernet (fiber).

IEEE 802.3ab: Gigabit ethernet (twisted pair).

IEEE 802.3ae: Ten gigabit ethernet.

IEEE 802.4: Token bus standard.

IEEE 802.5: Token ring standard.

IEEE 802.5t: Token ring (100 Mbps).

IEEE 802.5v: Token ring (gigabit).

IEEE 802.9: Iso-ethernet.

IEEE 802.11: CSMA/CA wireless LAN standard.

IEEE 802.11b: Wireless LAN (11 Mbps).

IEEE 802.12: Demand priority protocol.

IEEE 802.15: Bluetooth.

40.1 Introduction

In the last decades, separate communication networks have been deployed to support specific sets of services. For example, voice communication services (and, transparently, some low-speed data services) are supported by circuit switched networks, whereas packet switched networks have been specifically designed for low-to-medium speed data services. During the 1980s, a worldwide research effort was undertaken to show the feasibility of packet switches capable of supporting narrowband services, such as voice and low-to-medium speed communications, together with broadband services, such as high-speed data communications and those services typically based on video applications.

The challenge of the forthcoming broadband-Integrated Services Digital Network (B-ISDN), as envisioned by the International Telecommunication Union—Telecommunication Standardization Sector (ITU-TSS), is to deploy a unique transport network based on *asynchronous time-division* (ATD) multiplexing and switching that provides a B-ISDN interface flexible enough to support all of today's services (voice and data) as well as future narrowband (for data applications) and broadband (typically for video applications) services to be defined. With ATD, the bandwidth is not preallocated in the transmission and switching equipment of the broadband network so as to fully exploit by statistical multiplexing the available capacity of communication resources. ITU-TSS has defined a standard for the transfer mode based on ATD switching called the **asynchronous transfer mode (ATM)** [ITU, 1993].

This chapter is intended to present a brief review of the basic ATM concepts, as well as of the main architectural and performance issues of ATM switching. The basic principles of the asynchronous transfer mode are described in [Section 40.2](#), whereas the model of an ATM switch is presented in [Section 40.3](#) by discussing its main functions. Three main classes of ATM switching fabrics are identified therein based on the characteristics of their *interconnection network* (IN), and the basic characteristics and properties for each class are discussed in the following sections. ATM switches whose IN is blocking with minimum

depth and arbitrary depth are dealt with in [Sections 40.4](#) and [40.5](#), respectively, whereas architectures with nonblocking IN are reported on in [Section 40.6](#).

40.2 The ATM Standard

Time-division multiplexing (TDM) today is the most common technique used to transport on the same transmission medium tens or hundreds of channels, each carrying an independent digital flow of information, typically digitized voice signals. A preventive per-channel allocation of the transmission capacity, in terms of a set of slots within a periodic frame, is done with TDM that time interleaves the supported channels onto the same transmission medium. Therefore, a rigid allocation of the transmission resource is obtained, in which the available bandwidth is fully used only if all of the channels are active at any time; that is, all of the channel slots carry user information. Therefore, TDM is well suited to support communication services with a high activity rate, as in the case of voice services, since other services whose information sources are active only for a small percentage of time, typically data services, would waste transmission bandwidth.

The asynchronous time division (ATD) technique is intended to overcome this problem by enabling the sharing of transmission and switching resources by several channels without any preventive bandwidth allocation to the single users. Therefore, by means of a suitable storage capability, information from the single channels can be statistically multiplexed onto the same communication resource, thus avoiding resource wastage when the source activity is low. Asynchronous time-division multiplexing (ATDM) requires, however, each piece of information to be accompanied by the owner information, which is no longer given by the position of the information within a frame, as in the case of TDM. Switching ATDM channels requires the availability of ad-hoc packet switching fabrics designed to switch enormous amount of information when compared to the switching fabrics of current narrowband packet switched networks.

The B-ISDN envisioned by ITU-TSS is expected to support a heterogeneous set of narrowband and broadband services by sharing as much as possible the functionalities provided by a unique underlying transmission medium. ATM is the ATD-based transport mechanism to be adopted in the lower layers of the protocol architecture for this purpose [ITU, 1993]. Two distinctive features characterize an ATM network: (1) The user information is transferred through the network in small fixed-size units, called **ATM cells**, each 53 bytes long, divided into a *payload* (48 bytes) for the user information and a *header* (5 bytes) for control data. (2) It is a *connection-oriented* network, that is, cells are transferred onto previously set-up virtual links identified by a label carried in the cell header. Both *virtual connections* (VC) and *virtual paths* (VP) are defined in the B-ISDN. A logical connection between two end users consists of a series of $n + 1$ virtual channels if n switching nodes are crossed. A virtual path is a bundle of virtual channels. Since a virtual channel is labeled by means of a hierarchical key virtual path identified/virtual channel identifier (VPI/VCI), a switching fabric can operate either a full VC switching or just a VP switching.

The B-ISDN protocol architecture includes three layers that, from the bottom up, are referred to as the *physical layer*, *ATM layer*, and *ATM adaptation layer* (AAL) [ITU, 1991]. The task of the physical layer is to provide a transmission capability for the transfer of ATM cells. Its functionalities include some basic tasks, such as timing, cell delineation, cell header verification, etc. Since the standard interface has the minimum rate of about 150 Mb/s, even ATM switching nodes of medium size with, say, 128 input and output links must be capable of carrying loads of tens of gigabits per second. The ATM layer includes the VCI/VPI translation, the header generation and extraction, and the multiplexing/demultiplexing of cells with different VCI/VPI onto the same physical layer connection. The purpose of the ATM adaptation layer is to add different sets of functionalities to the ATM layer so as to differentiate the kinds of services provided to the higher layers. Four service classes are defined to support connection-oriented and connectionless services. These services range from circuit emulation and variable bit rate video to low-speed data services. Even if the quality-of-service parameters to be guaranteed for each class are still to be

defined, the B-ISDN network should be able to provide different traffic performance to each service class in terms of packet loss and delay figures.

40.3 Switch Model

Research in ATM switching has been developed worldwide for several years showing the feasibility of ATM switching fabrics. However, a unique taxonomy of ATM switching architectures is very hard to find since different keys used in different orders can be used to classify ATM switches. Very briefly, we can say that most of the ATM switch proposals rely on the adoption for the interconnection network, which is the switch core, of multistage arrangements of very simple switching elements (SEs), each using the **cell self-routing** concept. This technique consists of allowing each SE to switch (route) autonomously the received cell(s) only using a self-routing label preceding the cell. Even if other kinds of switching architectures can be used as well (e.g., shared memory or shared medium units), multistage INs provide the processing power required to carry the above-mentioned load foreseen for small-to-large-size ATM switches. The interconnection network, which is the ATM switch core, operates by transferring in a time window, called the *slot*, the packets, which are received aligned by the IN from the switch inlets to the requested switch outlets.

Rather than using technological features of the switching architecture, the main key to classify the switch proposals can be found in the functional relationship setup between inlets and outlets by the switch. Multistage INs can be basically classified as **blocking** or **nonblocking**. In the former case, different input/output (I/O) paths within the IN can share some interstage links; thus, the control of packet loss events requires the adoption of additional techniques, such as the packet storage capability in the SEs (**minimum-depth** INs) or deflection routing (**arbitrary-depth** INs). In the latter case, different I/O paths are available so that SEs do not need internal buffers and are much simpler to implement (a few tens of gates per SE). Nevertheless, these INs require more stages than blocking INs. A further distinctive feature of ATM switches is where the buffers holding cells are placed; three configurations are distinguished with reference to each single SE or to the whole IN, that is, **input queueing**, **output queueing**, and **shared queueing**.

We will refer here only to the cell switching of an ATM node by discussing the operations related to the transfer of cells from the inputs to the outputs of the switch. Thus, all of the functionalities relevant to the setup and teardown of the virtual connections through the switch are intentionally disregarded. The general model of an $N \times N$ switch is shown in Fig. 40.1. The reference switch includes N *input port controllers* (IPC), N *output port controllers* (OPC), and an interconnection network (IN), where the IN is capable of switching up to K cells to the same OPC in one slot. The IN is said to have a speedup K if $K > 1$ and no speedup if $K = 1$, since an internal bit rate higher than the external rate (or an equivalent space-division technique)

FIGURE 40.1 Model of ATM switch.

is required to allow the transfer of more than one cell to the same OPC. The IN is usually a multistage arrangement of very simple SEs, typically 2×2 , which can be either provided with input/output/shared buffers (*SE queueing*), or unbuffered (*IN queueing*). In this last case, input and output queueing, whenever adopted, take place at IPC and OPC, respectively, whereas shared queueing is accomplished by means of additional hardware associated to the IN. Depending on the type of interconnection network and the queueing adopted, three classes of ATM switches will be distinguished:

- *Blocking multistage IN with minimum depth.* SE queueing and no speedup are adopted; the interconnection network is blocking and makes available only one path per I/O pair.
- *Blocking multistage IN with arbitrary depth.* IN queueing (typically, output queueing) and a speedup K are adopted; the interconnection network is blocking but makes available more than one path per I/O pair.
- *Nonblocking IN.* IN queueing and a speedup K are adopted.

In general, two types of conflicts characterize the switching operation in the interconnection network in each slot, the **internal conflicts** and the **external conflicts**. The former occur when two I/O paths compete for the same internal resource, that is, the same interstage link in a multistage arrangement, whereas the latter take place when more than K packets are switched in the same slot to the same OPC. An interconnection network $N \times N$ with speedup K , $K \leq N$, is said to be nonblocking if it guarantees absence of internal conflicts for any arbitrary switching configuration free from external conflicts for the given **network speedup** value K . That is, a nonblocking IN is able to transfer to the OPCs up to N packets per slot, in which at most K of them address the same switch output. Note that the adoption of output queues either in an SE or in the IN is strictly related to a full exploitation of the switch speedup; in fact, a structure with $K = 1$ does not require output queues, since the output port is able to transmit downstream one packet per slot. Whenever queues are placed in different elements of the ATM switch, it is assumed that there is no backpressure between queues, so that packets can be lost in any queue due to buffer saturation.

The main functions of the port controllers are:

- Rate matching between the input/output channel rate and the switching fabric rate.
- Aligning cells for switching (IPC) and transmission (OPC) purposes (it requires a temporary buffer of one cell).
- Processing the cell received (IPC) according to the supported protocol functionalities at the ATM layer; a mandatory task is the routing (switching) function, that is, the allocation of a switch output and a new VPI/VCI to each cell, based on the VCI/VPI carried by the header of the received cell.
- Attaching (IPC) and stripping (OPC) self-routing labels to each cell.
- With IN queueing, storing (IPC) the packets to be transmitted and probing the availability of an I/O path through the IN to the addressed output if input queueing is adopted; queueing (OPC) the packets at the switch output if output queueing is adopted.

The traffic performance of the nonblocking ATM switches will be described by referring to an offered uniform random traffic, with $p(0 < p \leq 1)$ denoting the probability that a packet is received at a switch input in a slot. All packet arrival events at IPCs are mutually independent, and each switch outlet is selected with the same probability by the cells. Typically, three parameters are used to describe the switching fabric performance, all referred to as steady-state conditions: the *switch throughput* $\rho(0 < \rho \leq 1)$ (the traffic carried by the switch) expressed as a utilization factor of its output links; the *average packet delay* $T(T \geq 1)$, that is, average number of slots it takes for a packet received at a switch input to cross the network and thus be transmitted downstream by the addressed switch output, and the *packet loss probability* $\pi(0 < \pi \leq 1)$, defined as the probability that a packet received at a switch input is lost due to buffer overflow. The maximum throughput ρ_{\max} , also referred to as *switch capacity*, indicates the load carried by the switch for an offered load $p = 1$.

Needless to say, our dream is a switching architecture with minimum complexity, capacity very close to 1, average packet delay less than a few slots, and a packet loss probability as low as desired, for example, less than 10^{-9} . The target loss performance is usually the most difficult task to achieve in an ATM switch.

40.4 ATM Switch with Blocking Multistage IN and Minimum Depth

The class of ATM switch characterized by a blocking multistage IN with minimum depth is based on the adoption of a *banyan network* as IN. Banyan networks are multistage arrangements of very simple 2×2 switching elements without internal speedup with interstage connection patterns such that only one path exists between any inlet and outlet of the network and different I/O paths can share one or more interstage links. SEs in a banyan network are organized in $n = \log_2 N$ stages, each comprising $N/2$ SEs. Figure 40.2 represents the *reverse baseline network* [Wu and Feng, 1980]. An SE with high and low inlets (and outlets) labeled 0 and 1, respectively, can assume only two states, *straight* giving the I/O paths 0-0 and 1-1 in the SE, and *cross* giving the I/O paths 0-1 and 1-0.

The availability of only one I/O path per inlet/outlet pair with interstage links shared by several I/O paths causes the banyan network blocking due to the internal conflicts. In spite of its high blocking probability, the key property of banyan networks that suggests their adoption in ATM switches is their cell self-routing capability: an ATM cell preceded by an address label, the *routing tag*, is given an I/O path through the network in a distributed fashion by the network itself. For a given topology, this path is uniquely determined by the inlet address and by the routing tag, whose bits are used, one per stage, by the switching elements along the paths to route the cell to the requested outlet. The specific bit to be used, whose value 0(1) means that the cell requires the high (low) SE outlet, depends on the banyan network topology. An example of self-routing in a reverse baseline network is shown in Fig. 40.2, where a cell received on inlet 4 addresses outlet 9.

As is clear from the preceding description, the operations of the SEs in the network are mutually independent, so that the processing capability of each stage in an $N \times N$ switch is $N/2$ times the processing

FIGURE 40.2 Reverse baseline network with self-routing example.

FIGURE 40.3 Structure of a 2×2 SE with IQ, OQ, and SQ.

FIGURE 40.4 Throughput performance of banyan networks.

capability of one SE. Thus, a very high parallelism is attained in packet processing within the IN of an ATM switch by relying on space-division techniques.

As already mentioned, interstage links are shared by several I/O paths that cause packet loss if two packets require the same link in a slot. Provision of a queueing capability in the SE (SE queueing) is therefore mandatory to be able to control the packet loss performance of the switch. In general, three configurations are considered: input queueing (IQ), output queueing (OQ), and shared queueing (SQ), where a buffer is associated with each SE inlet, each SE outlet, or shared by all the SE inlets and outlets, respectively. Therefore, the SE routing is operated after (before) the packet storage with IQ (OQ), both before and after the storage with SQ (see Fig. 40.3). Note that these three solutions have an increasing hardware complexity: each buffer is read and written at most once per slot with IQ, read once and written twice per slot with OQ, and read twice and written twice per slot with SQ.

The maximum throughput of these networks increases with the total buffer size B (Fig. 40.4) from a value around $\rho_{\max} = 0.4 - 0.5$ for all of the cases to a value close to $\rho_{\max} = 0.75$ for input queueing and $\rho_{\max} = 1.0$ for output and shared queueing. These values are the asymptotic throughputs expected, since a very large buffer in each SE implies that the throughput degradation is only due to internal conflicts. By definition, these conflicts do not occur with OQ SEs and they give the asymptotic throughput of a single 2×2 SE with IQ and OQ SEs. Given a total SE buffer size, SQ gives the best cell loss performance; OQ is significantly better than IQ unless a very low offered load is considered, as shown in Fig. 40.5 for a total SE buffer of 16 ATM cells for a varying offered load p .

FIGURE 40.5 Loss performance of banyan networks.

40.5 ATM Switch with Blocking Multistage IN and Arbitrary Depth

Another class of ATM switches has been developed using the same concept of cell self-routing characterizing a banyan network but now based on the use of unbuffered SEs. The basic idea behind this type of switching fabric is that packet loss events that would occur because of multiple packets requiring the same interstage link are avoided by deflecting packets onto unrequested SE output links. Therefore, the packet loss performance is controlled by providing several paths between any inlet and outlet of the switch, which is generally accomplished by arranging a given number of self-routing stages cascaded one to another. Since each OPC of the switching fabric transmits at most one packet, queueing is still necessary when the interconnection network switches more than one packet in a slot to the same outlet interface (the IN has an internal speedup K). In this class of switch architectures, output queueing is obviously accomplished by providing each OPC of the switch with a queue.

The interconnection network of an $N \times N$ switch is a cascade of switching stages, each including $N/2$ unbuffered SEs, whose interstage link patterns depend on the specific ATM switch architecture. Unlike all other ATM switch classes, cells cross a variable number of stages before entering the addressed output queue, since direct connections to the output queues, through the SE local outlets, are also available from intermediate stages. Also, the routing strategy operated by the switching block depends on the specific architecture. However, the general switching rule of this kind of architecture is to route the packets onto the local outlet addressed by the cell as early as possible. Apparently, those cells that do not reach this outlet at the last switching stage are lost.

The cell output address, as well as any other control information needed during the routing operation, is transmitted through the network in front of the cell itself as the cell routing tag. A feature common to all ATM switch architectures based on deflection routing is the packet self-routing principle, meaning that each packet carries all of the information needed in the switching element it is crossing to be properly routed toward the network outlet it is addressing. Compared to the simplest case of self-routing operated in a banyan network, where the routing is based on the analysis of a single bit of the output address, here the routing function can be a little more complicated and varies according to the specific architecture considered. Now, however, depending on the specific network architecture, the cell self-routing requires the processing of more than one single bit; in some cases, the overall cell address must be processed in order to determine the path through the network for the cell.

Only two specific ATM switch architectures based on deflection routing will be described here to better clarify the principles of their internal operations, the *shuffleout* switch [Decina et al., 1991] and the *tandem banyan* switch [Tobagi et al., 1991], although other architectures have also been proposed.

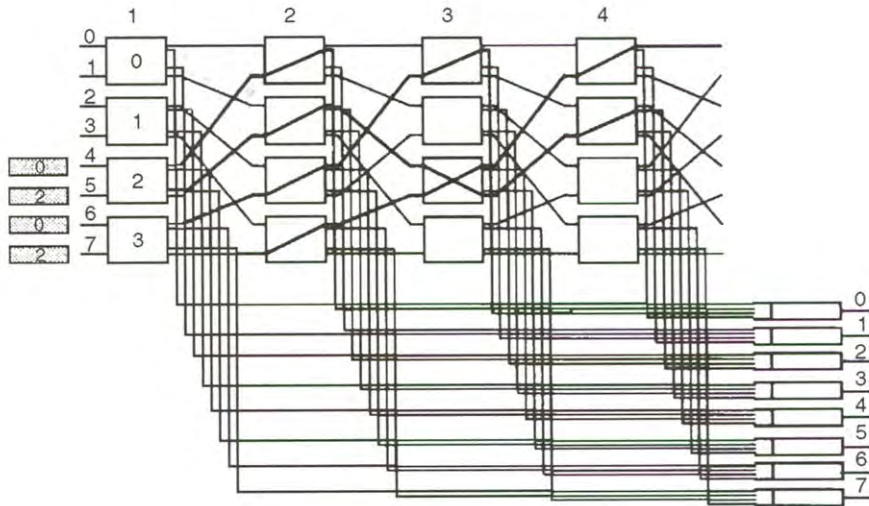

FIGURE 40.6 Routing example in shuffleout.

Each of the K switching stages in the shuffleout switch includes $N/2$ switching elements of size 2×4 , and the interstage connection pattern is a shuffle pattern. Thus, the network includes $N/2$ rows of SEs, numbered $0 - N/2 - 1$, each having K SEs. An SE is connected to the previous stage by its two inlets and to the next stage by its two interstage outlets; all of the SEs in row i ($0 \leq i \leq N/2 - 1$) have access to the output queues interfacing the outlets $2i$ and $2i + 1$ by means of the *local outlets*, thus accomplishing a speedup K . The shuffleout switch is shown in Fig. 40.6 for $N = 8$ and $K = 4$. The routing tag in the shuffleout switch is just the network output address.

The distributed routing algorithm adopted in the shuffleout interconnection network is jointly based on the *shortest path* and *deflection routing* principles. Therefore, an SE attempts to route the received cells along its outlet belonging to the minimum I/O path length to the required destination. The output distance d of a cell from the switching element it is crossing to the required outlet is defined as the minimum number of stages to be crossed by the cell in order to enter an SE interfacing the addressed output queue. After reading the cell output address, the SE can easily compute the cell output distance, whose value ranges from 0 to $\log_2 N - 1$ because of the shuffle interstage pattern.

When two cells require the same SE outlet (either local or interstage), only one can be correctly switched, whereas the other must be transmitted to a nonrequested interstage outlet, due to the memoryless structure of the SE. Thus, conflicts are resolved by the SE applying the deflection routing principle: if the conflicting cells have different output distances, then the closest one is routed to its required outlet, whereas the other is deflected to the other interstage link. If the cells have the same output distance, a random choice is carried out. If the conflict occurs for a local outlet, the loser packet is deflected onto an interstage outlet that is randomly selected.

An example of packet routing is shown in Fig. 40.6 for $N = 8$. In the first stage, both the SEs 2 and 3 receive two cells requiring the remote switch outlets 0 and 2, so that a conflict occurs for their upper interstage link. In both cases, the contending cells have the same distance ($d = 1$ in SE 2 and $d = 2$ in SE 3) and the random winner selection results in the deflection of the cells received on the low inlets. The two winner cells enter the output queue 0 at stages 2 and 3, whereas the other two cells addressing outlet 2 contend again at stage 3; the cell received at the low inlet now is the winner. This cell enters the output queue at the following stage, whereas the cell that has been deflected twice cannot reach the proper output queue within the fourth stage of the network and, thus, is lost.

Each output queue, which operates on a first-in first-out FIFO basis, is fed by K lines, one from each stage, so that up to K packets can be concurrently received in each slot. Since K can range up to several tens depending on the network parameter and performance target, it is necessary to limit the maximum

FIGURE 40.7 Architecture of the tandem banyan switch.

number of packets entering the queue in the same slot. Therefore, a *concentrator* with size $K \times C$ is generally equipped in each output queue interface so that up to C packets can enter the queue concurrently. The number C of outputs from the concentrator and the output queue size B (cells) will be properly engineered so as to provide a given cell loss performance target.

In the $N \times N$ tandem banyan switch, shown in Fig. 40.7, K banyan networks are serially arranged so that the total number of stages is now nK ($n = \log_2 N$) each including 2×2 switching elements. Different topologies can be chosen for the basic banyan network of the tandem banyan switch, such as the omega [Lawrie, 1975], the baseline [Wu and Feng, 1980], and others. Each output queue is fed now by only K links, one from each banyan network. The first banyan network routes the received packets according to the very simple bit-by-bit self-routing (the specific bit to be used depends on the specific topology of the banyan network). In case of a conflict for the same SE outlet, the winner, which is chosen randomly, is routed correctly; the loser is deflected onto the other SE outlet, also by setting to 1 a proper field D of the routing tag, which is initially set to 0. Since each banyan network is a single I/O-path network, after the first deflection the packet cannot reach its addressed outlet in the same network. To prevent a deflected packet from causing the deflection of an undeflected packet at a later stage of the same network, the SE always correctly routes the undeflected packet if two packets with different values of the field D are received.

The output queue i is fed by the outlet i of each of the K banyan networks, through proper packet filters that select for acceptance only those packets with $D = 0$, whose routing tag matches the output queue address. The k th banyan network ($k = 2, \dots, K$) behaves accordingly in handling the packets received from the upstream network $k - 1$: it filters out all of the undeflected packets and accepts only the deflected packets ($D = 1$). Analogously to all of the previous architectures, packets that emerge from the network K with $D = 1$ are lost.

Unlike shuffleout, here a much smaller number of links enter each output queue (one per banyan network) so that the output queue, in general, does not need to be equipped with a concentrator. On the other hand, in general, cells cross a larger number of stages here since the routing of a deflected cell is not restarted just after a deflection, but rather when the cell enters the next banyan network.

Unlike ATM switches with input queueing where the head-of-the-line blocking limits the throughput performance, the maximum throughput $\rho_{\max} = 1$ can be achieved in an ATM switch with deflection routing. Therefore, our attention will be focused on the cell loss probability. Cells can be lost in different parts of the switch, that is, in the interconnection network (a cell reaches the last stage without entering the addressed local outlet), the concentrator, and the output queue. Loss events in the concentrator and

FIGURE 40.8 Loss performance in shuffleout.

FIGURE 40.9 Loss performance in tandem banyan.

in the output queue can be easily constrained to arbitrarily low values by properly designing the number of concentrator outlets and the output queue size. A much more critical parameter to achieve a low loss is the selection of the number of stages in the interconnection network that gives a particular low cell loss probability. Figure 40.8 shows that less than 20 (50) stages are needed in shuffleout to provide a cell loss probability lower than 10^{-7} for a switch with size $N = 32$ (1024) under maximum input load. Less stages are required for lower input loads. Similar comments apply to the tandem banyan switch referred to the number of networks rather than to the number of stages. Figure 40.9 also shows that the banyan network topology significantly affects the overall performance. Adopting an omega topology (O) requires less networks than with a baseline topology (B).

40.6 ATM Switch with Nonblocking IN

The third class of ATM switching fabrics is characterized by a nonblocking IN with packet queuing capability placed in the IPCs (input queuing), the OPCs (output queuing), or placed within the IN itself (shared queuing). Mixed queuing strategies have been proposed as well. Requiring a nonblocking IN means referring to a network free from internal conflicts, that is, in principle, to a crossbar network (switching in an $N \times N$ crossbar network is accomplished by N^2 crosspoints, each dedicated to a specific I/O pair). Nevertheless, the centralized control characterizing a crossbar network makes this solution

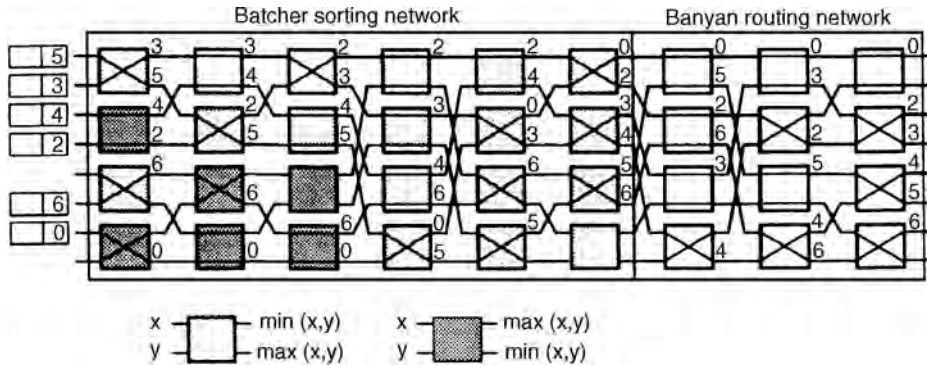

FIGURE 40.10 Example of cell switching in a Batcher-banyan network.

infeasible for a very high-speed ATM environment. As in the previous ATM switch classes, the only viable solutions are based on the adoption of multistage arrangements of very simple SEs, each capable of autonomously routing the cell to the required IN outlet.

The simplest ATM switch with nonblocking IN stores the cells in input queues located in the IPCs (IQ nonblocking IN). It is well known that a banyan network is nonblocking if the set of packets to be switched is *sorted* (by increasing or decreasing output addresses) and *compact* (packets received on adjacent network inlets). Therefore, the IN basically includes a sorting network and a routing banyan network, which are implemented as a multistage arrangement of very simple sorting and switching elements, respectively, whose size is typically 2×2 . The number of stages of these networks is $n(n + 1)/2$ for a Batcher sorting network [Batcher, 1968] and n for a banyan routing network, where $n = \log_2 N$, each stage including $N/2$ elements. The simplicity of these SEs, each requiring a gate count on the order of a few tens of gates, is the key feature allowing the implementation of these INs on a small number of chips by relying on the current very large size integrated (VLSI) complementary metallic oxide (CMOS) technology. An example of sorting-routing IN is given in Fig. 40.10 for an 8×8 ATM switch, where the six cells received by the IN are sorted by the Batcher network and offered as a compact set with increasing addresses to the n -cube banyan network. Note that the nonblocking feature of the IN means that the network is free from internal conflicts. Therefore, additional means must be available to guarantee the absence of external conflicts occurring when more than one cell addresses the same switch outlet. Input queues hold the packets that cannot be transmitted immediately, and specific hardware devices arbitrate among the head-of-the-line (HOL) cells in the different input queues to guarantee the absence of external conflicts.

An OQ $N \times N$ nonblocking ATM switch provides cell storage capability only at OPCs. Now the IN is able to transfer up to K packets from K different inlets to each output queue without blocking due to internal conflicts (it accomplishes an internal speedup K). Nevertheless, now there is no way of guaranteeing the absence of external conflicts for the speedup K , as N packets per slot can enter the IN without any possibility of them being stored to avoid external conflicts. Thus, here the packets in excess of K addressing a specific switch outlet in a slot are lost.

According to the first original proposal of an ATM switch with pure output queueing, known as a *knockout* switch [Yeh et al., 1987], the IN includes a nonblocking $N \times N$ structure followed by as many output concentrators as the switch outlets. The $N \times N$ nonblocking structure is a set of N buses, each connecting one of the switch inlets to all of the N output concentrators. Each of these is an $N \times K$ network that is provided with N packet filters (one per attached bus) at its inputs, so as to drop all of the packets addressing different switch outlets.

A nonblocking $N \times N$ ATM switch with shared queueing behaves as a memory unit available in the IN and shared by all of the switch inlets to contain the packets destined for all of the switch outlets. The simplest implementation for this SQ switch model is given by a shared memory unit with N concurrent write accesses by the N inlets and up to N concurrent read accesses by the outlets. Clearly, such structure

shows implementation limits due to memory access speed, considering that the bit rate of the external ATM links is about 150 Mb/s. The current VLSI CMOS technology seems to allow the implementation of such $N \times N$ switches up to a moderate size, say, $N = 16$ or 32.

Multistage structures still provide a good answer for the implementation of larger size switches. The most important proposal is the *starlite* switch [Huang and Knauer, 1984], whose IN is a Batcher-banyan structure improved with additional hardware enabling feedback to the IN inlets those packets that cannot be switched to the addressed outlets because of external conflicts (the architecture does not have an internal speedup). Therefore, if P recirculation lines are available, then the size of the Batcher sorting network must be increased up to $(N + P) \times (N + P)$. These recirculation lines act as a shared buffer of size P .

The maximum throughput of an (unbuffered) crossbar network is $\rho_{\max} = 0.632$ because of the unavoidable external conflicts, whereas it drops to $\rho_{\max} = 0.586$ in an IQ nonblocking IN for an infinitely large switch ($N = \infty$). Thus, in spite of the queueing capability of this architecture, its capacity is even worse than in a crossbar switch. This phenomenon is explained by considering that holding in the HOL position those cells that cannot be transmitted because of external conflicts is a statistically worse condition than regenerating all of the cells slot by slot. Note that in a squared $N \times N$ switch with all active port controllers (PCs), a number h of blocked HOL cells imply h idle switch outputs, thus resulting in a carried load in the slot of only $(N - h)/N$. Nevertheless, behind a blocked HOL cell, the queue can hold other cells addressing one of the idle switch outlets in the slot. Such an *HOL blocking* phenomenon is said to be responsible for the poor throughput performance of pure IQ switches.

At first glance, a question could arise: what is the advantage of adding input queueing to a nonblocking unbuffered structure (the crossbar switch), since this results in a decrease of the switch capacity? The answer is provided in Fig. 40.11 showing the packet loss probability for a crossbar switch and an IQ switch with an input queue size B_i ranging from 1 to 32 cells. If the target loss probability is, say, 10^{-9} , we simply limit the offered load to $p = 0.3$ with $B_i = 8$, or to $p = 0.5$ for $B_i = 32$ with an IQ switch, whereas the packet loss probability of the crossbar switch is above 10^{-2} even for $p = 0.05$. Thus, input queueing does control the packet loss performance.

OQ nonblocking ATM switches show a much better traffic performance than IQ nonblocking switches as they do not have any HOL blocking phenomenon. In fact, the OQ switch capacity is $\rho_{\max} = 1$ for $N = K$ and infinite output queue capacity. The loss performance is determined by the engineering of two parameters: the number of outlets per concentrator K , and the capacity of each output queue B_o . A speedup $K = 8$ is enough to guarantee a loss in the concentrator on the order of 10^{-8} with $p = 0.5$ and 10^{-6} with $p = 1.0$ for an arbitrary switch size. Moreover, the offered load p must be kept below a given threshold if we wish to keep the output queue capacity small by satisfying a given cell loss target (for example, $B_o = 64$ guarantees loss figures below 10^{-7} for loads up to $p = 0.9$). The delay vs. throughput performance in OQ switches is optimal since the packet delay is only determined by the congestion for the access to the same output link.

FIGURE 40.11 Loss performance with input queueing.

TABLE 40.1 Switch Capacity with Mixed Input/Output Queuing

x	$B_o = \infty$	$K = 2$	$K = 4$
	$\rho_m(K)$	$\rho_m(B_o)$	$\rho_m(B_o)$
1	0.586	0.623	0.633
2	0.885	0.754	0.785
4	0.996	0.830	0.883
8	1.000	0.869	0.938
16		0.882	0.967
32		0.885	0.982
64		0.885	0.990
128			0.994
256			0.996
∞	1.000	0.885	0.996

FIGURE 40.12 Loss performance with shared queuing.

Nonblocking ATM switches using multiple queuing strategies have also been proposed so as to overcome the performance limits of structures with input or shared queuing. Architectures with either mixed input/output queuing (IOQ) [Lee, 1990] or mixed shared/output queuing (SOQ) [Giacopelli et al., 1991] have been proposed. These architectures are basically an expansion of the respective basic Batcher-banyan structures in which K banyan networks are now available to switch up to K cells to the same OPC (the switch has an internal speedup K) and OPCs are equipped with output queues, each with a capacity B_o . The main performance results attained by these mixed queuing architectures are that the HOL blocking characterizing IQ switches is significantly reduced in an IOQ switch and the number of recirculators P that give a certain loss performance decrease considerably in an SOQ switch compared to the basic SQ switch.

Table 40.1 provides the switch capacity of an IOQ switch for different speedups and output queue sizes for $B_i = \infty$ and $N = \infty$. Note that the first column only contains the numerical values of the independent variable for which the switch capacity is evaluated, and its meaning is specified in each of the following columns. The switch capacity grows very fast with the speedup value K for an infinitely large output queue, $\rho_{\max} = 0.996$ for $K = 4$, whereas it grows quite slowly with the output queue size given a switch speedup K . In general, it is cheaper to provide larger output queues rather than increase the switch speedup, unless the switching modules are provided in VLSI chips that would prevent memory expansions. Thus, these results suggest that a prescribed switch capacity can be obtained acting on the output buffer size, given a speedup compatible with the selected architecture and the current technology.

Analogously to OQ switches, pure shared queuing provides maximum switch capacity $\rho_{\max} = 1$ for a shared queue with infinite capacity. The loss performance of SQ and SOQ architectures is given in Fig. 40.12 for $N = 32$ as a function of the normalized shared buffer size P/N for different offered loads.

It is seen that even a small shared queue of 32 cells ($P/N = 1$) requires the offered load to be limited to $\rho = 0.6$ if loss figures below 10^{-5} are required. It is interesting to note how the SOQ switch capacity approaches 1 even with a small shared buffer capacity by adopting a very little speedup ($\rho_{\max} = 1 - 10^{-6}$ for $K = 3$ and $P = 7$).

40.7 Conclusions

The main architectural and performance features of switching fabrics for broadband networks based on asynchronous time-division switching have been presented. It has been shown that multistage arrangements of very simple switching elements is the typical solution adopted in ATM switches, which enables the processing required by ATM cells to be compatible with the bit rate on the incoming links. All of the different switch classes presented are able to provide the required performance target in an ATM network, typically the cell loss probability, by means of a suitable limitation of the offered load. Choosing one architecture rather than another is just a matter of finding an acceptable tradeoff between implementation costs and traffic performance.

Defining Terms

- Arbitrary depth network:** Interconnection network providing more than one internal path per inlet/outlet pair.
- Asynchronous transfer mode (ATM):** Transport technique defined for the lower layers of the broadband communication network.
- ATM cell:** Basic fixed-size unit defined for the transport of user information in a broadband ATM network.
- Blocking network:** Network in which internal conflicts occur for an arbitrary permutation that is free from external conflicts for a given network speedup.
- Cell self-routing:** Property of a multistage interconnection network that consists of the autonomous routing of the packets in each switching element only based on a routing tag carried by the cell without the use of many central control.
- Deflection routing:** Routing technique that deviates a packet from its intended route through the network because of an internal conflict.
- External conflict:** Conflict between packets for the access to the same network outlet.
- Input queueing:** Queueing strategy in which the information units are stored in buffers associated with the inlets of the interconnection network (or a switching element).
- Internal conflict:** Conflict between packets for the access to the same link internal to the interconnection network.
- Minimum depth network:** Interconnection network providing only one internal path per inlet/outlet pair.
- Network speed-up:** Number of packets that can be concurrently received at each output interface of an interconnection network.
- Nonblocking network:** Network free from internal conflicts for an arbitrary permutation that is free from external conflicts for a given network speedup.
- Output queueing:** Queueing strategy in which the information units are stored in buffers associated with the outlets of the interconnection network (or a switching element).
- Shared queueing:** Queueing strategy in which the information units are stored in a buffer shared by all of the inlets and outlets of the interconnection network (or a switching element).

41.1 Introduction

Engineering an internetwork is a lot like a farmer getting his apples delivered from an orchard to the supermarket. First, the farmer needs something to put the apples in: a bag, a box, a basket, or maybe a crate; second, the farmer needs to drive on some roads over a specific route. Those same two problems confront an engineer trying to get data delivered from one local area network (LAN) to another. Developing an internetwork involves finding something to put the apples in and providing a way to transport them from the orchard to the supermarket. The apples are the data and the container is the communications protocol that encapsulates or contains the data. Communications protocols envelope the application data and provide a container to ensure the goods are delivered safely and reliably. Internetworks require compatible protocols at both the transmitting and receiving sites. Various communications protocols are available such as transmission control protocol/Internet protocol (TCP/IP), system network architecture (SNA), DECnet, IPX, AppleTalk, and XNS, to name a few.

Roads and routes the farmer travels on from the orchard to the supermarkets represent telecommunications circuits the communications protocols use to route the data from source to destination. Engineering an internetwork involves sizing circuits and designing routes for the efficient and optimal transfer of information between LANs. Providing cost-effective and properly performing internetworks involves designing the best type of circuits, either dedicated or switched, and sizing bandwidth requirements.

Internetworking is defined in the IBM dictionary of computing as “communication between two or more networks.” Miller [1991] defined the term as “communication between data processing devices on one network and other, possibly dissimilar devices on another network.” For the purpose of this chapter, internetworking will take on the meaning of connecting two or more LANs to broaden the scope of communications.

41.2 Internetworking Protocols

Understanding, designing, and optimizing an internetwork would be too difficult unless the problem were broken down into smaller subtasks. Communications architectures partition functionality into several layers, each providing some service to the layer above and using the services of the layer below.

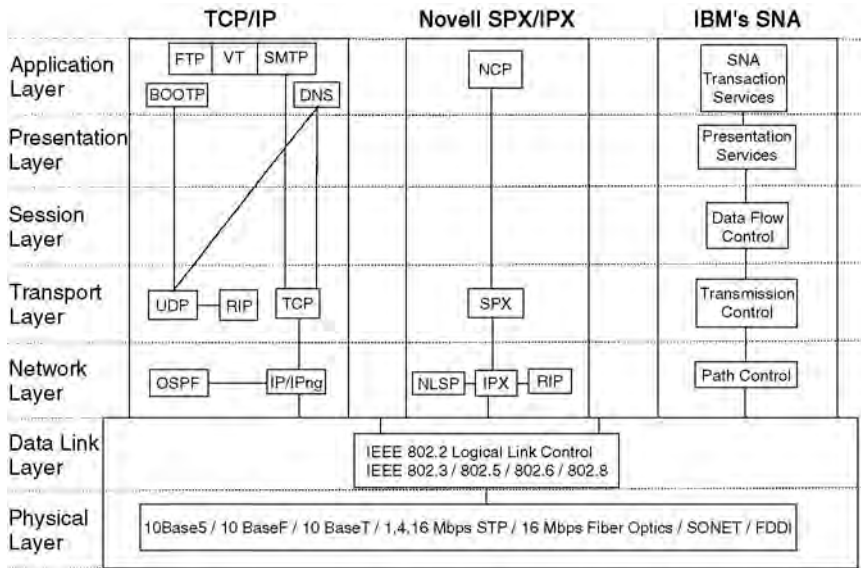

FIGURE 41.1 Internetworking communications protocol architectures.

Figure 41.1 illustrates the seven-layer International Organization for Standardization (ISO) open systems interconnection (OSI) reference model. TCP/IP, SNA, and sequence packet exchange/Internet packet exchange (SPX/IPX) are mapped into the seven-layer model. Each of the communications protocols converge at the data link and physical layers; however, the architectures all diverge at the network layer. Each communications protocol is represented uniquely at the upper five layers of the OSI communications model.

The data link layer is relevant to internetworking because this is where bridges operate. The service provided by the data link layer is important to routers—the key internetworking device, operating at the network layer. The transport layer is the user of network services and is influenced by the routing decisions made at the network layer. These three layers are the primary focus of internetworking.

Two models represent how an internetwork appears to endnodes. In the **connectionless** or datagram model, an endnode transmits packets containing data and the destination address to which the data is to be delivered. The network does the best to deliver the data, with some probability that the data will get lost, duplicated, or damaged. Packets are individually routed and the network does not guarantee the packets will be delivered in the same order they were sent.

The connectionless model is similar to the postal system in which each letter enters the postal system with the address where it should be delivered. The postal system does its best to deliver the data, with some probability that the letter will get lost or damaged. Letters are individually routed, and a letter posted on Monday might get delivered after a letter posted on Tuesday, even if both were posted from the same location and addressed to the same location.

The other model is the **connection-oriented** or virtual circuit. Here, an endnode first informs the network that it wishes to start a conversation with some other endnode. The network then notifies the destination that a conversation is requested, and the destination accepts or refuses. This is similar to the telephone system in which the caller informs the telephone system of the wish to start a conversation by dialing the telephone number of the destination. The telephone system establishes a path, reserves the necessary resources, contacts the destination by ringing its phone, and after the call is accepted, the conversation can take place. Often, a connection-oriented service has the following characteristics [Perlman, 1992]:

1. The network guarantees packet delivery.
2. A single path is established for the call and all data follows that path.
3. The network guarantees a certain minimal amount of bandwidth.
4. If the network becomes overly utilized, future call requests are refused.

TCP/IP Internetworking

TCP/IP has emerged as the primary communications protocol for developing internetworks. Why? The answer is simple: interoperability; almost every conceivable combination of computer hardware and operating system has a driver available for TCP/IP. International travelers know English is the speaking world's most common second language. A native language may be preferred when speaking with local family and friends, but English is the worldwide second language and is predominately used to communicate internationally. Similarly, TCP/IP has emerged as the primary protocol for communicating between networks.

The suite of TCP/IP protocols, adopted in the 1970s by the U.S. Department of Defense, is the Internet backbone. Now, over 3.1 million users are connected to the Internet, all speaking IP, up 81% from last year. The International Data Corporation (IDC), in Framingham, MA, estimates 4.5 million PCs are running TCP/IP and the cumulative installed base for TCP/IP is 8 million computers. TCP/IP is clearly the internetworking protocol of choice.

Endorsements of TCP/IP just keep coming. First, Microsoft tucked a TCP/IP stack into Windows NT Version 3.1 and declared TCP/IP its strategic wide-area network protocol family. Most recently, a federally commissioned panel recommended that the government sanction TCP/IP as a standard and surrender its open systems interconnection-only stance in the Government OSI Profile (GOSIP). TCP/IP, the preferred protocol for internetworking, is also becoming the primary backbone protocol for local communications.

One of the major forces driving TCP/IP to the PC desktop is UNIX, which usually includes TCP/IP. UNIX has become the de facto standard enterprise server OS. As users downsize from mainframe platforms and adopt UNIX-based servers, they must outfit their PCs with access to TCP/IP. Downsizing is a major trend as processing power becomes more cost effective in the minicomputer and microcomputer platforms. An Intel 286-based PC introduced in 1983 provided 1 MIPS performance, in 1986 the i386 offered 5 MIPS, in 1990 the i486 came with 20 MIPS, and more than 100 MIPS was available in 1993 with the Pentium. Intel plans to routinely increase desktop processing power with the i686 in 1995, offering 175 MIPS, the i786, slated to provide 250 MIPS in 1997, and the i886 in 1999, capable of approximately 2000 MIPS.

TCP/IP is a connectionless protocol. TCP operates the transport layer and IP is the network layer protocol based on 4 octet addresses. A portion of the address indicates a link number and the remaining portion a system or host on the network. A 32-bit **subnet mask** has 1s in the bits corresponding to the link portion of the IP address and 0s in the bits belonging to the host identifier field. If an IP address is X and its mask is Y, to determine whether a node with IP address Z is on the same link, AND the mask Y with X and AND the mask Y with Z. If the result is the same, then Z is on the same link.

Originally, IP addresses were grouped according to three distinct classes: class A contained the network address field in the first octet and host identifier in the remaining 3 octets, class B contained the network address field in the first two octets and the host in the remaining two fields, and class C contained the network address field in the first three octets and the host identifier in the remaining octet. Today, IP allows a variable sized subnet mask and even permits noncontiguous 1s in the mask. This can result in incredibly confusing and computationally inefficient addressing structures. Regardless, each node on a link must know the subnet mask of its own IP address.

IP routers connect networks by routing packets based on destination link numbers, not destination host identifiers. If IP routers had to route packets to destination hosts, enormous memory would be necessary to contain information about every machine on the Internet. Consequently, IP routing does not route to the destination endnode, it routes only to the destination link.

TCP/IP does have a certain amount of overhead associated with address resolution protocol (ARP) queries and responses that can degrade network performance significantly. The ARP allows a host to find the physical address of a target host on the same link number, given only the target's IP address. For example, if host A wanted to resolve the IP address of host B, a broadcast query would be transmitted and received by all hosts, but only host B would respond with its physical address. When A receives the reply, it uses the physical address to send packets directly to B. Considerable bandwidth and memory in

routers are consumed by routers keeping track of endnodes rather than just keeping track of links [Comer, 1991].

Improvement of the TCP/IP protocol suite will come in new protocols and emerging classes of applications. The dynamic host configuration protocol (DHCP) is being standardized to automatically gather detail configuration data for a PC when it joins the network, creating a plug-and-play environment. Historically, network administrators manually set parameters on each workstation, such as IP addresses and domains, but BOOTP and DHCP have advanced TCP/IP to an automated installation process.

Two classes of emerging applications for TCP/IP include interenterprise and personal interenterprise. Interenterprise applications unite different organizations' networks; for example, a retailer could order automatically from his suppliers or check credit-card information, all by TCP/IP. This brings electronic data interchange transactions, typically separate dial-up links, into the TCP/IP network. Personal interenterprise applications customize a PC view of the Internet, so that when connected, specific information is automatically presented, such as stock portfolio data.

The Internet is the largest network in the world, a network of networks that unarguably demonstrates the usefulness of TCP/IP. But TCP/IP is suffering from its own success. By the year 2020, the Internet will likely have exhausted all available addressing space. The Internet's standards-setting body, the Internet Engineering Task Force, has adopted the next generation IP. Called **IPng**, this new version of the IP layer will solve the problem of dwindling address space by supporting 16-byte addresses that will allow billions more users to surf the Internet. The new protocol (to be assigned version number IP6) will not require any immediate changes to users' existing IP internetworks. However, users will need to upgrade their routers and eventually change applications if they want to take advantage of the advanced features of IPng, such as flow control, autoconfiguration, and encryption-based security.

SNA Internetworking

IBM's SNA traffic is difficult to integrate into a multiprotocol internetwork because it is a nonroutable protocol. NetBIOS and Digital's local area transport (LAT) are also nonroutable protocols. Although it is unfortunate, these nonroutable protocols are without network addresses. Without network layer functionality, only bridges can internetwork native SNA. There is no intrinsic reason why these protocols could not have been designed to run with network layer addresses, they just were not. Perhaps designers never believed LANs would be internetworked.

Routers, as opposed to bridges, are the primary internetworking devices used to direct traffic from its source to its destination. Bridging is useful in simple point-to-point networks where alternate paths are not available and where protocol overhead is not a significant factor. Disadvantages of bridges relative to routers include:

- Bridges can use only a subnet of the topology (a spanning tree). Routers can use the best path that physically exists between source and destination.
- Reconfiguration after a topological change is an order of magnitude slower in bridges than routers.
- The total number of stations that can be interconnected through bridges is limited to the tens of thousands. With routers, the total size of the network is, for all practical purposes, unlimited (at least with ISO).
- Bridges limit the intermediate hop count to seven, significantly restricting the size of an internetwork.
- Bridges offer no firewall protection against broadcast storms.
- Bridges drop packets too large to forward, since the data link layer cannot fragment and reassemble packets.
- Bridges cannot give congestion feedback to the endnodes.

For the past several years, most corporations relied on token ring bridges implementing SNA's data link protocol, Logical Link Control 2 (LLC2), to give PCs on remote LANs a way to access IBM mainframe data.

Frames are forwarded throughout the internetwork by token ring bridges using source-route bridging protocol to ensure data is delivered to the proper destination. The problem is that even a few seconds of congestion on the wide area network (WAN) link can drop the SNA/LLC2 sessions.

IBM's **data link switching (DLSw)** standard provides the reliability needed to integrate mission-critical SNA networks with IP backbones. DLSw products integrate SDLC with IP by stripping off the synchronous data link control (SDLC) header and replacing it with a TCP/IP header. Prior to DLSw routers, SNA data was encapsulated in TCP/IP, leaving the SDLC headers intact. Current testing of router vendors' DLSw implementations indicate they keep SNA sessions from being dropped over even the most congested internetwork links. Performance at full speed of the WAN link is another big improvement over token ring bridges. A successor to source-route bridging, DLSw routers deliver high-performance SNA inter-networking even with significantly more complexity than source-route bridging.

The DLSw scheme allows routing IP and internetwork packet exchange (IPX) traffic alongside connection-oriented SNA. DLSw routers have the added complexity of blending connectionless LAN traffic with connection-oriented SNA traffic by sending messages to the stations on each end of the connections, acknowledging that a path is still open between them. Preventing the SNA connection from timing out and dropping sessions involves considerable overhead traffic, such as frequent receiver ready, keep alive broadcasts, and timing signals for constant responses.

DLSw routers are criticized by some SNA users because of the inconsistent performance associated with contention-based internetworks. IP response time may be nearly instantaneous one time and may take a second the next, frustrating SNA users accustomed to consistent performance. DLSw can benefit large SNA networks suffering from time outs, hop limits, alternate routing disruptions, and the lack of security mechanisms. DLSw routing gives non-routable SNA traffic the robustness of nondisruptive alternate routing when links or nodes fail, the benefits from open nonproprietary protocols, and the cost effectiveness of standard TCP/IP-based solutions.

For IBM users, there is the option of remaining all "blue" with IBM's advanced peer-to-peer networking (APPN) family of protocols, the next generation of SNA. IBM continues to develop, position, and promote its own APPN as the only viable next-generation networking technology for its mainframe customers. The need for guaranteed response time in their mission-critical mainframe applications makes APPN an attractive option. Other advantages to the APPN approach include full class of service application priorities, enhanced fault management through NetView monitoring, the added efficiency from not encapsulating SNA into a routable protocols like TCP/IP and thereby doubling the addressing overhead, and improved accounting from SNA usage statistics.

SPX/IPX Internetworking

The number one LAN protocol is undoubtedly Novell's sequence packet exchange/Internet packet exchange (SPX/IPX), but most network administrators use TCP/IP for internetworking. As a result, Novell has taken two significant steps to improve the performance of SPX/IPX for internetworking: **packet burst** and the network link services protocol (NLSP).

Before packet burst, the NetWare core protocol (NCP) was strictly a ping-pong discipline. The workstation and the server were limited to communicating by taking turns sending a single-packet request and receiving a single-packet response. Packet burst is an NCP call permitting a sliding window technique for multiple packet acknowledgment. By transmitting a number of packets in a burst, before waiting for an acknowledgment or request, packet burst eliminates the ping-pong effect and can provide up to a 60% reduction in the number of packets to read or write large files. Limited to only file reads and writes, packet burst cannot reduce the ping-pong method of all other NCP communications such as opening directory handles, locating and opening files, and querying the bindery.

Rather than reducing the number of packets when the receiving station or internetwork becomes congested, as do most transport layer protocols, packet burst actually varies the interpacket gap (IPG). The IPG is the time between the end of one packet and beginning of the next packet. Varying the IPG for flow control is called packet metering.

The amount of data sent during a burst is called the message. Message size is based on the number of packets in the burst, called the window size, and the media access method of the link. The default window size has been optimized for most communications to 16 packets for a read and 10 for a write. For example, 16 reads on a token ring link with a 4096 packet size gives a 53-KB message. On an ethernet link, a read message is about 22 KB (16 × 1500 bytes). The number of packets in the burst window can be increased on high-speed links and where the degree of transmission success is high. If a packet or packets are lost in transmission for any reason, the client will send a request for retransmission of the lost packets. The server will retransmit only those packets that were lost. Once the client has all of the packets, it requests another message; however, since packets were lost, the IPG is increased for the next transmission. The IPG will continue to be increased until packets are no longer being lost.

NLSLP is another internetworking improvement to NetWare. Novell developed the **link-state router** protocol NLSLP, to replace the older IPX distance-vector based router information protocol (RIP). IPX RIP is similar to Cisco's IGRP, IP RIP, and RTMP in the AppleTalk suite. **Distance-vector routing** requires each node to maintain the distance from itself to each possible destination. Distance vectors are computed using the information in neighbors' distance vectors and store this information in routing tables that show only the next hop in the routing chain rather than an entire map of the network. As a result, RIP frequently broadcasts these summaries to adjacent routers.

Distance-vector routing is efficient for routers with limited memory and processing power, but newer routers typically have reduced instruction set computer (RISC) processors with power to spare. Link-state routers can provide full knowledge of the network including all disabled links with a single query. With distance-vector routers, this would involve querying most, if not all, of the routers. In addition, link state routers, like NLSLP, converge more quickly than distance-vector routers, which cannot pass routing information on until distance vector has been recomputed. NLSLP supports large, complex IPX internetworks without the overhead present in NetWare distance-vector routers.

NLSLP routers compress service advertizing protocol (SAP) information and only broadcast SAP packets every two hours unless a change is made to network services, such as print servers or file servers. SAP broadcast overhead can be significant, especially with many servers or services. Novell has also reduced SAP traffic on the network by using NetWare Directory Services (NDS) to keep all network services information on a central server. NDS is available in NetWare 4.x and is similar to TCP/IP's domain name server (DNS). Novell also provides the capability to communicate with different systems through NetWare for SAA, NetWare NFS, and NetWare TCP/IP Gateway.

41.3 The Total Network Engineering Process

This guide to internetworking provides a step-by-step engineering approach. Migrating from a LAN or several LANs to an internetwork is no small undertaking. Key to the process of analyzing and designing internetworking strategies is employing analytic heuristic algorithms and simulation techniques. Network design tools are essential to effectively evaluate alternative internetworking schemes while attempting to optimize communications resources. As new networking requirements surface, engineers design capacity and equipment to satisfy the demands. Facing requirements on an as-needed basis results in network evolution. Networks developed in an evolutionary manner provide incremental solutions to an array of individual requirements. With each new requirement, the most cost-effective configuration of equipment and communications lines is determined, focusing on the specific need. Unfortunately, design decisions are often made without rigorous analysis of the entire network, addressing only the incremental expansion. This approach seldom provides the best design for the total communications environment.

The preferred method of addressing network requirements is through a structured-design approach. Here, alternative design techniques for the entire network are evaluated in terms of response time, cost, availability, and reliability. While avoiding excessive redesign and allowing for orderly capacity expansion, the process of network engineering evaluates current networking requirements and plans for future network expansion.

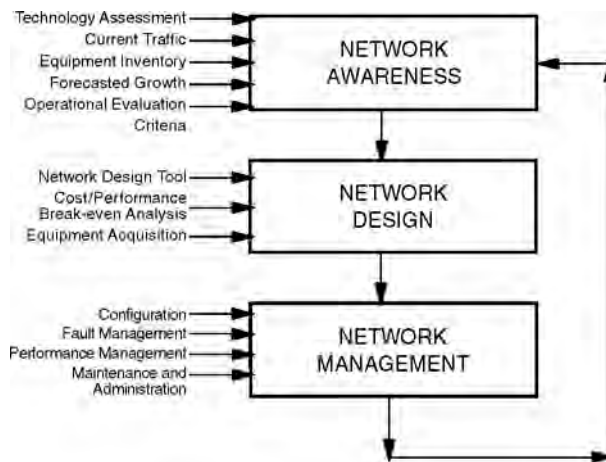

FIGURE 41.2 The total network engineering process.

Figure 41.2 shows the **total network engineering process** and its three phases: awareness, design, and management. **Network awareness** quantifies current traffic, equipment inventories, forecasted growth, and operational objectives. **Network design** uses design tools, performs a cost/performance breakeven analysis, and develops line configurations. **Network management** encompasses management of configuration, faults, performance, accounting, and security. Equipment and network software is acquired, verified, installed, maintained, and administered.

Network Awareness

The process of network awareness includes the following operations:

- conducting a traffic inventory by collecting measurements of current traffic
- mapping the physical inventory of networking equipment into the logical interconnections
- forecasting requirements for network growth through surveying line management
- qualifying through senior management the criteria used to evaluate operational tradeoffs

Many of these inputs are, of necessity, qualitative or conceptual in nature, whereas others can be quantified with varying degrees of accuracy. Using a network design process often requires a greater level of network awareness than most engineers generally possess. When an engineer has an accurate understanding of the network—including possible bottlenecks, response time spikes, and traffic patterns—the process of network design can begin. Gaining an accurate awareness of network traffic involves monitoring current loads via a network analysis tool, like the LANalyzer, Sniffer, or through the use of RMON probes. Traffic statistics for network planning should be collected, not only for all significant hours of each day, but also for a significant number of days in a year. CCITT recommends measuring carried traffic statistics for at least the 30 days (not necessarily consecutive) of the previous 12 months in which the mean busy hour traffic is the highest. A second-choice method recommended by CCITT, when the first method is not possible, consists of a measuring period of 10 consecutive normal working days during the busiest season of the year [CCITT, 1979]. Both average and peak loads are characterized hourly over the sampling period to understand current bandwidth requirements. Monitoring new networked applications predicts their impacts to the internetwork. Traffic must also be differentiated between what stays local, remaining only within a LAN, and traffic that is internetworked between remote locations via WAN links.

Interviews with line management help to forecast growth requirements. Many managers have hidden agendas for using the network for a variety of business purposes. Without surveys or interviews of key

management personnel, predicting future network requirements is impossible. Questions need to center around four key areas:

1. Future business communications requirements based on the use of advancing technologies
2. Planned facility changes and population shifts through developing new business partners
3. Forecasted needs for external connectivity with customers, vendors, and new markets
4. Changes in business practices based on new programs, applications, and remote systems access.

A little-publicized problem, but one that nevertheless causes big headaches, is developing an inventory of current network equipment. Obtaining an accurate image of the inventory database is helpful in the network engineering process to gain an improved network awareness. Based on network discovery techniques, like IP discovery and IPX SAP, routing nodes may be identified throughout the internetwork. These techniques only find network layer routing devices; however, internetworks are primarily based on routers rather than data link layer bridges. Once these devices are identified, MIB browsers are effective to understand what mix of protocol traffic is being routed throughout the internetwork. Finally, a topological map can be developed by translating the logical routing to physical locations.

Top level management must also be involved to quantify the operational evaluation criteria. Every business has established measures for effective operations. A network exists to meet the needs of those who use the network, not the preferences of those who maintain it. Therefore, objectives for the communications resources should be a reflection of those criteria held by the business as a whole. Five key operational evaluation criteria or network design goals characterize most networks: performance, availability, reliability, cost, and security. Manufacturing industries and start-up companies often choose cost minimization, financial markets mandate high reliability, security is of utmost importance throughout classified governmental networks like the Department of Energy (DOE) nuclear weapons complex, and high performance is necessary to mass merchandise retail companies. Key operational evaluation criteria are described below.

Cost minimization is a weighty design factor that includes both monthly recurring and nonrecurring fees. To compare competing alternatives with different cost outlays, the time value of money must be considered and the net present value method is usually the best method for financial analysis. In the name of cost minimization, depending on the specific operational objective, one may be led to different solutions given the same problem. Variations of cost minimization goals include: build the cheapest network, get the most network for the dollar, maximize profit by allowing the firm to reach new markets, minimize risk of loss, or maximize growth opportunity.

All network designs include an inventory of lines, equipment, and software needed to make them run. Including all of the cost elements (installation costs, shipping costs, purchase price, monthly lease costs, maintenance costs, and service costs) in the optimization process prevents unpleasant surprises. Total network costs C_{TOT} include the three major cost components in a network design: line costs, equipment costs, and software costs:

$$C_{TOT} = C_{AL} + C_{TL} + C_{IE} + C_{WAE} + C_S \tag{41.1}$$

where:

- C_{AL} = access line costs
- C_{TL} = interoffice channel (IXC) line costs
- C_{IE} = internetworking equipment costs (remote bridge, router, gateway, etc.)
- C_{WAE} = WAN access equipment costs [modems, computer software unit/data software unit (CSU/DSU), channel banks, etc.]
- C_S = software costs

Too often, availability and reliability are mistakenly assumed to be synonymous. Reliability and serviceability are both components of availability. Network availability, a value between zero and one, reflects stability characteristics of communications systems connecting end users. Availability A is composed of two factors: reliability, the probability a system will not fail during a given time, is expressed as mean

time between failure (MTBF), and serviceability, including the time required to diagnosis and repair, is expressed as mean time to repair (MTTR),

$$A = \text{MTBF}/(\text{MTBF} + \text{MTTR}) \quad (41.2)$$

Performance is another key operational evaluation criteria. Represented by average transaction response times RT, it can be calculated by the following formula:

$$R_{RT} = I_T + H_T + O_T \quad (41.3)$$

where

I_T = input message transmission time: number of bits in input message/link speed bits per second + propagation delay

H_T = host processing time

O_T = output message transmission time: number of bits in output message/link speed bits per second + propagation delay

At the completion of the network awareness phase, the network planner must objectively evaluate whether or not this phase has been completed adequately for the purpose of the design process. Questions that might be addressed are:

- Do I have a reasonable assessment of current technology in this networking arena?
- Have I quantified the current network traffic?
- Is there a justifiable forecast of network growth?
- Are the operational objectives and goals quantified and agreed upon by upper level management?

Upon completion, quantifiable operational evaluation criteria are available as input into the network design phase.

Network Design

For too long, networks merely evolved to their present condition by adding users and applications without analyzing performance impacts. The better way is for engineers to describe the topology and media via a network modeling tool. In many network design tools, models are constructed by connecting icons representing specific network devices or segments. Behind the model, powerful software simulates and analyzes the behavior of the network. Also, network conditions such as protocols, traffic patterns, and number of nodes are specified in the model. Traffic can be characterized from statistical traffic models or actual traces of network traffic taken from an analyzer. Simulation and performance evaluation predict network performance and explore future design options. Graphical user interfaces (GUI) simplify changing assumptions on number of users, type of media protocol stacks, application mix, traffic patterns, and so on. When the network model is in place, proposals for adding or deleting resources (such as controllers, terminals, multiplexers, protocol converters, remote front-end processors), redesigning application software, or changing routing strategies may be evaluated.

Network design consists of applying network design tools, evaluating alternative network configurations through a cost/performance breakeven analysis, and optimizing communications lines. Because there are many ways to configure a network and interconnect transmission components, it is not realistic to evaluate exhaustively every possible option. However, by using certain shortcuts, called heuristics (procedures that approximate an optimal condition using algorithms), the number of feasible designs can be scaled down to a manageable few.

Network design tools are developed using heuristic algorithms that abbreviate the optimization process greatly by making a few well-chosen approximations. Queuing theory is incorporated in the algorithms

that calculate response times. A convenient notation used to label queues is:

$$A/B/n/K/p \tag{41.4}$$

where:

- A* = arrival process by which messages are generated
- B* = queue discipline, describing how messages are handled
- n* = number of servers available
- K* = number of buffering positions available
- p* = ultimate population size that may possibly request service

Some of the more typical queuing models pertaining to internetworking are as follows:

- Memoryless (exponential) interarrival distribution, memoryless service distribution, one server (M/M/1) is typical of situations involving a communications server or a file server of electronic mail.
- Memoryless (exponential) interarrival distribution, memoryless service distribution, *c* servers (M/M/*c*) are typical of situations involving dial-up ports for modem pools or private branch exchange (PBX) trunks.
- Memoryless (exponential) interarrival distribution, fixed (deterministic) service time, one server (M/D/1) is representative of a trunk servicing a packet switched network.

A number of internetworking situations require a more advanced model involving distributions other than exponential or deterministic. For the terminal nodes of a communications system, the queue type that is most appropriate is M/G/1 distributions, referring to a generic service time represented by G. This means the process messages that arrive are modeled as Markovian. The M/G/1 solution of queuing delay is given by the Pollaczek–Khinchin (PK) formula:

$$d = m + l * m^2 / [2(1 - p)] \tag{41.5}$$

where

- d* = total delay
- m* = average time to transmit a message
- l* = number of arriving messages/second
- p* = utilization of the facility, expressed as a ratio

After a network model is produced, network engineers often use the tool to evaluate different scenarios of transmission components and traffic profiles. Through an iterative process of network refinement, “what if” questions may be addressed concerning various alternative configurations:

- What would be the impact on performance and utilization if more nodes are added to my network?
- How would response times change if my internetwork links were upgraded from voice grade private lines to 56-kb/s digital circuits; from fractional T-1 dedicated circuits to fast packet switched frame relay?
- How will downsizing to client/server technologies impact the network?
- Should I segment the network with high-speed switches or with traditional routers?
- How much additional capacity is available before having to reconfigure?
- What effect do priorities for applications and protocols have on user response times?

Each of the various alternative configurations will have associated costs and performance impacts. This produces a family of cost/performance curves that forms a solution set of alternative network designs. With the cost/performance curves complete, the final selection of an optimum configuration can be left up to the manager responsible for balancing budget constraints against user service levels.

At the completion of network design, the network planner must objectively evaluate whether or not this phase has been completed adequately for the purpose of the design process. Questions that might be asked are:

- Is the model verified by accurately representing the inputs and generating output that satisfy the operational evaluation criteria?
- Is the cost/performance breakeven analysis selected from the family of feasible solutions the one best configuration based on the operational evaluation criteria?
- Is the equipment rated to function well within the design objectives?

When this phase is complete, an optimized implementable network design is available as input into the network management phase.

Network Management

Network management includes equipment acquisition, verification, installation, maintenance, and administration. This phase of the network engineering process feeds information into the network awareness component, which completes the cycle and begins the iterations of design and refinement.

Network design tools use statistical techniques to make certain assumptions about the behavior of a network and the profiles of transactions in the network. These assumptions in terms of lengths, distributions, and volumes of traffic make the mathematics easier, at the expense of accuracy. Operational networks often violate, to a certain extent, many design assumptions. The optimized network designs confront the real world of actual network performance during the network management phase. Detected variances between optimized network designs and actual network performance provide an improved awareness concerning host processing requirements, traffic profiles, and protocol characteristics.

In a nutshell, network management improves awareness. Design iterations and refinement based on improved network awareness progress toward the optimum. Network management refines operational evaluation criteria. Cost/performance ratios are evaluated against the operational objectives and goals an organization is employing. Network management avoids crises by reacting proactively to changing trends in utilization and performance.

At the completion of network management, the network planner must objectively evaluate whether or not this phase has been completed adequately for the purpose of the design process. Questions that might be asked are:

- Is the network operating error free or are there periodic or isolated errors?
- Is the network performing properly by satisfying response time and availability goals?

When this phase is complete, an operational network is available.

Finally, the network engineer must verify and validate the model by asking: is the model validated by the performance of the operational network? If this objective evaluation results in discrepancies between the model and the real world operational network, then there must be a return to the network awareness phase for model refinement and, possibly, improved optimization. Whenever new needs are placed on the network, the process must be reinitiated, with a revised needs analysis reflecting these new requirements. When the model is fully validated and verified, the network planner can exit the total network engineering decision process with an optimized operational network.

41.4 Internetwork Simulation

Today, with an overwhelming variety of alternative internetwork implementation options, engineers are often uncertain which technology is best suited for their applications. A few years ago, there were relatively few systems from each of several vendors. Times have changed, and now a multitude of interconnection options exist. LAN media choices involve twisted pair, coaxial cable, fiber optics (single mode and multimode), and even wireless systems. LAN media access protocols include token ring (4 or 16 Mb/s),

token bus, ethernet's carrier sense multiple access/collision delay (CSMA/CD), 100 Mb/s ethernet, 100 base VGAnyLAN, full duplex ethernet, switched ethernet, full duplex switched ethernet, fiber distributed data interface (FDDI), and distributed queue dual bus (DQDB.) Cabling strategies include star-shaped intelligent hub wiring, distributed cabling interconnected through a high-speed backbone, and centralized tree-type cabling alternatives.

Discrete event **simulation** is the preferred design technique for internetworks involving varied LAN architectures and high-speed routers connected via WAN links. Here, performance prediction is the primary objective. Engineers specify new or proposed LAN configurations with building blocks of common LAN components. LAN simulation tools predict measures of utilization, queuing buffer capacity, delays, and response times. Proposed configurations of departmental LANs or enterprise internetworks can be modeled, evaluating the capabilities of competing designs involving hardware components, protocols, and architectures. This can be achieved without learning complex programming languages or possessing a depth of queuing theory background. Several excellent design tools have been developed and marketed in recent years for simulation-based modeling and analysis of internetworks.

Can your present configuration handle an increased workload or are hardware upgrades needed? What part of the internetwork hardware should be changed: The backbone? The server? The router or bridge? How reliable is the internetwork, and how can it recover from component failure? Predictive methods preclude the unnecessary expense of modifying a network only to discover it still does not satisfy user requirements. What-if analysis applied to network models helps evaluate topologies and plot performance against workloads. Performance and reliability tradeoffs can be effectively identified with simulation. This is essential in service level planning.

Simulation is beneficial throughout the life cycle of a communications system. It can occur before significant development, during the planning stage, as an ongoing part of development, through installation, or as a part of ongoing operations. Alternatives of different configurations are compared and accurate performance is predicted before implementing new network systems. Presizing networks based on current workloads and anticipated growth demands and pretesting application performance impact are just a few of the benefits of simulation design.

Simulation tools expedite investigating internetwork capacities and defining growth. Knowing whether circuits, servers, node processing, or networked applications are the bottlenecks in performance is useful to any engineer. Managing incremental growth and predicting the impact of additional networking demands are other advantages. Justifying configuration designs to upper level management is another big asset of internetwork simulation.

41.5 Internetwork Optimization

Optimization tools balance performance and cost tradeoffs. Acceptable network performance is essential, but due to the nonlinear nature of tariffs, cost calculations are critical. Tariff calculations are not trivial. Designs based on various routing, multiplexing, and bridging approaches can yield widely varying prices. Tariff data changes weekly, further complicating cost calculations. With new tariff filings, there may be new optimal designs. The best topology of circuit routes and circuit speeds can significantly differ from previously optimal designs when re-evaluating with new tariff data. All optimization tools evaluate cost calculations against performance requirements.

Figure 41.3 graphically illustrates this cost/performance relationship. The ideal cost/performance point is where traffic matches capacity, with acceptable zones around this ideal. Acceptable oversizing is due to economies of scale or forecasted growth, and undersizing is due to excessive rebuilding costs. Outside this acceptable zone, networks need redesign. Where capacity significantly exceeds traffic, the network feels the effects of overbuilding (performance goals satisfied at unnecessarily high costs). Conversely, where traffic is greater than capacity, the network has been underbuilt (cost goals satisfied yet at the expense of performance objectives) and rebuilding is necessary.

Network optimization techniques have become even more complex due to recent introductions of new service offerings, such as frame relay, integrated services digital network (ISDN), synchronous digital

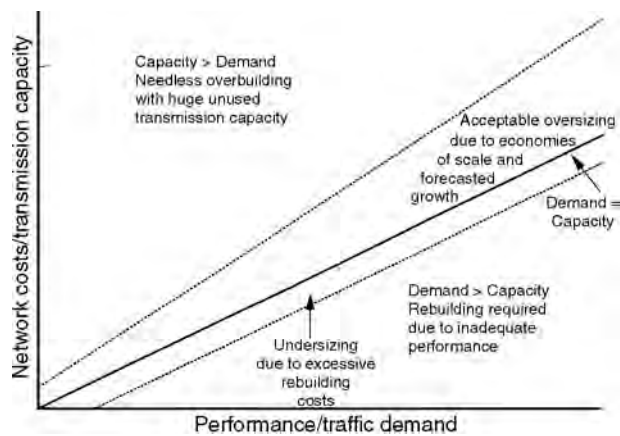

FIGURE 41.3 The cost/performance and capacity/demand relationship.

network (SONET), SMDS and asynchronous transfer mode (ATM), and hubless digital services. These new services are offered by the major interexchange carriers, specialized fiber carriers, and regional Bell operating companies (RBOCs). In addition to reducing costs, new services when designed properly can also increase network reliability.

The enormous variability in circuit costs is illustrated in pricing a single 56-kb/s circuit. An interexchange circuit between Atlanta and Kansas City varies based on service types (DDS and fractional T-1) and service providers (AT&T, MCI, and WTG) between a high of \$2751/month and a low of \$795/month. Similarly, an intraLATA circuit between San Jose and Campbell, California varies based on service types (DDS and new hubless digital) and service providers (AT&T, MCI, U.S. Sprint, and LEC-PacBell) between a high of \$1339/month and a low of \$136/month.

Furthermore, a variety of customer equipment-based multiplexing alternatives run the gamut from simple point-to-point multiplexing, to sophisticated dynamic bandwidth contention multiplexing, to multiplexer cascading, to colocating the CPE-based multiplexing equipment in the serving central office. Numerous networking options make the network engineer's job more complex, requiring optimization tools to evaluate these many new design techniques.

41.6 Summary

Information management today calls for effectively accommodating expansion of interconnected networks and accurately forecasting networking requirements. Only those who have an accurate awareness of their current communications requirements who can apply a structured design approach when evaluating competing networking techniques can confront this formidable challenge. James Jewett, co-founder of Telco Research, states, "Today, U.S. businesses frequently spend up to 40% more than is necessary on telecommunications services. Managers must be willing to scrutinize current communications networks and alternative networking techniques."

This is an age when communications budgets are being tightened, head counts are being trimmed, and major capital outlays are being delayed. Vendors selling LANs, internetworking gear, and long distance services feel cutbacks in flat revenues and intensely competitive bids. Network engineers feel the pinch as they try to meet increasingly demanding enduser performance objectives with dwindling budgets. Many network managers spend hundreds of thousands of dollars monthly on communications resources. These high costs reflect the importance of networks. Yet, with the high priority placed on LAN/WAN internetworking and the significant expenses devoted to maintain them, insufficient emphasis is placed on rigorous design and analysis. Network engineers tend to focus solely on operational capabilities. As long as the network is up and running, analysis or design is rarely conducted.

An engineering process of analysis and design for internetworks was presented. The process includes three interrelated phases: network awareness, network design, and network management. Each phase is part of a feedback control mechanism, progressing toward a network optimum. The industry emphasizes developing internetworking technologies; however, modeling techniques incorporating these technologies into operational networks have received little attention. Engineers applying this design and analysis process will be able to optimize their internetworks.

Defining Terms

Connectionless: A best-effort packet delivery model where the network does not guarantee delivery and data may be lost, duplicated, damaged, or delivered out of order; also called datagram services.

Connection-oriented: A guaranteed packet delivery model where a virtual circuit with minimal bandwidth is established before any data transfer occurs and packets are delivered sequentially over a single path.

Data link switching (DLSw): A routing standard for integrating SNA data into IP-based internetworks by stripping off the SDLC header and replacing it with a TCP/IP header.

Distance-vector routing: An early routing information protocol implementation common to IPX RIP, IGRP, IP RIP, and AppleTalk's RTMP.

Internetwork optimization: This class of network design tools balance performance, cost, and reliability tradeoffs. Optimization algorithms apply heuristic procedures to greatly abbreviate the optimization process by making a few well-chosen approximations. Queuing theory is also incorporated in the algorithms to calculate response times.

Internetwork simulation: Discrete event simulation tools predict network performance and identify bottlenecks. The nondeterministic nature of internetworking communications is reflected in models by pseudorandom numbers that generate interarrival times of messages, lengths of message, time between failures, and transmission errors.

IPng: The new version of the IP layer that supports 16-byte addresses and offers advanced features such as flow control, autoconfiguration, and encryption-based security.

Link state routing: A new breed of efficient routing information protocols designed for large, complex internetworking environments and implemented in OSPF, IS-to-IS, and Novell's NSLP.

Network awareness: The first component in the network design process, in which existing technology is reviewed, future technology trends are evaluated, current traffic is determined, equipment is inventoried, and future growth is forecasted. An organization's unique operational evaluation criteria are also chosen during this phase.

Network design: The second component of the network design process, which includes network design tools, performing a cost-performance breakeven analysis, and developing link configurations.

Network management: The third component of the network design process, which encompasses management of configuration, faults, performance, accounting, and security. Equipment and network software is acquired, verified, installed, maintained, and administered.

Packet burst: A sliding window implementation that allows transmitting multiple packets and receiving a multiple packet acknowledgment, greatly improving the efficiency of SPX/IPX internetworking.

Subnet mask: A four octet field used to identify the link portion of an IP address by setting bits to 1 where the network is to treat the corresponding bit in the IP address as part of the network address.

Total network engineering process: A process to engineer and optimize internetworks including the three phases of awareness, design, and management, with a feedback control mechanism, progressing toward a network optimum.

42.1 Introduction

The main feature of the integrated services digital network (ISDN) concept is the support of a wide range of audio, video, and data applications in the same network. Broadband ISDN (B-ISDN) is based on ISDN concepts and has been evolving during the last decade by progressively incorporating directly into the network additional B-ISDN functions enabling new and advanced services. B-ISDN supports switched, semipermanent and permanent, and point-to-point and point-to-multipoint connections and provides on-demand reserved and permanent services. B-ISDN connections support both circuit-mode and packet-mode services of a mono- and multimedia type with connectionless or connection-oriented nature, in bidirectional and unidirectional configurations.

Since the completion of the initial standardization work on B-ISDN in the late 1980s, there has been a tremendous amount of standards work toward defining B-ISDN interfaces, physical layers, signalling, and transfer mode. Asynchronous transfer mode (ATM) is the transfer mode of choice for B-ISDN. ATM is a connection-oriented, packet switching technique. The ATM architecture and related standards define the basic framework on which different services with varying source characteristics and quality of service

(QoS) requirements can be supported in an integrated manner. However, enabling B-ISDNs requires the design and development of a complete architectural framework that complements the ATM standards and includes network services such as congestion-control and path-selection frameworks, directory services, and group management protocols.

In this chapter, we first review the B-ISDN architecture, the architectural drivers such as high-bandwidth application requirements, and the changes in the networking infrastructure that need to be taken into account to enable ATM networks. We then present a high-level overview of a comprehensive, high-speed multimedia architecture developed by IBM to address the challenges of enabling ATM networks.

42.2 Broadband Integrated Services Digital Network (B-ISDN) Framework

B-ISDN is envisioned as providing universal communications based on a set of standard interfaces and scalability in both distance and speed. B-ISDN physical layer interfaces, including the ones currently being defined, scale from 1.5 to 622 Mb/s. We have already started to see ATM being deployed in the local area, while a number of network providers have started to experiment with ATM in the wide area, providing seamless integration from local to wide area networks. Furthermore, B-ISDN services conceptually include every application that we can think of as we go forward into the future:

- Applications with or without timing relationship among the end users
- Variable and continuous bit rate services
- Connectionless and connection-oriented services

Voice and video are two applications that require an end-to-end timing relationship whereas there is no such requirement for data services. Most applications generate traffic at varying rates. Voice traffic alternates between talk spurts and silent periods. The amount of data generated per frame in a video service varies, depending on the compression algorithm used and how much information from the previous frame(s) can be used to reconstruct a new frame at the destination station while providing the required QoS. Variable bit rate (VBR) service refers to a source traffic behavior in which the rate of traffic submitted to the network varies over time. Early video and audio services in early ATM networks are expected to be supported using continuous bit rate (CBR) traffic in which the traffic is submitted to the network at a constant rate. This is mainly because of the fact that the bandwidth scalability provided by ATM is a relatively new concept, and our previous experience in supporting such services is based on circuit switching, that is, PCM voice and H.222 video. As we understand traffic patterns and source characteristics better, VBR service is expected to replace CBR service for most real-time applications.

ATM is a connection-oriented service, that is, end-to-end connections must be established prior to data transmission. However, most network applications in current packet switching networks are developed on top of a connectionless service. In order to protect customer investment in current applications, ATM should support connectionless service. This is provided mainly by providing an overlay on top of ATM.

Enabling Asynchronous Transfer Mode Networks

The main question in enabling ATM networks is how to make it all work as an integrated network. The answer to this challenge is the ATM standards and the development of network services such as congestion control, bandwidth management, path selection, and multicast and group-management mechanisms that complement the ATM standards while achieving high-resource utilization in the network.

The ATM standards have been developed by the International Telecommunications Union–Telecommunications Standardization Sector (ITU-TS) and various national standardization organizations such as American National Standards Institute (ANSI) and ETSI. The ATM Forum, on the other hand, is a consortium of more than 500 companies established to speed up the development and deployment of ATM products through interoperability specifications based on standards whenever available. Hereafter, we do not differentiate between the standards and the ATM Forum’s specifications.

User-network signalling Q.2931
ATM adaptation layer (AAL)
ATM layer
Physical layer

FIGURE 42.1 Current ATM framework.

Figure 42.1 illustrates the current ATM architecture. A variety of physical layer interfaces are defined, including different transmission mediums such as multimode and single-mode fiber, shielded twisted pair, and coax. Transmission speeds now vary from 45 Mb/s (DS-3) to 622 Mb/s synchronous optical network (SONET).

The ATM layer is based on the use of 53-byte fixed-size cells composed of a 5-byte header and a 48-byte payload. Of the 5-byte cell header, 28 b are used for routing. There is an 8-b header error check field to ensure the integrity of the cell header. This leaves only 4 b, of which 1 b is used for cell loss priority (high or low), and 3 b are used to identify the type of payload information and carry the explicit forward-congestion indicator. As discussed next, there is not really much time to do any processing in the network nodes as the transmission speeds increase. Some networking experts may have desired an extra byte or two to provide more features at the ATM layer. However, it would have been difficult and/or expensive to process this additional information as transmission speeds reach several gigabits per second.

Nevertheless, more features than the ATM cell header supports are required to meet application requirements. Considering a wide variety of services with different requirements, the ITU-TS grouped functions are common to most applications at the ATM adaptation layer (AAL). AAL type 1 is defined for CBR services that require an end-to-end timing relationship. The VBR counterpart of these services will be supported via AAL type 2, which is currently being defined. AAL type 3/4 is defined for the initial connection-oriented and connectionless services. AAL type 5 is a more efficient way of supporting data services. All AAL services are defined among end stations only; they are transparent to intermediate switches in the network.

ATM connections may be pre-established or may be established dynamically on request. Connections that are pre-established are defined by the network's management layer (not discussed here). Switched connections, on the other hand, require the definition of interfaces and signalling at these interfaces. Signalling at an ATM user-network interface (UNI) provides the capabilities needed to signal the network and to request a connection to a destination. Various capabilities included in UNI version 3.0 [ATM, 1994] can be summarized as follows:

- Establishment of point-to-point and point-to-multipoint virtual channel connections
- Three different private ATM address formats
- One public ATM address format
- Symmetric and asymmetric QoS connections with declared QoS class
- Symmetric and asymmetric bandwidth connections with declared bandwidth
- Transport of network transparent parameters among end nodes
- Support of error handling

An ATM user signals to request a connection from the network to a particular destination(s) with a specified QoS. Information elements such as peak cell rate, sustainable cell rate, cell delay tolerance, maximum burst size, AAL type, and address of destination end node(s) are included in the signalling messages exchanged across a UNI. Despite the tremendous effort that has gone into the defining these specifications, it will take a lot more work to enable high-bandwidth, multimedia applications in ATM networks. Various additional services are required:

- Locating destination end node(s): The addresses of end nodes are provided in a related signalling message. Determining the exact location of these end nodes, however, is not a part of the current standards.

- Determining how much network resources are needed to provide the required QoS: Guaranteeing the QoS needs of network applications requires, in general, that resources in the network be reserved. Although the traffic characteristics would be included in the connection request, a way of determining the commitment of resources needed to support different applications is not a part of today's ATM.
- Determining a path in the network that can support the connection: Path selection framework in ATM networks is quite different from path selection in current packet switching networks. While meeting the QoS requirements of applications, it is highly desirable to minimize resources used by the network in order to achieve economic resource utilization. This requires the solution of a constrained optimization problem unlike the shortest path problem posed by traditional packet networks.
- Establishing and managing connections in the network: Routing in ATM networks remains largely an unresolved issue. Routing metrics and the decision place (i.e., source routing) are the two areas that are being studied currently at the ATM Forum. However, the efficient distribution of control information in a subnetwork and the quick dissemination of connection establishment and termination flows are two areas that are not addressed in the ATM standards.

42.3 Architectural Drivers

Before discussing how some of these issues may be addressed, let us look at various application requirements and the changes in the networking infrastructure imposed by advances in the transmission technology.

Perhaps one of the main drivers for emerging ATM networks is the deployment of multimedia applications. Although initial ATM networks may be deployed as data-overlay networks that keep voice separate, it is unavoidable that voice, video, and data will come together as multimedia applications begin to emerge (i.e., videoconferencing, video distribution, distant learning). After all, multimedia networks supporting multimedia applications have been the main driving force behind the B-ISDN initiative.

Multimedia applications differ from monoapplications in various ways. They often take place among a group involving more than two users. This necessitates the existence of group-management and multicast services. Group-management functions would basically allow users to join and leave the group as they wish and would manage the connection among the group's members. Multicast trees provide a connection path among these users efficiently compared with point-to-point connections. Yet, the construction of a multicast tree that satisfies end-to-end delay constraints while achieving high-resource utilization is a hard problem with an exponentially growing time complexity. Addressing this problem in real time requires the development of efficient heuristics.

Multimedia applications also combine the different QoS requirements of individual applications into a single application. This requires the integration of the service demands of different applications and the definition of network services that can support such requirements. As an example, voice and lip motion need to be tightly synchronized in a video service, whereas the synchronization of subtitles (i.e., data) to video does not need to be as stringent.

ATM networks will support a wide variety of traffic with different traffic characteristics. Using the source parameters defined in the ATM Forum's UNI 3.0 specification, a user may pass its peak and sustainable cell rates to the network during the connection-establishment phase. The burstiness (defined in this context as the ratio of peak to average bit rates) of various applications envisioned in ATM networks varies from 1 (e.g., for CBR service) to 100 s (e.g., for distributed computing). As the burstiness of a source increases, the predictability of its traffic decreases. Accordingly, it becomes harder for the network to accommodate highly bursty sources while achieving high resource utilization. Another challenge is the integration of highly bursty sources in the network with less bursty sources, say, CBR services, while meeting the mean-delay and jitter requirements. Let us consider two applications at the opposite ends of the spectrum with respect to their burstiness, voice, and distributed computing. When a distributed computing source becomes active, it generates traffic at the rate of, say, 100Mb/s. An active period is

followed by a silent period during which the source processes data in its memory and does not generate any network traffic. The high burstiness of the source would mean that the periods of activity persist for considerably less time than the periods of inactivity. On the other hand, consider a PCM voice application generating frames at the constant rate of 64 Kb/s. The challenge is to provide network services such that when the two sources are active simultaneously on one or more physical links, the QoS provided to the voice source does not degrade due to a sudden spurt of cells belonging to the distributed computing application. The problem of dealing with applications with widely varying burstiness in an integrated manner cannot be avoided as we move toward VBR multimedia services; network services that meet this challenge are needed to deploy integrated services.

In addition to having to deal with varying source characteristics, ATM networks should support services with quite different QoS requirements. For example, most data applications require fully reliable service (i.e., a banking transaction). However, these services can use the functions provided by a higher layer protocol (i.e., a transport service) on top of an ATM connection that will recover lost data by retransmission. Voice applications can tolerate moderate cell losses without affecting the quality of the service. Interactive VBR video services have very stringent loss requirements since a lost cell could cause the loss of frame synchronization, which in turn would cause the service to degrade for seconds until the stream was refreshed. All of these applications with different requirements are integrated in the network. Network services designed to support these applications should take into consideration their QoS requirements explicitly if high resource utilization in the network is desired.

In addressing the challenges of supporting application requirements, it is necessary to consider the constraints inherent to high-speed networking. As transmission speed increases, two considerations start to play important roles in designing network services: in-flight data becomes huge, and available processing time at the intermediate nodes decreases.

With high-speed transmission links in the network, the amount of in-flight data increases dramatically as the link propagation delay increases. As an example, when the one-way propagation delay on a T1 link is 20 ms (i.e., across the U.S.), there can be up to 3750 bytes simultaneously on the link at any particular time. This number increases to 2.5 million bytes on a 1 Gb/s link. If hop-by-hop flow control were applied between the two ends of such a link, which works well in current packet networks with low-speed links, millions of bytes of data could be lost by the time a control packet traversed the network from one end to the other. This phenomenon dramatically changes the congestion-control framework in high-speed networks. Another aspect of this is the challenge of providing efficient and accurate distribution of control information in the network, that is, link failures, resource reservation levels, actual link utilization, etc.

Another key challenge high-speed links introduce is to keep the functions at intermediate network nodes simple while providing enough functionality for high-resource utilization. Consider a 9.6-kb link and a processor with one million instructions per second capability. Then, up to 44, 166 instructions can be executed for each cell while keeping the link full. When the transmission rate reaches gigabits per second, however, this number goes below one. Even with processors that run at 30 MIPS, the functionality at an intermediate node should be minimized to keep up with high-speed links. Most required functions need to be simple enough to be implemented in hardware. This, perhaps, is one of the main reasons for keeping the ATM cell header so simple.

Simple Solutions: At a Cost

Most of these challenges could be addressed rather easily if the network resource utilization were not taken into consideration. For example, all applications can be treated in the network with the most stringent loss and delay requirements. Though simple, this approach might prove to be quite costly, in that an artificially large amount of network resources might be reserved in the network to support applications that could tolerate moderate loss and/or delay.

As another example, a very small amount of buffering can be provided at each network node with deterministic multiplexing (i.e., peak rate bandwidth allocation). Although this scheme minimizes queuing

delays at each node and guarantees practically no loss, it causes resource utilization in the network to be unacceptably low. As an illustration, consider a source with peak and average bit rate of 10 Mb/s and 1 Mb/s, respectively. On a 100-Mb/s link, only 10 of these connections can be multiplexed, which results in an average link utilization of 10%.

Similarly, point-to-point connections can be used to provide communication among a group of users. This might, however, artificially increase the number of links used to provide a multipoint communication compared with a multicast tree and thereby reduce the availability of extra links for use in point-to-point connections to support traffic from other sources.

In summary, simple things can be done to enable ATM networks; the challenge, however, is to provide network services that will meet the application requirements economically.

42.4 Review of Broadband Network Services

This section presents a high-level review of IBM's broadband network services (BBNS) architecture. BBNS is a comprehensive approach to providing network services for high-speed, multimedia networking based on existing ATM standards and ATM Forum specifications. Conceptually, the BBNS architecture is broken down into the following three functional groups:

- *Access services* provide the framework for supporting standards-based and industry-pervasive interfaces and protocols.
- *Transport services* provide the pipes and the trees needed to switch voice, video, and data across the network in an integrated structure with appropriate QoS guarantees.
- *Control point services* manage network resources by providing the distributed brain power that enables all network services.

Access services can be thought of as locators and translators. They interface with the foreign protocols outside the BBNS network and translate them into what the network understands inside.

Transport services are the transfer modes defined in the architecture and related services developed to support different types of applications with varying service requirements. In addition to ATM, the BBNS architecture supports variable length packets to provide a migration path from the current state of the art in networking today to an all-ATM network. Other services developed include the datagram and multicast services and mechanisms to support different delay priorities.

Control point services mainly provide congestion control, path selection, group management for multimedia applications, directory services, and distribution of network control information.

42.5 How Does It All Fit Together?

Before proceeding with the details of the BBNS architecture, we discuss how the various functions required to enable high-speed networking relate to each other. This discussion uses can setup as a vehicle.

A new connection request is first received by an access agent at the edge of the network. The agent runs an address resolution mechanism to find the destination end node. Then, using the source traffic characteristics and application requirements, the amount of bandwidth required by the application is determined. Bandwidth calculation takes into consideration the cell loss requirement of the application, uses the source traffic characteristics, and determines a guaranteed upper bound on the bandwidth required to support the application when this connection is multiplexed with the connections already established in the network. Then, the path-selection algorithm is run to determine a path from the origin node to the destination node(s). In determining this path, the end-to-end delay requirement of the application is taken into consideration explicitly. In particular, the algorithm finds a minimum-hop path in the network that can support the bandwidth end-to-end requirements of the application.

Once a path is found, an end-to-end connection is established using internal signalling. The traffic can start flowing after every node along the path accepts the connection establishment request. In this

framework, source routing is used; paths are determined by the nodes the connections originate. This approach requires that each node that supports an access service knows the topology of the network (which is subject to change due to link and node failures) and the utilization and current reservation levels of network resources. Although the topology of the network does not change that often, utilization levels change frequently. This necessitates an efficient means of distributing network control information that maximizes the amount of information available to each node while minimizing the amount of network control traffic overhead. These two objectives are contradictory, and the design and development of this feature is a complex task.

At this stage, let us consider the network operating with traffic flowing through a large number of connections. At the edge of the network, it is necessary to monitor the traffic generated by each source to ensure that each source stays within the parameters negotiated at the call establishment phase. Otherwise, nonconforming sources would cause the QoS provided to conforming sources to degrade. A leaky bucket mechanism is used for this purpose. The main challenge in using a leaky bucket is to determine its parameters such that its operation would be transparent to conforming sources while ensuring that nonconforming traffic is detected.

Let us now focus on the nonconforming traffic. There are various reasons that a source might not stay within the parameters negotiated at the call setup time: the source might not be able to characterize its traffic behavior accurately, there might be an equipment malfunction, or the source might simply be cheating. There are two mechanisms developed in the BBNS architecture to provide some amount of forgiveness to nonconforming sources. The first one is the adaptation function which filters the traffic and estimates the amount of bandwidth required by connections based on the actual traffic generated by each source. The second mechanism is the use of so called red/green marking. In this mechanism, conforming traffic is marked green before it is transmitted. Red marking allows (some) nonconforming traffic to enter the network to achieve higher utilization of network resources. Doing so, however, requires the development of mechanisms so that the services provided to conforming traffic in the traffic are not affected by the non-conforming traffic when a node becomes congested.

Another feature required in the network is to minimize the negative effects of resource failures to the service provided to applications. A closely associated function is that of providing support for different priority connections. Nondisruptive path switching is used to reroute connections established on a link (node) around failures in a way that the impact of the failure to the service provided to these affected connections is minimal. Similarly, different connections may have different priorities. Depending on the availability of resources in the network, it may be necessary to take down some low-priority connections in order to accommodate a high-priority connection in the network. The main challenge here is to minimize the cascading effect that may occur when a connection that was taken down tries to re-establish a new connection.

A multimedia network should support connections with different delay requirements. The architecture classifies the multimedia traffic into three categories: real-time, nonreal-time, and nonreserved. Real-time traffic has the stringent delay and loss requirements and requires bandwidth reservation to guarantee its QoS metrics. Nonreal-time traffic also requires bandwidth reservation but only for the loss guarantee, that is, this type of traffic can tolerate moderate delay. Nonreserved traffic, on the other hand, can tolerate both loss and delay. Accordingly, there is no bandwidth reserved for this type of traffic.

42.6 Broadband Network Services

Although the availability of high-speed links in the network infrastructure is important, what really matters is what customers are able to do with them. Two important steps need to be taken to realize fully the promise of ATM. They are:

- The development of high-bandwidth applications
- The development of networking services based on the evolving standards

So far, we have discussed various application requirements and types of services that are required to enable high-bandwidth applications in ATM networks. In this section, we will present a more detailed view of IBM's broadband network services.

Current predominant networking technologies are designed to emphasize service for one or two of these QoS classes, for example, telex (delay and loss tolerant); telephony (delay intolerant); TV and community antenna television (CATV) (delay intolerant); and packet-switched networks like X.25, frame relay, APPN, transport control protocol/Internet protocol (TCP/IP), and SNA (delay tolerant). The promise of ATM is that networks can be built on a single technology to accommodate all QoS classes. BBNS is a comprehensive approach to providing network services for high-speed, multimedia networks based on the existing ATM standards and ATM Forum implementation agreements. Various services developed in this architecture are presented next.

Access Services

While providing users with a high-speed, multimedia networking infrastructure for emerging high-bandwidth applications, it is necessary to support existing user applications that have been developed based on multiple protocols. Broadband network services achieve this through access services that support multiple protocols including frame relay, ATM, voice, IP, and HDLC data, to name a few. External nodes connected to BBNS do not require any special knowledge of any BBNS features, that is, these stations communicate with BBNS access services using their native protocol.

Functions performed by access services include the following:

- Understanding and interpreting the external service or protocol
- Performing an address resolution function to locate the target resource
- Maintaining and taking down connections across the network in response (for example) to connection requests received at the ATM UNI
- Selecting the switching mode and network connection parameters that are optimal for the external protocol and the service requested
- Mapping the QoS parameters of the external protocol the parameters used by the architecture to ensure the availability of sufficient network resources to guarantee that the QoS requirements are met
- Ensuring fairness among users by calling on BBNS bandwidth management services.

Transport Services

BBNS transport services provide a transport facility across the network for user traffic generated at the edges of the network and accommodated by access services. These include transmission scheduling, hardware-based switching with multicast capability, and provision of a switching mode that meets the requirements of external protocols efficiently. In particular, the architecture supports the following switching modes:

- ATM switching
- Automatic network routing, which provides source-routing capability
- Label swap (with tree support)
- Remote access to label-swap tree

The architecture supports ATM natively. Depending on product implementation and customer choice, a network built based on this architecture can support network trunks that carry either ATM cells only or a mix of ATM cells and variable length packets, with the former being transported in standard ATM cell format. Just as ATM cells provide native transport for the ATM UNI, BBNS offers support for other interfaces such as HDLC, frame relay, and IP. This feature allows customers to introduce early ATM applications using ATM transport without any changes or performance penalty in supporting their

existing applications. However, any customer committed to ATM-only networking is fully supported through the BBNS architecture.

To provide service appropriate to the QoS classes discussed previously, BBNS supports two types of traffic priorities: delay and loss. Three different delay priorities are defined: real-time reserved bandwidth, nonreal-time reserved bandwidth, and best-effort service. Logically, each delay class is routed through a corresponding queue in each node. Similarly, four different loss priorities are defined for real-time traffic, and two different loss priorities are defined for nonreal-time traffic. Combined with the power of BBNS bandwidth management, these delay and loss priorities offer the flexibility to support a broad range of QoS requirements and, thus, to handle efficiently the emerging multimedia applications.

Control Point Services

BBNS control point services control, allocate, and manage network resources. Among other things, these services include bandwidth reservation, route computation, topology updates, address resolution, and the group management support needed for multipoint connections. Some of these services are briefly described next.

Set Management

Set management provides the mechanism to group user resources for the purpose of defining multiple logical (i.e., virtual private) networks. This is a critical requirement for service-provider networks, where resources belonging to one customer may have to be isolated from those of other customers. The same mechanism can also be used to define multiple virtual local area networks (LANs) on a network.

Set management also gives a network the ability to learn about new resources and users automatically, thereby reducing system definition and increasing productivity. In essence, set management allows a network function or a user port to be defined only once to make it available to the entire network. Furthermore, it provides full flexibility and mobility in naming/addressing. A user can be moved from one point to another without being forced to change his external address (phone number, for example).

Bandwidth Management

BBNS bandwidth management, congestion control, and path selection enable a network to provide quality of service guarantees on measures such as end-to-end delay, delay jitter, and packet (or cell) loss ratio, while significantly reducing recurring bandwidth cost. This is achieved through efficient bandwidth reservation, load balancing, and dynamic bandwidth allocation.

For each reserved bandwidth connection requiring QoS guarantees, the architecture reserves a sufficient amount of bandwidth on the links traversed by the connection. The BBNS approach, which depends on the connection's traffic characteristics and QoS requirements, computes sufficient bandwidth to satisfy the QoS requirements, taking into account the statistical multiplexing at the links. BBNS path selection finds a path from source to destination that satisfies the connection's QoS requirements using algorithms that minimize the number of hops in the path and balance the network traffic load.

The architectural approach supports both reserved and nonreserved bandwidth transport of user frames or cells. Note that no QoS support is provided for nonreserved traffic. When reserved bandwidth connections are used to support bursty connections (like traditional data traffic), the challenge of setting network connection parameters can be significant. When a user has a good understanding of his traffic characteristics, the user may be unable to signal those characteristics to the network until the workstation implements a new interface, such as the ATM UNI. Even when it is possible to set traffic parameters correctly initially, the bandwidth requirements may change dramatically on the order of seconds to minutes. To mitigate these problems, the architecture offers bandwidth adaptation (dynamic bandwidth allocation) as an optional added value. First, BBNS bandwidth management will enforce an existing traffic contract on a cell time scale of milliseconds or lower. Then, at user option, bandwidth management will learn the actual bandwidth requirements of a connection and adapt by rereserving (and possibly rerouting) the connection using a longer time scale on the order of the roundtrip delay (seconds).

Efficient Distribution of Control Information

BBNS hardware-based multicast switching capability allows fast and efficient distribution of network control messages. Messages such as topology and link-state updates are multicast on the control-point (CP) spanning tree (a multipoint connection, or tree, that extends to every node in the network) at close to propagation speed. Furthermore, since these update messages are carried only by links on the CP spanning tree ($n - 1$ links in an n -node network), the bandwidth needed by the control traffic is greatly reduced. The BBNS CP spanning tree algorithm maintains the integrity of the spanning tree. The algorithm builds the tree and automatically repairs it in case of partitioning caused by link or node failures. The topology algorithm provides reliable delivery of multicast messages. Control messages such as connection setup requests and connection maintenance messages also benefit significantly from the hardware multicast capability. These messages are multicast linearly to every intermediate node along a connection's path, thus allowing connection setups and takedowns much faster than through hop-by-hop signalling methods.

Nondisruptive Path Switching (NDPS)

Nondisruptive path switching (NDPS) makes it possible for a network to reroute network connections automatically in the face of node and/or link failures while minimizing user disruption. Although such a feature is common to other networking architectures, the BBNS version is extremely efficient. First, changes to the network planned or unplanned, are nearly instantly known throughout the network because of the CP spanning tree. Second, all rerouting decisions are made in parallel in a distributed fashion, rather than sequentially at a central control point. This allows for rapid network stabilization.

Call Pre-emption

Call pre-emption enables a network to provide different levels of network availability to users with different relative priorities. When required, call pre-emption will reroute existing connections to accommodate higher priority connections. BBNS call pre-emption strategy intelligently selects connections to be pre-empted, minimizing the possible rippling effects. NDPS is used to reroute the pre-empted connections; thus, disruption is kept to a minimum. The architecture gives the network operator the flexibility of assigning a wide range of priorities to network users.

42.7 Conclusions

There are various issues that need to be satisfactorily addressed in order for ATM networks to become a reality. In this chapter, we reviewed some of these issues based on application requirements and changing networking infrastructure. Then, we presented a high-level review of IBM's architecture for high-speed, multimedia networking that addresses some of these challenges while achieving high resource utilization in the network. ATM, related standards, and IBM's broadband network services architecture are evolving over time. Despite the tremendous amount of work completed on the standards and various networking issues, and the fact that vendors have been working on the design and development of an architectural framework to enable ATM networks, there still remain several issues that need to be satisfactorily resolved. This includes the design and development of applications that can take advantage of high bandwidth in customer premises and public networks as well as network services that can meet the application requirements while maximizing the usage of network resources. ATM is positioned as the transport method with the greatest potential to provide unified voice, video, and data service for high-speed networks supporting multimedia applications. Much work has been done in defining the B-ISDN standards in which ATM transport is featured. Both international standards bodies and the ATM Forum continue the prolific work to enhance the standards and implementers' agreements that are fundamental to realizing customer expectations. Yet, various vendors are expected to provide value-added services that complement the ATM standards, thereby distinguishing their products from others. Broadband network services

are IBM's architecture for value addition to various ATM networking that includes:

- A set of transport services that allow efficient integration of traffic generated by different sources with varying delay and loss requirements
- Bandwidth management framework that provides quality of service guarantees while achieving high-resource utilization in the network
- Efficient distribution of control information in the network minimizing the resources used for network control overhead while updating control information at the network nodes (at propagation delay speeds)
- Set management techniques that define and maintain logical groups and allow the network to learn about new resources and users automatically
- Nondisruptive path switching that minimizes disruption to users in case of network resource failures
- Call pre-emption that allows priority handling of connections and minimizes possible cascading of connection takedowns
- A path selection framework that addresses the requirements of different types of applications with varying delay and loss demands while achieving high utilization of network resources (this framework includes both point-to-point and point-to-multipoint path construction)
- The flexibility to help users evolve their existing applications and networks to ATM transport by matching the switching mode provided by the network to the native transport mode of existing protocols and applications.

Comverse Network Systems

- 43.1 Introduction
- 43.2 Signaling and Control in PSTN
- 43.3 General Attributes and Requirements of NGN
- 43.4 A Broad Outline of the NGN Architecture
Connectivity Network Domain • Application Services Domain • Application Services Infrastructure (ASI) Domain
- 43.5 Evolution Towards NGN: Trials and Tribulations
NGN as a Voice-over-Packet Network • Transition to NGN Beyond Voice
- 43.6 Conclusions

This chapter discusses the challenges and opportunities associated with a fundamental transformation of current networks towards a multiservice ubiquitous infrastructure with a unified control and management architecture. After articulating the major driving forces behind network evolution, we outline the fundamental reasons why neither the service control infrastructure of the public switched telephone network (PSTN), nor that of the present-day Internet, are adequate to support the myriad of new application services in next generation networks. Although NGN will inherit heavily from both the Internet and the PSTN, its fundamental service control and management architecture is likely to be radically different from both and will be anchored on a clean separation between a QoS-enabled connectivity network domain and a component-oriented application service infrastructure domain, with a distributed processing environment that glues things together by providing universal support for distribution, redundancy, and communication between distributed components. Finally, we allude to the transition issues and show how voice-over-packet services are emerging as the bootstrap application for marshaling in the NGN architecture.

43.1 Introduction

The future vision of “information and communication anytime, anywhere, and in any form” is starting to come into focus as major players begin to position themselves for a fundamental transformation of their connectivity network and application service infrastructures (ASI). It has become increasingly

clear that a prerequisite for realization of such a vision is the convergence of the current multiple networks—each employing different transport and control technologies—into a unified, multiservice, data-centric network offering services at different qualities and costs on open service platforms. The evolution towards such a vision is undeniably influenced by the growing trends of deregulation in the telecommunication industry on the one hand, and the rapidly evolving technological convergence between distributed computing and communication (singularly embodied in the Internet and its associated technologies) on the other hand. In a real sense, the necessary technological and environmental underpinnings are coming together for next generation service providers to begin the process of transforming their infrastructures in ways that will enable provision of many new innovative services rapidly, economically, on a mass scale, and with the required quality of service. System, hardware, and especially software vendors will also need to revamp and retune their production processes to meet the challenges of convergence in next generation networks.

At a high level, the fundamental driving forces for next generation networks can be categorized as follows.

Environmental drivers reflect changes that have been happening in the telecommunication business environment in the course of the past decade and a half. In this period, the global telecommunication industry as a whole has been gradually moving away from the model of state-owned and/or regulated monopolies into the model of a competitive industry operating in an open market. The process started with the breakup of AT&T in 1984, picked up speed with privatization of state-owned enterprises in the late 1980s and early 1990s, was greatly accelerated by the US Telecom act of 1996, and has picked up momentum by the progressive opening up of global telecommunication markets in the late 1990s. The rising tide of deregulation and privatization and the emerging competitive landscape, hand-in-hand with market and technology drivers (to be mentioned later), have caused unprecedented regrouping and consolidation of service providers and, in parallel, of system and equipment vendors that serve them.

Market/business drivers on the one hand reflect the continuously expanding set of capabilities and features that various markets demand to satisfy an expanding set of personal and professional needs, either as end users of services (consumers), or as intermediaries (wholesalers) who enhance the acquired services and offer them to their customers. For example, mobility of various kinds (user, access device, or application) has become a paramount requirement of services in different markets. On the other hand, the never-ending market pressure to minimize costs leads to transformational changes in the core of the network that may not even be visible to customers. Transformation of the TDM core of the circuit switched network into packet is an example of a business-driven initiative to minimize cost. Other market-driven needs include ready access to information, easy-to-use communication capabilities involving more than one medium (of both real-time and non-real-time vintage), greater and more granular end-user control over services, and progressively higher-quality content delivered for purposes of entertainment and/or education. Market drivers, even as other factors modulate them, are unquestionably the decisive factors for architecture evolution because **services are what customers use and pay for** and service providers constantly strive to reduce the cost of providing such services.

Technology drivers include all the technological enablers that a service provider, in partnership with its vendors, can take advantage of in the course of architecting and composing its repertoire of services. In today's information society, technology drivers have a lot to do with shaping customer expectations, thereby modulating market and environmental drivers. It is interesting to recall how common it was not too long ago to relegate technology drivers to the backseat and position business considerations and short-term customer needs as the only driver for network evolution. However, the spectacular rise of the Internet on the heels of the convergence of distributed computing and communication technologies has underlined the critical importance of technology drivers in elevating and reshaping customer expectations and in pushing out the restrictive envelope of regulatory constraints. The Internet, with the technologies it has spawned, is perhaps the single most prominent technology driver of our time.

These drivers, operating against the backdrop of some mega trends—including the growing diversity and complexity of new application services, the increasing variety and power of end user devices, and

the competitive push to minimize time-to-market—unmistakably underline the urgency of fundamental transformation in communication network and application service infrastructures. This chapter attempts to draw the broad outline and requirements of a target next generation architecture, which can serve the role of the distant “lighthouse” that guides the overall process of architecture evolution over the long haul. Any target NGN architecture would necessarily have to abstract away the current product limitations to provide a somewhat idealized, top-down perspective of next-generation networks. Throughout the discussion, it will be assumed without further elaboration that the architectural principles of scalability, reliability, evolvability, controllability, and efficiency will be applied to any concrete intermediate instantiation of the architecture.

Before outlining the fundamental requirements and salient features of service control and management in next generation networks, it may be appropriate to sketch an outline of signaling and control in modern PSTN and elaborate on its strengths and weaknesses in the context of evolution towards next generation networks.

43.2 Signaling and Control in PSTN

Since the advent of digital networks a quarter of a century ago, control of the TDM-based public switched telephone network (PSTN) has by and large been delegated to a physically separate signaling network with its own distinct transport infrastructure and protocol suite. The initial signaling network was the Common Channel Interoffice Signaling 6 (CCIS6) network deployed by AT&T in the mid-1970s. This network eventually evolved to the Signaling System No. 7 (SS7) network about a decade later, which is the current most widely deployed signaling network in the world [1]. The SS7 network provides a real-time highly reliable means for switches to communicate and exchange call/connection/service control information. PSTN switch software and SS7 call control protocols (e.g., ISUP) also typically provide support for a number of supplementary services beyond simple call setup. Call forwarding, call waiting, and calling number identification are some of the better-known switch-based services of this type.

To analyze a simplified call setup (involving only two local switches), the central office (CO) switch can be decomposed into four functional modules (Fig. 43.1). When a telephone connected to the originating CO switch goes off-hook, the line module is responsible for detecting the off-hook event, providing a dial tone to the telephone over the analog local loop, and collecting the dialed digits such as the called party’s telephone number. The line module then hands over the dialed digits for processing to the call processing module. After analyzing the collected digits and determining the appropriate route to complete the call, the call processing module asks the signaling module to initiate appropriate

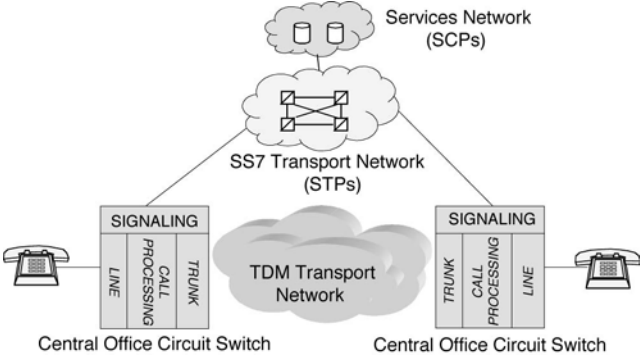

FIGURE 43.1 The fundamental structure of signaling and control in modern PSTN.

signaling over the SS7 network. The SS7 network carries the call setup message to the CO switch serving the called party and initiates establishment of a bearer channel between the originating and terminating switches over the TDM-based transport network. The line module of the terminating switch applies a ringing tone to the called party's telephone. When the called party answers, the call is established between the two parties. The trunk module converts analog speech to digital and appropriately formats it for transmission over the TDM trunks. At the terminating CO switch, the reverse process takes place. When one of the telephones goes on-hook, the line module serving that telephone detects the on-hook event and sets off appropriate signaling through the SS7 network to release the resources allocated for the call.

The complexity of the monolithic switch software, coupled with the inherent lack of flexibility and control over its capabilities by the service providers, led to the inception and deployment of intelligent networks (IN) in the early 1980s and advanced intelligent networks (AIN) [2] about a decade later. Here, some of the call processing logic and data were moved to separate centralized network nodes called service control points (SCPs). SCPs were also connected to the highly reliable SS7 transport network of signal transfer points (STP) just like switches (Fig. 43.1). The signaling network then evolved to support a client-server protocol for communication between the switches and SCPs in support of IN/AIN services. When the call processing module of the originating switch detects a "trigger" (e.g., a free-phone dialed number), it passes control of the call to the SCP through a series of signaling messages sent over the SS7 network. The SCP continues processing the call and instructs the switch, for example, by providing it a routable number, on how to proceed completing the service. The connection setup phase of the call would proceed in the same manner described above for a simple call [2]. Note that Fig. 43.1 does not show other resources that may be attached to the switch, such as intelligent peripherals to provide additional services like announcements and tone detection for enhanced services. Nor does it show any tandem switches that may be involved in the call.

IN/AIN effected a partial decoupling between call/connection control and enhanced service control through the use of SCPs, greatly reducing the time-to-market for new SCP-hosted services and features. This enriched the service repertoire of the telephone companies, a process that is still going strong albeit at a slower pace. As some services are switch-based while others are provided by IN/AIN, and because even IN/AIN services are dependent on triggers embedded in switch software, the decoupling of service control and call/connection control in PSTN/IN is only partial, with substantial dependence still remaining on switch vendors for service provisioning.

Some of the attributes and characteristics of the signaling and control infrastructure in modern PSTN that are particularly relevant to architecture evolution towards NGN are as follows:

- The fundamental assumption about the underlying transport network is that it is a TDM-based network supported by (local and tandem) circuit switches and used almost exclusively for voice and/or voice-band communication.
- The signaling and control infrastructure of PSTN and its associated protocols are optimized to provide voice-centric services.
- The control infrastructure of PSTN is proprietary and by and large closed to third-party service providers. This, among other things, implies a fairly high degree of operational complexity when one network or service provider has to interface to another provider. It also means that the knowledge required for service creation in this environment is narrowly specialized and relatively hard to find or nurture, further contributing to delays in service rollout.
- The customer premise equipment (CPE) used for PSTN access has very limited capabilities and is predominantly analog in nature (the "dumb phone"). Even when this access device is digital, as in the case of an ISDN terminal, its capabilities are still quite restrictive and limited.
- Control and management in PSTN are totally separate domains with different requirements. PSTN signaling and control requirements are much more real-time sensitive, and call for far greater reliability and robustness, than PSTN management (operation, administration, and maintenance, or OA&M) requirements.

43.3 General Attributes and Requirements of NGN

Consider some of the attributes and characteristics of NGN and the services that it needs to support. Following the same thread as the one at the end of the previous section, one can note the following:

- The underlying transport network in NGN is unquestionably packet based. This packet infrastructure is expected to support a large variety of new QoS-enabled (broadband and narrowband) application services involving an arbitrary combination of voice, video, and data. This is in sharp contrast to the predominantly narrowband, single QoS, voice-centric services of PSTN and the best effort, non-QoS-enabled, data services of the Internet.
- The control infrastructure of NGN has to be optimized to support a large variety of broadband multimedia applications on a QoS-enabled packet services. Nonetheless, it will still have to exhibit a high degree of reliability and robustness, just as signaling does in PSTN.
- The application service infrastructure of NGN has to be open in order to allow third-party application service providers to easily integrate their services into it. This is simply recognition of the fact that, as the Internet has proven, there is no way a single service provider can create all or even the majority of the application services that its customers need. This openness also makes the whole architecture more easily evolvable, with a much larger pool of technical staff who can quickly become productive in creating new application services and features.
- Given the nature of services supported by NGN, the CPE involved in service delivery can become far more sophisticated than the low functionality phone in PSTN. PCs of various kinds will probably constitute the dominant kind of powerful CPE in next generation networks. NGN, however, will need to support a wide range of other wired and wireless devices ranging from screen phones to sophisticated multimedia workstations and media centers. Sophisticated CPE gear will not only facilitate end-to-end multimedia communication and information retrieval, but will provide a hitherto unprecedented computing platform for local execution of logic and storage of data in concert with network-based servers. This, in turn, will have enormous implications for the service control infrastructure of NGN.
- Finally, the demarcation between control and management is already beginning to fade and will completely disappear in NGN. Application service, and to a large extent network, management functions are beginning to require real-time performance, thanks to the rising expectations brought about by the Internet. Also, because of an increasing level of reliance by customers on their application (and network) services, the reliability of the associated management functions needs to converge to the level of reliability of real-time control functions. In short, management and control functions in NGN will not be distinguishable any longer and need to be supported by the same architecture.

As we highlight some of the fundamental differences between PSTN and NGN, it may be instructive to also highlight the major differences between the Internet and NGN. While the Internet and NGN are both packet-based and support sophisticated CPE for service delivery, two fundamental differences exist between them. One is that the current Internet by and large provides services only on a best-effort basis. This means that neither reliability nor quality of the delivered service can be guaranteed. Such will clearly not be the case for NGN, where QoS and reliability of services (both network services and application services) will have to be engineered and guaranteed (and duly paid for). The other major difference is that the service architecture in the Internet is ad-hoc: application servers are at the edges of the network and each application service is architected in its own way without fitting into a unified service infrastructure. NGN, on the other hand, needs to have a fairly sophisticated connectivity network architecture supporting a unified application service infrastructure that optimizes the distribution of intelligence between network servers and end systems and ties into a powerful service creation environment. In the absence of such a unified application service architecture, it is highly doubtful that the Internet, even with enhanced capabilities to address QoS, can become the single ubiquitous infrastructure for delivery of sophisticated multimedia multi-party services of the future. Nonetheless, there is no doubt that NGN

TABLE 43.1 Some of the Attributes of PSTN/IN, Current Internet, and NGN

Parameter	PSTN/IN	Internet	NGN
Multimedia services	No	Yes	Yes
QoS-enabled	Yes (voice)	No	Yes
Network intelligence	Yes	No	Yes
Intelligent CPE	No	Yes	Yes
Underlying transport network	TDM	Packet	Packet
Service architecture	Semi-distinct	Ad-hoc	Distinct
Integrated control and management	No	Yes	Yes
Service reliability	High	Low	High
Service creation	Complex	Ad-hoc	Systematic
Ease of use of services	Medium	High	High
Evolvability/modularity	Low	Medium	High
Time to market of services	Long	Short	Short
Architecture openness	Low	High	High

will inherit far more from the Internet paradigm than from the PSTN paradigm. Some of the similarities and differences between NGN, PSTN/IN, and the current Internet are highlighted in [Table 43.1](#).

43.4 A Broad Outline of the NGN Architecture

As implied by [Table 43.1](#), next generation networks will have both similarities and differences with PSTN/IN, as well as with the Internet. The fact that the connectivity network in NGN is going to be packet-based opens up vast possibilities in terms of new application services, services that could not even be imagined in a TDM environment. Application services, and service interactions, will be much more diverse and complex, requiring a far more sophisticated system of control and management. In the interest of reducing time to market, as well as management of complexity through separation of concerns, NGN will require a clean separation of functions and domains with maximum degree of reuse built into the architecture and its components. Three distinct, separable, and interacting domains will exist in NGN with clearly defined boundaries. These are the **connectivity network** domain, the **application services** domain, and the **application services infrastructure (ASI)** domain. Although these domains functionally exist in PSTN/AIN as well, their capabilities are quite limited and boundaries between them are hard to distinguish and maintain.

These three domains are pictorially shown in [Fig. 43.2](#). The two types of customers (residences and businesses) are each depicted to have their own internal networks and devices with gateways connecting them to the service provider's infrastructure. The mobile users shown in the figure by cars can be either business or residential customers. Business networks could also contain servers, which can be thought of as third-party servers. Note that all four types of relationships (residence–residence, residence–business, business–residence, and business–business) have to be supported, with the service provider directly or more likely indirectly through third parties, enabling rollout of all kinds of broadband application services to its customers. This enablement on the part of the next generation service provider consists primarily of providing and operating a highly reliable and large-scale ASI, and to a lesser extent and more selectively a connectivity network infrastructure. Let us now consider in more detail what constitutes the three domains.

Connectivity Network Domain

This domain provides connectivity requested by other domains using an underlying packet-based transport infrastructure. Such connectivity is characterized by communication associations that meet the requirements of QoS, scalability, traffic engineering, and reliability. These associations can be based on either connection-oriented or connectionless network services, although connectionless network services

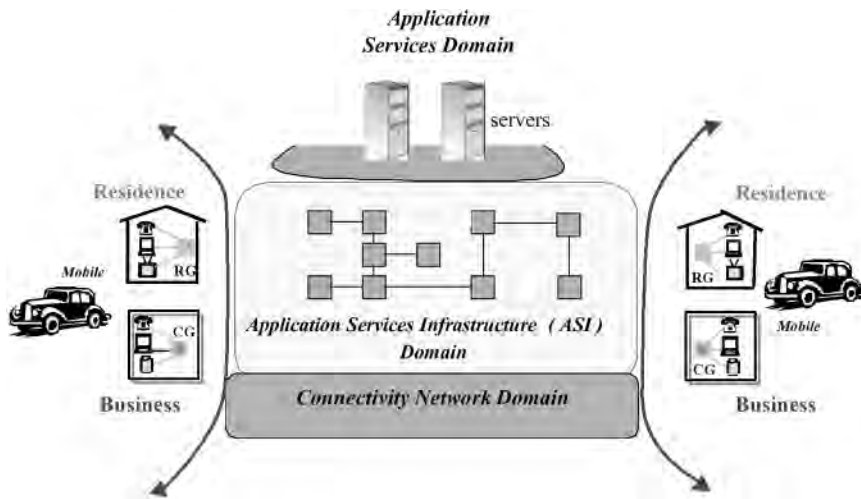

FIGURE 43.2 A high-level view of various domains in next-generation networks.

using IP will become dominant. The connectivity network domain would provide all functions generally attributed to the lower four layers of the OSI model.

A communications session in the ASI domain maps to a **connectivity session** in the connectivity network domain. ASI can initiate two types of connectivity sessions. A **default connectivity session** gives a customer access to the network. Activities such as web browsing, notification, and sending and receiving email can occur in such a session, and do not require ASI to establish new sessions specific to such activities. Only limited, provisioned QoS is available for such activities (which could in most cases use a best-effort service). An **enhanced connectivity session** would go beyond the default connectivity session to support some combination of QoS guarantees, policy, and billing. It is within an enhanced connectivity session, mapped to a communication session, that ASI can exert control over establishing and managing connections and/or associations.

Application Services Domain

In broad terms and for the purposes of this chapter, an **application service** is defined as a software application that provides a useful and well-defined functionality to the user. An application service is realized by a set of interacting software components distributed across multiple computing elements.

The user of the application service can be any human or machine entity. It may be useful to classify application services into a few major categories to gain insight into architectural issues that impact ASI requirements in next generation networks.

The first, and perhaps most prominent, class of application services offered by the NGN will be interactive *communication services*. These include real-time communication services involving multiple parties interacting in real-time and using multiple media (voice, video, and data). Multiple qualities or grades of these services will need to be supported. Services of this kind will constitute the evolution of today's voice telephony into next-generation, multimedia, multiparty, communication. Because of their real-time performance and dynamic control requirements, these services are likely to become the most complex set of services that NGN will offer to its customers. Communication services also include non-real-time services involving multiple parties and multiple media. These will constitute the evolution of today's messaging (predominantly e-mail and voice mail) into a unified set of store-and-forward multimedia services that have elaborate terminal adaptability, control, and media conversion capabilities.

The second major class of application services can be broadly labeled *information/data services*. These services may be thought of as the evolution of today's Internet services: browsing, information retrieval,

on-line directories, scheduled information delivery, e-commerce, advertising, productivity and other network computing services that the Internet can ubiquitously provide today (excluding e-mail, which we classified as a communication service). They also include a rich set of remote access and control services such as telemetry, monitoring, security, network management, and other data-oriented services. The evolution of this class of services will not only include their rudimentary versions that exist today, but major improvements to enhance response time and reliability and provide sophisticated billing, quality of service, and policy enforcement options. What will need to be preserved, however, and indeed extended to all other NGN services, is the ease of use inherent in today's Internet paradigm.

The third class of services that a next generation service provider will inevitably need to offer and/or enable is delivery of content. Typically, such content delivery is for purposes of entertainment, education, training, etc. We label these *content delivery services*. These services can be offered on demand, nearly on demand, on a broadcast or multicast basis, or on a deferred-delivery basis for use at a later time. The various flavors of on-demand and/or multicast services (video-on-demand, high quality music-on-demand, etc.) can pose interesting technical challenges from the point of view of scalability. The NGN's application services infrastructure must address these challenges and provide an efficient and economical way to support them.

Finally, there is another class of services that has to do with management of other services. These services may or may not have revenue-generating potentials by themselves, but they are otherwise every bit as useful and necessary as any other service. These are categorized as *ancillary/management services*. This class includes services such as subscription, customer provisioning, customer network management, customer service management, etc. The dominant mode of accessing these services is likely to be through a Web-based interface. Many services in this category typically are needed in support of other end-user services and, hence, are ancillary in nature. Other services in this class include configuration management, performance monitoring and management, billing and accounting management, service security management, policy enforcement, and similar services. The users of some of these services may be internal customers (typically IT personnel). Offering efficient and user-friendly versions of these application services, in conjunction with primary services, will become a strong service differentiator in next-generation networks. Although these services have much in common with information and data services, they are separately classified to draw attention to their ancillary and/or management nature. As alluded to earlier, and unlike in PSTN/IN, the same application service infrastructure domain that supports primary services can support ancillary/management services, thereby virtually eliminating some of the biggest historical obstacles in the path of drastic reduction in time-to-market.

The different application service categories and representative examples are shown in [Table 43.2](#).

As shown in [Fig. 43.2](#), the application-specific parts of these services will be hosted in application servers, content servers, and media servers that may belong to and be operated by the next generation service provider or, what is more likely, by different kinds of third party application service providers.

Application Services Infrastructure (ASI) Domain

As mentioned earlier, the PSTN/IN infrastructure is optimized for narrowband, circuit-switched, voice-centric services. The application services infrastructure of next generation networks seeks to provide a universal, large-scale, open component-oriented software platform on which a large variety of broadband

TABLE 43.2 NGN Application Service Categories and Examples

Application Service Category	Representative Examples
Communication services	Multimedia, multiparty conferencing; unified multimedia messaging
Information/data services	Internet browsing; e-commerce; directory services; push services; office productivity services
Content delivery services	Video-on-demand; music-on-demand; distance learning; multiplayer network games
Ancillary/management services	Subscription services; Web-based provisioning; service management

(as well as narrowband) services can be architected. Software components distributed on various computing platforms and communicating with one another constitute the “service plumbing” that the application services need for their realization. This service plumbing is the essence of the ASI. Fundamental to ASI and its support of the application service categories mentioned above is the notion of a **session**. A session represents the evolution and outgrowth of the notion of a “call” in telecommunication networks. A session can be defined as the **context** that brings together related activities, resources, and interactions in an application service. A service session can be further specialized into three distinguishable types. An **access session** is the starting point of interaction between the user of a service and the service provider. Authentication, authorization, and similar access-control functions would take place within the access session. A **usage session** is the actual context in which application service execution takes place and constitutes the utilization phase of the service. Clearly, multiple usage sessions can be associated with the same access session over time. A **communication session** provides an abstract view by ASI of connection-related resources necessary for the delivery of a particular service. A communication session is typically associated with a unique usage session while a usage session can involve multiple communication sessions. The actual connection-related resources are provided by the connectivity network through a connectivity session.

In order to support the development and deployment of distributed applications in the next generation networks, mechanisms are needed for load-balanced and reliable distribution of software components among computing platforms, and for communication among those components. These mechanisms are embodied in a distributed processing environment (DPE). DPE is the invisible “ether” that enables service components (and potentially transport components) to interact with one another. It relieves application services of having to deal with and solve the difficult problems of distribution, currency control, and communication on a per service basis. Components communicate with other components as though all components were resident on the same local host. Thus, application service developers are by and large relieved of explicit concerns about details and complexities associated with distributed processing, communication protocol design, concurrency control, fail-over strategy, platform redundancy and reliability, etc. These are all addressed by DPE experts, resulting in a separation of concerns that is crucial for evolvability as well as for minimizing time to market and managing complexity. Signaling System No. 7 is the closest approximation to a DPE in the voice-centric narrowband network of today. Clearly, DPE in next generation networks will inherit the high-level functions of today’s SS7 and add much more functionality to satisfy the requirements of next-generation broadband data-centric application services. Common object request broker architecture (CORBA) may be a good approximation of what NGN’s DPE may look like, provided real-time and reliability issues of CORBA are successfully addressed. Extended markup language (XML), simple object access protocol (SOAP), and related technologies may provide another way of realizing DPE functionality in NGN.

43.5 Evolution Towards NGN: Trials and Tribulations

We have briefly sketched a broad outline of the target NGN architecture and discussed how service control in NGN differs from signaling and control in legacy PSTN networks. The fundamental question that needs to be addressed now is how the transition from PSTN/IN (and the current Internet) to NGN is likely to take place, given the fact that such a transition has to preserve the huge investment that the incumbent carriers have in their legacy networks. New entrants clearly have less of a problem in that respect but still need to proceed intelligently as all the technologies to support NGN are not yet ready for prime time. This is a monumental challenge no matter how it is viewed, making the transition to NGN decidedly prolonged and painful.

Curiously, the bootstrap engine for evolution towards NGN seems to have become voice-over-packet (VoP) applications. This may at first seem strange since voice services are currently provided ubiquitously and in a more or less optimal fashion by PSTN/IN. Enter the Internet again! The advent and rapid proliferation of a universal packet network infrastructure, in conjunction with the changing environmental

constraints, prompted initially new and subsequently incumbent service providers to turn what, at one point, was a decidedly low quality (international) long-distance bypass technology into a system that will parallel the service capabilities of PSTN/IN in an economical manner. But unlike PSTN/IN, this new infrastructure will have almost unlimited potential in providing innovative new broadband application services, including multimedia, thereby becoming the beginning of, and the nexus to, the next generation network. Loss of focus on this enormous potential, and looking at packet voice application as a be-all-end-all application, can cost prospective service providers their viability in NGN space.

NGN as a Voice-over-Packet Network

Imagine separating all the functional components of a CO switch, as shown in Fig. 43.1, into the following components of an NGN network:

- A residential gateway (RG) or, equivalently, a customer gateway (CG) that includes the functions of the line module
- A trunk gateway that replaces the trunk module
- A signaling gateway that replaces the signaling module
- A softswitch or media gateway controller (also known as a call agent) that replaces the call processing module

Now, if a packet switching network such as an IP/ATM network underlies platforms that host these four components, and with an appropriate DPE in place, the result is a network similar to the one shown in Fig. 43.3. Interconnection to the PSTN/IN is required in order to allow arbitrary point-to-point communication. When the CO switch functions are distributed as shown, one can view the combined set of functions as a distributed switch. But now protocols are needed for communication between the distributed entities. And, as can be seen from the figure, there is no shortage of possibilities here! What has been achieved in this transition architecture, however, is the historically unprecedented complete separation of bearer/connection control (connectivity network domain) from call/session control (application service domain). This is no small step in the overall evolutionary path of network transformation along the lines that we have sketched towards the NGN target architecture. Note that initially, a ubiquitous DPE capability may not exist due to the immaturity of the middleware products. This, unfortunately, forces adoption of a growing number of protocols to address specific inter-component communication and application needs.

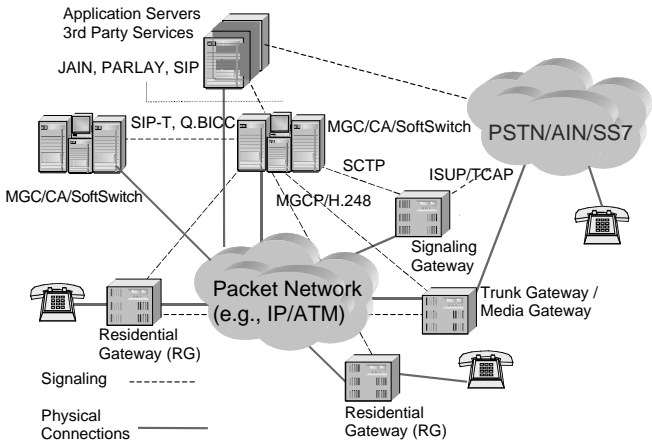

FIGURE 43.3 Towards NGN with packet voice as the bootstrap engine.

When a DPE eventually gets deployed, only the application-related parts of these protocols will be needed as the DPE will take care of lower levels of communication in a distributed environment.

To provide voice-over-packet services, the protocol between the residential gateway (or trunk gateway) and the softswitch becomes critical. This is identified as the IETF Media Gateway Control Protocol (MGCP) evolving to Megaco/ITU-T's H.248 protocol [3]. A simple call setup scenario proceeds as follows:

- The telephone goes off-hook.
- The residential gateway (RG) serving the telephone detects the off-hook event, applies a dial tone, collects the dialed digits, and notifies the softswitch using MGCP messages. The RG informs the softswitch that it is able to receive real-time transport protocol (RTP) streams at a certain port address and the type of audio coding it is able to support.
- The softswitch processes the digits, identifies an egress signaling gateway (if the called party is connected to the PSTN) or RG (if the called party is connected to the IP network) that can send signaling messages to the called party. It also provides the egress gateway with the port and coding information provided by the calling RG.
- Assuming the simple case of the called party being served directly by another RG, the egress RG informs the softswitch that it can receive audio streams from the called party on a certain port. It also applies a ringing tone to the called party's telephone.
- The softswitch informs the calling RG of the port and audio coding information provided by the egress RG.
- Since the RGs at both ends of the call now know which port to send audio RTP packets to and which one to receive on, once the called party answers, the bearer channels are set up and the parties begin to communicate.

Note that the circuit-switched connection in PSTN is now replaced by routing RTP packets over the user datagram protocol (UDP). RTP refers to the IETF real-time transport protocol standard for the transport of real-time data such as audio and video. It provides time stamping, sequence numbering, and delivery monitoring. RTP does not guarantee real-time delivery but must be used in conjunction with other protocols to guarantee quality of service (QoS). RTP control protocol (RTCP) supports feedback from receivers that can be used for monitoring the quality of service. It also supports media stream synchronization for support of multimedia applications. Another protocol that appears in [Fig. 43.3](#) is the streaming control transmission protocol (SCTP), which is designed for the purpose of reliably transporting SS7 application-part messages (ISUP and TCAP) over an IP network. It may find broader applications beyond signaling transport [4].

We have described only a basic two-party call setup over NGN. Intelligent network (IN) services such as free-phone service or local number portability (LNP) and other supplementary services such as call forwarding and three-way calling may be implemented in a separate server. Alternatively, services in the PSTN/AIN that are implemented in an SCP may be directly accessed by NGN entities, while others that are currently switch-based may be integrated directly into the softswitch. The figure shows that the softswitch can provide an open application programming interface (API) to facilitate provision of enhanced services by the service provider or by third parties.

Transition to NGN Beyond Voice

Service providers may begin transitioning to NGN by introducing softswitching technologies in an overlay fashion. Initially, the core of the TDM switching network may be progressively transformed into packet with softswitch control to carry tandem and interoffice voice traffic. Such transformations are generally triggered by tandem switch exhaust. In the second step, packet voice services, enhanced by innovative data features, are extended to the end users in the form of additional lines consuming part of the broadband access bandwidth. Going beyond this stage into offers of integrated voice, data, and multimedia application

services to intelligent terminals requires introduction of session control functions and an extensive infrastructure of application servers supported by ubiquitous DPE (the true beginnings of ASI). The current state of technology in this space includes activities to validate key architectural assumptions through modeling, simulation, and prototyping. Session control capabilities in support of true NGN application services are only beginning to be understood and prototyped. The pull of the market for new advanced services, coupled with strategic visions of NGN, will determine how fast providers of large scale application service infrastructures and their technology vendors will move in this direction.

43.6 Conclusions

We have discussed the major driving forces for evolution towards the next-generation networks and the challenges and opportunities that characterize this evolution. Limitations of the current control and management infrastructures in pre-NGN networks have been discussed, and various classes of application services that NGN will have to support have been elaborated on. True to the principle of separation of concerns to maximize evolvability and minimize time to market, the basic building blocks of NGN have been identified in three domains: the connectivity network domain, the application services infrastructure (ASI) domain, and the application services domain. We have also shown how the softswitching technology can be used as a stepping stone towards NGN by providing packet voice services initially in the core and subsequently to end devices. Evolution beyond voice-centric softswitching to support NGN application services will require development and deployment of session control functions and their integration into the current softswitching paradigm.

44.1 Introduction

Transmission via beams of light traveling over thin glass fibers is a relative newcomer to communications technology, beginning in the 1970s, reaching full acceptance in the early 1980s, and continuing to evolve since then [Chaffee, 1988]. Fibers now form a major part of the infrastructure for national telecommunications information highways in the U.S. and elsewhere and serve as the transmission media of choice for numerous local area networks. In addition, short lengths of fiber serve as transmission paths for the control of manufacturing processes and for sensor applications.

This section presents the fundamentals of fiber communications and lays foundations for the more detailed descriptions to follow in this chapter. Many full-length books (e.g., Hoss [1990], Jeunhomme [1990], Palais [1998], and Keiser [1991]) exist for additional reference.

Earlier chapters in this handbook covered data rates and bandwidth requirements for telephone systems and local area networks. The steadily increasing demand for information capacity has driven the search for transmission media capable of delivering the required bandwidths. Optical carrier transmission has been able to meet the demand and should continue to do so for many years. Reasons for this are given in the following paragraphs.

Optical communications refers to the transmission of information signals over carrier waves that oscillate at optical frequencies. Optical fields oscillate at frequencies much higher than radio waves or microwaves, as indicated on the abbreviated chart of the electromagnetic spectrum in Fig. 44.1. Frequencies and wavelengths are indicated on the figure.

For historical reasons, optical oscillations are usually described by their wavelengths rather than their frequencies. The two are related by

$$l = c/f \tag{44.1}$$

where f is the frequency in hertz, l is the wavelength, and c is the velocity of light in empty space (3×10^8 m/s). A frequency of 3×10^{14} Hz corresponds to a wavelength of 10^{-6} m (a millionth of a meter is often called a micrometer). Wavelengths of interest for optical communications are on the order of a

FIGURE 44.1 Portion of the electromagnetic spectrum.

FIGURE 44.2 Attenuation of a silica glass fiber showing the three wavelength regions where most fiber systems operate. (Source: Palais, J.C. 1998. *Fiber Optic Communications*, 4th ed., Prentice-Hall, Englewood Cliffs, NJ, p. 112. With permission.)

micrometer. Glass fibers have low loss in the three regions illustrated in Fig. 44.2, covering a range from 0.8 to 1.6 μm (800 to 1600 nm). This corresponds to a total bandwidth of almost 2×10^{14} Hz. The loss is specified in decibels, defined by

$$\text{dB} = 10 \log P_2/P_1 \quad (44.2)$$

where P_1 and P_2 are the input and output powers. Typically, fiber transmission components are characterized by their loss or gain in decibels. The beauty of the decibel scale is that the total decibel value for a series of components is simply the sum of their individual decibel gains and losses.

Although the dB scale is relative, it can be made absolute by specifying a reference level. Two popular references are the milliwatt and microwatt. The respective scales are the dBm (decibels relative to a milliwatt) and the dBm (decibels relative to a microwatt). That is,

$$P(\text{dBm}) = 10 \log P(\text{mW}) \quad (44.3a)$$

$$P(\text{dBm}) = 10 \log P(\text{mW}) \quad (44.3b)$$

Optical power measuring meters are often calibrated in dBm and dBm. Light emitter power and receiver sensitivity (the amount of power required at the receiver) are often given in these units.

Losses in the fiber and in other components limit the length over which transmission can occur. Optical amplification and regeneration are needed to boost the power levels of weak signals for very long paths.

The characteristically high frequencies of optical waves (on the order of 2×10^{14} Hz) allow vast amounts of information to be carried. A single optical channel utilizing a bandwidth of just 1% of this center frequency would have an enormous bandwidth of 2×10^{12} Hz. As an example of this capacity, consider frequency-division multiplexing of commercial television programs. Since each TV channel occupies 6 MHz, over 300,000 television programs could be transmitted over a single optical channel. Although it would be difficult to actually modulate light beams at rates as high as those suggested in this example, tens of gigahertz rates have been achieved.

In addition to electronic multiplexing schemes, such as frequency-division multiplexing of analog signals and time-division multiplexing of digital signals, numerous optical multiplexing techniques exist for taking advantage of the large bandwidths available in the optical spectrum. They include **wavelength-division multiplexing (WDM)** and **optical frequency-division multiplexing (OFDM)**. These technologies allow the use of large portions of the optical spectrum. The total available bandwidth for fibers approaches 2×10^{14} Hz (corresponding to the 0.8-1.6 mm range). Such a huge resource is hard to ignore.

Although atmospheric propagation is possible, the vast majority of optical communications utilizes the waveguiding glass fiber.

A key element for optical communications, a coherent source of light, became available in 1960 with the demonstration of the first **laser**. This discovery was quickly followed by plans for numerous laser applications, including atmospheric optical communications. Developments on empty space optical systems in the 1960s laid the groundwork for fiber communications in the 1970s. The first low-loss optical waveguide, the glass fiber, was fabricated in 1970. Soon after, fiber transmission systems were being designed, tested, and installed. Fibers have proven to be practical for path lengths of under a meter to distances as long as needed on the Earth's surface and under its oceans (for example, almost 10,000 km for transpacific links).

44.2 Optical Communications Systems Topologies

Fiber communications are now common for telephone, local area, and cable television networks. Fibers are also found in short data links (such as required in manufacturing plants), closed-circuit video links, and sensor information generation and transmission.

A block diagram of a point-to-point fiber optical communications system appears in Fig. 44.3. This is the structure typical of the telephone network. The various components will be described later in this section and in succeeding sections of this chapter.

FIGURE 44.3 Major components in a point-to-point fiber transmission system.

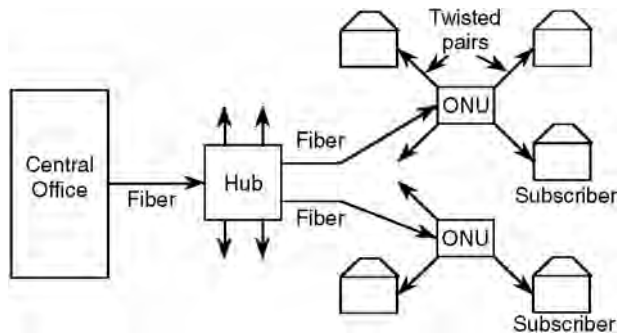

FIGURE 44.4 Fiber-to-the-curb network.

The fiber telephone network is digital, operating at data rates from a few megabits per second up to 2.5 Gb/s and beyond. At the 2.5-Gb/s rate, several thousand digitized voice channels (each operating at 64 kb/s) can be transmitted along a single fiber using time-division multiplexing (TDM).

Because cables may contain more than one fiber (in fact, some cables contain hundreds of fibers), a single cable may be carrying hundreds of thousands of voice channels. Rates in the tens of gigabit per second are attainable, further increasing the potential capacity of a single fiber.

Telephone applications may be broken down into several distinctly different areas: transmission between telephone exchanges, long-distance links, undersea links, and distribution in the local loop (that is, to subscribers). Although similarities exist among these systems, the requirements are somewhat different. Between telephone exchanges, large numbers of calls must be transferred over moderate distances. Because of the moderate path lengths, optical amplifiers or regenerators are not required. On the other hand, long-distance links (such as between major cities) require signal boosting of some sort (either regenerators or optical amplifiers). Undersea links (such as transatlantic or transpacific) require multiple boosts in the signal because of the long path lengths involved [Thiennot, Pirio, and Thomine, 1993].

The local loop does not involve long path lengths but does include division of the optical power in order to share fiber transmission paths over all but the last few tens of meters or so into the subscriber's premises. One architecture for the subscriber distribution network, called fiber-to-the-curb (FTTC), is depicted in Fig. 44.4. Signals are transmitted over fibers through distribution hubs into the neighborhoods. The fibers terminate at optical network units (ONUs) located close to the subscriber. The ONU converts the optical signal into an electrical one for transmission over copper cables for the remaining short distance to the subscriber. Because of the power division at the hubs, optical amplifiers are needed to keep the signal levels high enough for proper signal reception.

Cable television distribution remained totally conducting for many years. This was due to the distortion produced by optical analog transmitters. Production of highly linear laser diodes [such as the distributed feedback (DFB) laser diode] in the late 1980s allowed the design of practical analog television fiber distribution links.

Conversion from analog to digital cable television transmission will be facilitated by the vast bandwidths that fibers make available and by signal compression techniques that reduce the required bandwidths for digital video signals.

Applications such as local area networks (LANs) require distribution of the signals over shared transmission fiber. Possible topologies include the passive star, the active star, and the ring network [Hoss, 1990]. These are illustrated in Figs. 44.5 through 44.7.

The major components found in optical communications systems (called out in Figs. 44.3 through 44.7) are modulators, light sources, fibers, photodetectors, connectors, splices, directional couplers, star couplers, regenerators, and optical amplifiers. They are briefly described in the remainder of this section. More complete descriptions appear in the succeeding sections of this chapter.

FIGURE 44.5 Passive star network: *T* represents an optical transmitter and *R* represents an optical receiver.

FIGURE 44.6 Active star network: *T* represents an optical transmitter and *R* represents an optical receiver. The active star consists of electronic circuits, which direct the messages to their intended destination terminals.

Fibers

Fiber links spanning more than a kilometer typically use silica glass fibers, as they have lower losses than either plastic or plastic clad silica fibers. The loss properties of silica fibers were indicated in Fig. 44.2.

Material and waveguide **dispersion** cause pulse spreading, leading to intersymbol interference. This limits the fiber's bandwidth and, subsequently, its data-carrying capability. The amount of pulse spreading is given by

$$Dt = (M + M_g)LD/\lambda \quad (44.4)$$

where *M* is the material dispersion factor and *M_g* is the waveguide dispersion factor, *L* is the fiber length, and $D\lambda$ is the spectral width of the emitting light source. Because dispersion is wavelength dependent, the spreading depends on the chosen wavelength and on the spectral width of the light source. The total dispersion (*M* + *M_g*) has values near 120, 0, and 15 ps/(nm × km) at wavelengths 850, 1300, and 1550 nm, respectively.

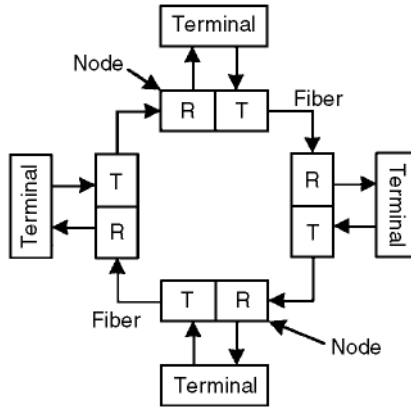

FIGURE 44.7 Ring network: *T* represents an optical transmitter and *R* represents an optical receiver. The nodes act as optical regenerators. Fibers connect the nodes together, while the terminals and nodes are connected electronically.

The fiber's bandwidth and subsequent data rate is inversely proportional to the pulse spreading. As noted, dispersion is a minimum in the second window, actually passing through zero close to 1300 nm for conventional fibers. Special fibers are designed to compensate for the material dispersion by adjusting the waveguide dispersion to cancel it at the low-loss 1550-nm third window. Such fibers (called *dispersion shifted*) are ideal for long fiber links because of their low loss and low dispersion.

Multimode fibers allow more than one mode to simultaneously traverse the fiber. This produces distortion in the form of widened pulses because the energy in different modes travels at different velocities. Again, intersymbol interference occurs. For this reason, multimode fibers are only used for applications where the bandwidth (or data rate) and path length are not large.

Single-mode fibers limit the propagation to a single mode, thus eliminating multimode spreading. Since they suffer only material and waveguide dispersive pulse spreading, these fibers (when operating close to the zero dispersion wavelength) have greater bandwidths than multimode fibers and are used for the longest and highest data rate systems.

Table 44.1 lists bandwidth limits for several types of fibers and Table 44.2 illustrates typical fiber sizes. Step index fibers (SI) have a core having one value of refractive index and a cladding of another value. Graded-index (GRIN) fibers have a core index whose refractive index decreases with distance from the axis and is constant in the cladding. As noted, single-mode fibers have the greatest bandwidths. To limit the number of modes to just one, the cores of single-mode fibers must be much smaller than those of multimode fibers.

Because of the relatively high loss and large dispersion in the 800-nm first window, applications there are restricted to moderately short path lengths (typically less than a kilometer). Because of the limited length, multimode fiber is practical in the first window. Light sources and photodetectors operating in this window tend to be cheaper than those operating at the longer wavelength second and third windows.

The 1300-nm second window, having moderately low losses and nearly zero dispersion, is utilized for moderate to long path lengths. Nonrepeated paths up to 70 km or so are attainable in this window. In this window, both single-mode and multimode applications exist. Multimode is feasible for short lengths required by LANs (up to a few kilometer) and single-mode for longer point-to-point links.

Fiber systems operating in the 1550-nm third window cover the highest rates and longest unamplified, unrepeated distances. Lengths on the order of 200 km are possible. Single-mode fibers are typically used in this window. Erbium-doped optical amplifiers operate in the third window, boosting the signal levels for very long systems (such as those traversing the oceans).

TABLE 44.1 Typical Fiber Bandwidths

Fiber	Wavelength, nm	Source	Bandwidth, MHz ¥ km
Multimode SI	850	LED	30
Multimode GRIN	850	LD	500
Multimode GRIN	1300	LD or LED	1000
Single mode	1300	LD	>10,000
Single mode	1550	LD	>10,000

TABLE 44.2 Glass Fiber Sizes

Core, μm	Cladding, μm	Numerical Aperture	Operation
8	125	0.11	Single mode
50	125	0.2	Multimode
62.5	125	0.27	Multimode
85	125	0.26	Multimode
100	140	—	Multimode
200	280	—	Multimode

Other Components

Semiconductor **laser diodes (LD)** or **light-emitting diodes (LED)** serve as the light sources for most fiber systems. These sources are typically modulated by electronic driving circuits. The conversion from signal current i to optical power P is given by

$$P = a_0 + a_1 i \quad (44.5)$$

where a_0 and a_1 are constants. Thus, the optical power waveform is a replica of the modulation current.

For very high-rate modulation, external **integrated optic devices** are available to modulate the light beam after its generation by the source. Laser diodes are more coherent (they have smaller spectral widths) than LEDs and thus produce less dispersive pulse spreading, according to Eq. (44.4). In addition, laser diodes can be modulated at higher rates (tens of gigabit per second) than LEDs (which are limited to rates of just a few hundred megabit per second). LEDs have the advantage of lower cost and simpler driving electronics.

Photodetectors convert the optical beam back into an electrical current. Semiconductor **PIN photodiodes** and **avalanche photodiodes (APD)** are normally used. The conversion for the PIN diode is given by the linear equation

$$i = \rho P \quad (44.6)$$

where i is the detected current, P is the incident optical power, and ρ is the photodetector's **responsivity**. Typical values of the responsivity are on the order of 0.5 mA/mW.

Avalanche photodiodes follow the same equation but include an amplification factor that can be as high as several hundred. They improve the **sensitivity** of the receiver.

According to Eq. (44.6), the receiver current is a replica of the optical power waveform (which is itself a replica of the modulating current). Thus, the receiver current is a replica of the original modulating signal current, as desired.

An optical regenerator (or repeater) consists of an optical receiver, electronic processor, and an optical transmitter. Regenerators detect (that is, convert to electrical signals) pulse streams that have weakened because of travel over long fiber paths, electronically determine the value of each binary pulse, and transmit a new optical pulse stream replicating the one originally transmitted. Using a series of regenerators spaced

at distances of tens to hundreds of kilometers, total link lengths of thousands of kilometers are produced. Regenerators can only be used in digital systems.

Optical amplifiers simply boost the optical signal level without conversion to the electrical domain. This simplifies the system compared to the use of regenerators. In addition, optical amplifiers work with both analog and digital signals.

Splices and connectors are required in all fiber systems. Many types are available. Losses tend to be less than 0.1 dB for good splices and just a few tenths of a decibel for good connectors. Fibers are spliced either mechanically or by actually fusing the fibers together.

Directional couplers split an optical beam traveling along a single fiber into two parts, each traveling along a separate fiber. The splitting ratio is determined by the coupler design. In a star coupler (see Fig. 44.5), the beam entering the star is evenly divided among all of the output ports of the star. Typical stars operate as 8×8 , 16×16 , or 32×32 couplers. As an example, a 32×32 port star can accommodate 32 terminals on a LAN.

44.3 Signal Quality

Signal quality is measured by the **signal-to-noise ratio** (S/N) in analog systems and by the **bit error rate** (**BER**) in digital links.

The signal-to-noise ratio in a digital network determines the error rate and is given by

$$\frac{S}{\bar{N}} = \frac{(M\rho P)^2 R_L}{M^n 2eR_L B(I_D + \rho P) + 4kTB} \quad (44.7)$$

where P is the received optical power, ρ is the detector's unamplified responsivity, M is the detector gain if an APD is used, n (usually between 2 and 3) accounts for the excess noise of the APD, B is the receiver's bandwidth, k is the Boltzmann constant ($k = 1.38 \times 10^{-23}$ J/K), e is the magnitude of the charge on an electron (1.6×10^{-19} C), T is the receiver's temperature in kelvin, I_D is the detector's dark current, and R_L is the resistance of the load resistor that follows the photodetector.

The first term in the denominator of Eq. (44.7) is caused by shot noise, and the second term is attributed to thermal noise in the receiver. If the shot noise term dominates (and the APD excess loss and dark current are negligible), the system is *shot-noise limited*. If the second term dominates, the system is *thermal-noise limited*.

In a thermal-noise limited system, the probability of error P_e (which is the same as the bit error rate) is

$$P_e = 0.5 - 0.5 \operatorname{erf}(0.354\sqrt{S/N}) \quad (44.8)$$

where erf is the error function, tabulated in many references [Palais, 1998]. An error rate of 10^{-9} requires a signal-to-noise ratio of nearly 22 dB ($S/N = 158.5$).

44.4 System Design

System design involves ensuring that the signal level at the receiver is sufficient to produce the desired signal quality. The difference between the power available from the transmitting light source (e.g., P_t in dBm) and the receiver's sensitivity (e.g., P_r in dBm) defines the system power budget L . Thus, the power budget is the allowed accumulated loss for all system components and is given (in decibels) by

$$L(\text{dB}) = P_t(\text{dBm}) - P_r(\text{dBm}) \quad (44.9)$$

In addition to ensuring sufficient available power, the system must meet the bandwidth requirements for the given information rate. This requires that the bandwidths of the transmitter, the fiber, and the receiver are sufficient for transmission of the message.

Defining Terms

Avalanche photodiode: Semiconductor photodetector that has internal gain caused by avalanche breakdown.

Bit error rate: Fractional rate at which errors occur in the detection of a digital pulse stream. It is equal to the probability of error.

Dispersion: Wavelength-dependent phase velocity commonly caused by the glass material and the structure of the fiber. It leads to pulse spreading because all available sources emit light covering a (small) range of wavelengths. That is, the emissions have a nonzero spectral width.

Integrated optics: Technology for constructing one or more optical devices on a common waveguiding substrate.

Laser: A source of coherent light, that is, a source of light having a small spectral width.

Laser diode: A semiconductor laser. Typical spectral widths are on the order of 1–5 nm.

Light-emitting diode: A semiconductor emitter whose radiation typically is not as coherent as that of a laser. Typical spectral widths are on the order of 20–100 nm.

Multimode fiber: A fiber that allows the propagation of many modes.

Optical frequency-division multiplexing: Multiplexing many closely spaced optical carriers onto a single fiber. Theoretically, hundreds (and even thousands) of channels can be simultaneously transmitted using this technology.

PIN photodiode: Semiconductor photodetector converting the optical radiation into an electrical current.

Receiver sensitivity: The optical power required at the receiver to obtain the desired performance (either the desired signal-to-noise ratio or bit error rate).

Responsivity: The current produced per unit of incident optical power by a photodetector.

Signal-to-noise ratio: Ratio of signal power to noise power.

Single-mode fiber: Fiber that restricts propagation to a single mode. This eliminates modal pulse spreading, increasing the fiber's bandwidth.

Wavelength-division multiplexing: Multiplexing several optical channels onto a single fiber. The channels tend to be widely spaced (e.g., a two-channel system operating at 1300 nm and 1550 nm).

45.1 Transmission Along Fibers

Light that finds itself at one end of an **optical fiber** may or may not find its way to the other end. For a randomly chosen combination of the properties and configuration of the light, the optical power has only a small chance of propagating significant distances along the fiber. With proper design of the fiber and of the mechanism for launching the light, however, the signal carried by the light can be transmitted over many kilometers without severe leakage or loss [Diament, 1990; Palais, 1988; Jones, 1988; Cheo, 1985; Basch, 1987; Green, 1993; Hoss and Lacy, 1993; Buckman, 1992; Sterling, 1987].

In its simplest form, an optical fiber consists of a long cylindrical **core** of glass, surrounded by a **cladding** of slightly less **optically dense** glass. See Fig. 45.1. Since both the core and cladding are transparent, propagation depends on the ability of the combination to confine the light and thwart its escape across the side of the fiber. It is the interface between the core and cladding that acts as a reflector to confine any light that would otherwise escape the core and leak away from the cladding into the outside world. The mechanism for confinement to the core is that of **total internal reflection**, a process that is easy to understand for a planar interface between two dissimilar dielectric media [Diament, 1990; Born and Wolf, 1965]. See Fig. 45.2. That process applies as well to the cylindrical geometry of the interface between the core and cladding of the optical fiber.

45.2 Total Internal Reflection

When light strikes the planar interface between two dissimilar transparent media, part of the light is transmitted and the rest is reflected. The proportions of each depend on the impedance mismatch between the two media; this, in turn, depends on the dissimilarity of the indices of refraction of the two materials. The **index of refraction** n measures how much more slowly light travels in the medium than it does in a vacuum.

FIGURE 45.1 Structure of an optical fiber: core of radius a , refractive index n_1 , surrounded by cladding of index n_2 . Typical core diameter is $50\ \mu\text{m}$.

FIGURE 45.2 Ordinary refraction at a planar interface between two media (left), with angle of incidence less than the critical angle, compared with total internal reflection (right), with angle of incidence exceeding the critical angle. Light is incident from the denser medium ($n_1 > n_2$).

FIGURE 45.3 Snell's law determines the angle of refraction θ_2 at an interface; the angle of reflection θ_1 equals the angle of incidence. The case $n_1 > n_2$ is illustrated. When the angle of incidence θ_1 reaches the critical value $\theta_c = \sin^{-1}(n_2/n_1)$, refraction is at $\theta_2 = 90^\circ$. Beyond the critical angle, there is total internal reflection.

When light strikes the interface at an angle to the normal, rather than head-on, the light that is transmitted is **refracted**, or bent away from its original direction, in accordance with **Snell's law**,

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \quad (45.1)$$

where n_1 and n_2 are the refractive indices of the two media and θ_1 and θ_2 are the angles of the ray to the normal to the interface in the two regions. See Fig. 45.3. If the light is incident onto the interface from the denser medium and if the ray's direction is close to grazing, so that the angle of incidence θ_1 is sufficiently large, then it may happen that $n_1 \sin \theta_1$ exceeds n_2 and there is then no solution for the angle of refraction θ_2 from Snell's law, since the quantity $\sin \theta_2$ can never exceed unity. Instead of partial reflection into the denser medium and partial refraction into the other region, there is then no transmission into the less dense medium. Rather, all of the light is reflected back into the denser medium. Total internal

FIGURE 45.4 Standing wave across the core, formed by a repeatedly reflecting ray, with decaying field strength in the cladding, formed by the process of total internal reflection at the cylindrical boundary. The entire field pattern propagates along the axis of the fiber.

reflection occurs (internal to the denser medium in which the light originated), and the escape of the light into the less dense medium has been thwarted.

There is more to the process of total internal reflection at a planar boundary than merely reflection from the interface. Although the light does not leak into the less dense medium and thereby get transmitted outward, it does seep across the interface and propagate, but only parallel to that interface surface [Diament, 1990]. In the direction normal to the interface, there is no propagation on the less dense side of the surface but the strength of the light that appears there decays exponentially. The spatial rate of decay increases with the angle of incidence, beyond the critical angle at which total internal reflection begins. If the decay is sufficiently strong, the light that seeps across is effectively constrained to a thin layer beyond the interface and propagates along it, while the light left behind is reflected back into the denser region with its original strength. The **reflection coefficient** is 100%. There is undiminished optical power flow along the reflected ray in the denser medium, but only storage of optical energy in the light that seeps across the interface into the less dense region.

Much the same process occurs along the curved, cylindrical interface between the core and cladding of the optical fiber. When the light strikes this interface at a sufficiently high grazing angle, total internal reflection occurs, keeping the optical power propagating at an angle within the core and along the axial direction in the cladding. The reflected light strikes the core again on the other side of the axis and is again totally internally reflected there. This confines the light to the core and to a thin layer beyond the interface in the cladding and keeps it propagating indefinitely along the axial direction. The overall result is that the light is guided by the fiber and not permitted to leak away across the side of the fiber, provided the light rays within the core encounter the interface at a sufficiently high grazing angle. See Fig. 45.4.

45.3 Modes of Propagation

For the cylindrical geometry of core and cladding in a fiber, the equivalent of a ray of light in an unbounded medium is any one of a set of **modes** of optical propagation. These refer to configurations of electromagnetic fields that satisfy **Maxwell's equations** and the boundary conditions imposed by the core-cladding interface and also conform to the total internal reflection requirement of grazing incidence to allow guided-wave propagation of the mode along the fiber [Diament, 1990; Born and Wolf, 1965].

These modes are nearly all **hybrid**, meaning that neither the electric nor the magnetic field of the mode is fully transverse to the axial direction of propagation, as can be the case for **waveguides** formed by hollow conducting pipes. Whereas the field configuration in a rectangular metallic waveguide varies as a sine function across the guide, that of an optical fiber follows a **Bessel function** variation. Bessel functions oscillate, much like trigonometric ones, but not with a constant amplitude. In the cladding, the fields decay in the radial direction away from the interface, but not exponentially as at a planar interface under total internal reflection. Rather, the fields in the cladding decay as **modified Bessel functions**, but the effect is the same: confinement to a thin layer just beyond the interface.

Just as the modes of hollow metal pipes are classified as **transverse electric** (TE) and **transverse magnetic** (TM), the hybrid modes of optical fibers also come in two distinguishable varieties [Schlesinger, Diament, and Vigants, 1961], labeled HE and EH, with pairs of subscripts appended to indicate the number of oscillations of the fields azimuthally (around the axis) and radially (across the core). For practical designs of optical fibers, dictated by the smallness of optical wavelengths, the indices of refraction of the core and cladding are very close to each other, and there exist combinations of the hybrid modes that are very nearly of the more familiar transverse, **linearly polarized** types and of greatly simplified description; these are designated LP modes [Gloge, 1971]. The **dominant mode**, which has no constraint of a minimum frequency, is the HE₁₁ mode, also designated the LP₀₁ mode in the simplified version. All other modes have a **cutoff** frequency, a minimum frequency for axial propagation of a confined mode. Even the dominant mode, in practical cases, has fields that are virtually unconfined when the frequency is too low.

In frequency, then, optical fibers behave as **high-pass filters**. In angular distribution, fibers allow propagation of only those rays that are directed in a sufficiently narrow cone about the axis to satisfy the conditions of total internal reflection.

45.4 Parameters of Fibers

A few parameters are in common use to describe the ability of the fiber to transmit light. One is the **numerical aperture**, NA , defined for the fiber as

$$NA = \sqrt{(n_1^2 - n_2^2)} \quad (45.2)$$

and measuring the dissimilarity of the core and cladding indices, n_1 and n_2 . This number corresponds more generally for any optical interface to

$$NA = n \sin \theta_{\max} \quad (45.3)$$

a quantity that is conserved across any such interface, by Snell's law, and that measures how great the deviation of an incoming ray from the axial direction can get and still allow capture by, and propagation along, the optical system.

The numerical aperture enters into the formula for the key fiber parameter V , often referred to as the **normalized frequency** or sometimes as the **mode volume parameter**. This is defined for a **step-index fiber** of core radius a and for light of vacuum wavelength λ as

$$V = (2\pi a/\lambda) NA \quad (45.4)$$

The V parameter combines many physical attributes of the fiber and the light source; it is proportional to the frequency of the light and to the size of the core, as well as to the numerical aperture. It determines whether a particular mode of the fiber can propagate; in effect, it tells whether the light in that mode strikes the core-cladding interface at a sufficiently high grazing angle to be captured by the fiber. Consequently, it also furnishes an estimate of how many modes can propagate along the fiber. For large values of V , the approximate number of distinguishable modes that are above cutoff and can therefore propagate is given by $V^2/2$.

For many purposes, including efficiency of launching and detection of the light and maintenance of the integrity of the signal carried by the light, it is undesirable to have a multiplicity of modes able to propagate along the fiber. For single-mode operation, the parameter V must be small, less than 2.4048 [which is the argument at which the Bessel function $J_0(x)$ first goes through zero]. This is not easy to achieve, because wavelengths of light are so tiny: for a core diameter of $2a = 50 \mu\text{m}$ and an operating wavelength of $\lambda = 0.8 \mu\text{m}$, we have $V \approx 200(NA)$ and the core and cladding indices have to be extremely

close, yet dissimilar, to attain **single-mode operation**. A much thinner core is needed for a single-mode fiber than for **multimode operation**. For the more readily achieved refractive index differences and core diameters, NA may be about 0.15 and several hundred modes can propagate along the fiber. A consequence of this multiplicity of modes is that each travels along the fiber at its own speed and the resulting confusion of arrival times for the various fractions of the total light energy carried by the many modes contributes to signal distortion ascribed to **dispersion**.

45.5 Attenuation

Dispersion limits the operation of the fiber at high data rates; losses limit it at low data rates. Light attenuation due to losses is ascribable to both **absorption** and **scattering**. Absorption occurs when impurities in the glass are encountered; the hydroxyl ion of water present in the glass as an impurity contributes heavily to absorption, along with certain metal ions and oxides. Careful control of impurity levels during fabrication of fibers has allowed light attenuation due to absorption to be kept below 1 dB/km.

Scattering is caused by imperfections in the structure of the fiber. A lower limit on losses is due to **Rayleigh scattering**, which arises from thermal density fluctuations in the glass, frozen into it during manufacture. The typical attenuation constant α from Rayleigh scattering varies as the inverse fourth power of the optical wavelength λ ,

$$\alpha = \alpha_0(\lambda_0/\lambda)^4; \quad \alpha_0 = 1.7 \text{ dB/km}, \quad \lambda_0 = 0.85 \text{ } \mu\text{m}. \quad (45.5)$$

This makes operation at longer wavelengths less subject to losses, but molecular absorption bands at wavelengths beyond about $1.8 \text{ } \mu\text{m}$ must be avoided. Rayleigh scattering is excessive below about $0.8 \text{ } \mu\text{m}$ and, between these limits, the hydroxyl ion absorption peak near $1.39 \text{ } \mu\text{m}$ must also be avoided. This has left three useful transmission windows for fiber optic systems, in the ranges $0.8\text{--}0.9 \text{ } \mu\text{m}$, $1.2\text{--}1.3 \text{ } \mu\text{m}$, and $1.55\text{--}1.6 \text{ } \mu\text{m}$.

45.6 Dispersion

Dispersion is a major concern in a communication system. It refers to processes that cause different components of the light signal to be affected differently. In particular, the speeds at which the different components are propagated along the fiber can vary enough to result in significantly different transmission delays or arrival times for the various portions of the signal. The outcome is distortion of the signal when it is reconstructed from all its components at the receiver or **repeater**. The signal components referred to may be the various frequencies in its spectrum, or they can comprise the multiplicity of modes that each carry their respective fraction of the total optical power to be transmitted.

For optical fibers, there are two aspects to dispersion effects. One is **material dispersion**, also called **intramodal** or **chromatic dispersion**; the other is termed **multimode dispersion**, or also **intermodal dispersion**. Material dispersion arises from the properties of the fiber material that cause the index of refraction to depend on frequency. Since the light source is never truly **monochromatic** but, rather, has a **linewidth**, the various frequencies in the light signal are subject to slightly different refractive index values, which entails different speeds of transmission along the fiber even if there is only one mode of propagation. It is the spread in transmission delays that distorts the signal, and this spread depends on the second derivative of the refractive index with respect to wavelength. One way to minimize this source of dispersion is to operate at about $1.3 \text{ } \mu\text{m}$ because silica glass has a second derivative that goes through zero at that wavelength.

Multimode dispersion arises from the fact that the optical energy is distributed among the many modes of propagation of the fiber and each mode has its own **group velocity**, the rate at which a signal carried by that mode is transmitted. The relevant measure of dispersion is then the difference between

the propagation delays of the slowest and the fastest of the participating modes. For a step-index fiber, multimode dispersion is much more severe than material dispersion, although it is somewhat mitigated by the fact that different modes do not propagate independently in a real, imperfect fiber. The phenomena of **mode mixing** and of greater attenuation of high-order modes (those with many field oscillations within the core) tend to reduce the differences in arrival times of the various modes that carry the signal. Nevertheless, intermodal dispersion imposes a severe limitation on data transmission along a step-index fiber.

45.7 Graded-Index Fibers

The way to reduce the deleterious effects of multimode dispersion on the propagation of a signal along a fiber becomes clear when the mechanism of this sort of dispersion is understood. That different modes should exhibit significantly different propagation delays follows from consideration of where the bulk of the field energy resides in each mode. As mentioned, high-order modes have field profiles that oscillate more than those of low-order modes. This includes oscillations in both the radial and the azimuthal directions. Examination of the behavior of Bessel functions indicates that high-order modes have most of their energy nearer to the core-cladding boundary than do the low-order ones. The azimuthal variation of the fields corresponds to propagation at an angle to the fiber axis so that there is progression azimuthally, around the axis, even as the mode propagates along the axis.

For the high-order modes, the azimuthal component of the propagation is more significant than it is for low-order modes, with the result that the overall progression of the high-order mode is in a spiral around the axis, whereas the low-order modes tend to progress more nearly axially than helically. The spiral trajectories of the energy also tend to concentrate far from the axis, nearer to the cladding, as compared to the straighter ones of the low-order modes, whose energy is massed near the axis and travels more nearly straight along it, as suggested in Fig. 45.5. The difference in propagation delay is then readily understood as arising from the longer, spiral path of the modal energy for high-order modes, as compared with the shorter, more direct path taken by the energy in the low-order modes.

This picture of the underlying mechanism for multimode dispersion suggests an equalization scheme aimed at slowing down the low-order modes that are concentrated near the axis, while speeding up the high-order ones that spiral around as they progress and are to be found primarily near the core-cladding interface, farther from the axis. This is achieved by varying the index of refraction of the core gradually, from a high value (for slower speed) near the axis to a lower one (for higher speed) near the cladding. Fibers so fabricated are termed **graded-index** (or **GRIN**) fibers. It is found that a refractive index profile that varies approximately (but not precisely) quadratically with radius can be effective in reducing multimode dispersion dramatically by equalizing the speeds of propagation of various modes of that fiber. Figure 45.6 illustrates the radial variation of the refractive index $n(r)$ for both a step-index fiber and a GRIN fiber.

FIGURE 45.5 Spiral path of light energy in higher order modes, compared to more direct trajectory for lower order ones. High-order modes have their energy concentrated near the core-cladding interface; lower order ones are concentrated closer to the axis. The spiral path takes longer to traverse than the direct one.

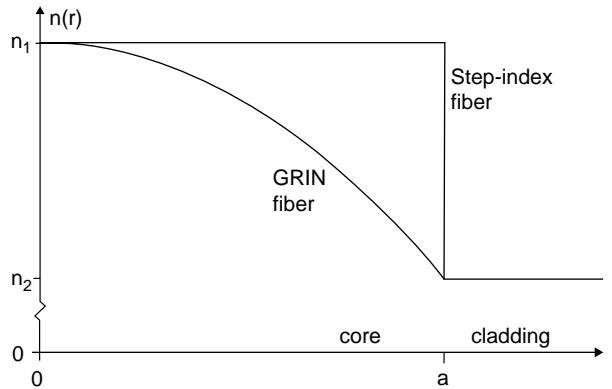

FIGURE 45.6 Radial index profiles of step-index and graded-index fibers. The broken vertical axis is a reminder that the maximum core index n_1 is quite close to the cladding index n_2 for practical fibers.

45.8 Mode Coupling

One more consideration affecting propagation along an optical fiber is the possibility of **mode coupling**. Although the theoretical modes of propagation travel independently along fibers of perfect constitution and perfect geometry, real fibers inevitably have imperfections that can cause different modes to couple and exchange energy between them as they propagate.

A fiber may be imperfect in geometry in that it may not be perfectly straight axially, or its core may not be perfectly round, or it may have been bent. The core and cladding may deviate from their nominal refractive indices. More importantly, there may be fluctuations in their material properties, or the graded-index profile may not be the ideal one. All such imperfections give rise to coupling between modes of propagation of the ideal version of the fiber, such that some of the power in one mode is drained and feeds another mode. When the other mode becomes the stronger one, energy is fed back to the first mode and thereafter sloshes back and forth repeatedly between the modes as the light travels along the fiber. How many modes participate in this periodic exchange of energy depends on the nature of the fluctuations of the imperfections.

A **perturbation analysis** of the effects of fluctuations in some parameter that would be constant in an ideal fiber reveals that the relevant property is the **spatial Fourier spectrum** of the fluctuations. The strength of the coupling between any two modes is proportional to the statistical average of the **power spectrum** of the fluctuations, evaluated at the difference between the **propagation constants** of the two modes in the ideal structure.

This implies that deviations on a large scale, such as gradual bending of the fiber, will affect only a certain group of modes. In this case, the spatial power spectrum exhibits a relatively narrow bandwidth, near zero **spatial frequency**. This allows only modes whose ideal propagation constants are very close to each other to be coupled by the large-scale fluctuations. Such deviations, therefore, couple only modes that are nearly **degenerate** (have nearly equal propagation constants).

On the other hand, periodic fluctuations, such as striations in the material properties, exhibit a spatial spectrum that is peaked in a spectral region corresponding to the period of the striations. In that case, coupling will be significant for modes whose propagation constants differ by the **spatial wavenumber** associated with the periodicity of the fluctuations.

One effect of coupling among modes is to increase losses along the fiber, because energy can get transferred to modes that are not trapped within the core. Some of that energy can then leak out into the cladding and be lost before it can return to the propagating mode. Another effect, however, is to average the dispersion associated with many modes and thereby reduce the overall **pulse spreading**. For example, for closely coupled modes, propagation delays may vary as only the square root of the distance traveled, rather than with the more severe variation, proportional to distance, for uncoupled modes.

45.9 Summary

The step-index optical fiber comprises a dielectric cylindrical core surrounded by a cladding of slightly lower refractive index. This constitutes a dielectric cylinder, which is capable of acting as a waveguide. The mechanism involved in confining and guiding the optical power is that of total internal reflection at the cylindrical boundary between the core and the cladding. This phenomenon results in a **standing wave** pattern within the core and a decaying field in the cladding, with the entire field pattern propagating along the cylinder. The general modes of propagation are hybrid modes, having axial components of both the electric and the magnetic fields, and they advance along the fiber by spiraling around the axis. The exceptional transverse electric or transverse magnetic types are the azimuthally symmetric ones, which do not twist about the axis as they progress along the fiber. The dominant mode is hybrid, however.

Because the optical wavelengths are so short, the core is normally many wavelengths across, with the result that a large number of modes can propagate along the fiber, even when the refractive indices of the core and cladding are kept quite close to each other. Unless single-mode fiber operation is achieved, this entails multimode dispersion effects. Efforts to overcome the limitations this imposes on data transmission have led to the development of graded-index fibers, with an advantageous refractive index profile of the core that tends to equalize the propagation delays of different modes. With careful fabrication of the fibers and with selections of appropriate source wavelengths and bandwidths, attenuation along the fiber can be kept quite low and dispersive effects can be controlled, making optical fibers the medium of choice for propagation of optical signals.

Defining Terms

Absorption: Process by which light energy is drained from a wave and transferred to the material in which it propagates.

Bessel function: A type of mathematical function that oscillates and also decays in amplitude; descriptive of the radial dependence of the fields in a uniform-index core.

Chromatic dispersion: The variation of a material's index of refraction with frequency or wavelength.

Cladding: The outer, optically less dense portion of an optical fiber, surrounding the core.

Core: The inner, optically dense portion of an optical fiber, surrounded by the cladding.

Cutoff: The condition (usually too low an operating frequency) under which a mode is not capable of propagating; the cutoff frequency is the minimum frequency for propagation of a mode.

Degenerate modes: Modes whose propagation constants are equal or nearly equal.

Dispersion: The property of a fiber (or any wave-propagating system) that causes different frequencies (or operating wavelengths) to propagate at different speeds; it is a cause of distortion of signals transmitted along the structure.

Dominant mode: The mode that can propagate under conditions (usually a specific frequency range) that do not allow any other modes to propagate.

Graded-index fiber: The type of optical fiber whose core has a nonuniform index of refraction.

GRIN fiber: Graded-index fiber.

Group velocity: The velocity of propagation of a signal whose spectrum occupies a narrow range of frequencies about some carrier frequency; the rate of change of frequency with respect to propagation constant.

High-pass filter: A circuit or structure that passes high-frequency signals but blocks low-frequency ones.

Hybrid: Describing a mode for which neither the electric nor the magnetic field vector is fully transverse to the direction of propagation.

Index of refraction: Ratio of the vacuum speed of light to its speed in the medium.

Intermodal dispersion: Dispersion effect that arises from a signal's being carried by many modes that travel at different speeds.

Intramodal dispersion: The variation of a material's index of refraction with frequency or wavelength, resulting in dispersive effects for a single mode.

Linearly polarized: Descriptive of a mode of propagation whose field vectors each maintain a fixed orientation in space as they oscillate in time.

Linewidth: The range of frequency or wavelength contained within a nominally monochromatic signal.

Material dispersion: The variation of a material's index of refraction with frequency or wavelength.

Maxwell's equations: The mathematical laws governing the propagation of light and other electromagnetic waves.

Mode: Field configuration of light with well-defined propagation characteristics.

Mode coupling: Process by which different modes of propagation can interchange their energy instead of propagating independently of each other.

Mode mixing: Process of transfer or interchange of light energy among different modes of propagation.

Mode volume parameter: The V parameter, which determines how many modes can propagate along an optical fiber; it is proportional to the frequency of the light, to the size of the core, and to the numerical aperture.

Modified Bessel function: A type of mathematical function that either grows or decays in amplitude; descriptive of the radial dependence of the fields in a uniform-index cladding.

Monochromatic: Of a single frequency or wavelength.

Multimode dispersion: Dispersion effect that arises from a signal's being carried by many modes that travel at different speeds.

Multimode operation: Operation of an optical fiber under conditions that allow many modes to propagate along it.

Normalized frequency: The V parameter, which determines whether a mode can propagate along an optical fiber; it is proportional to the frequency of the light, to the size of the core, and to the numerical aperture.

Numerical aperture (NA): A measure of the ability of an optical structure or instrument to capture incident light; $NA = n \sin \theta$, where n is the refractive index and θ is the maximum angle of deviation from the optical axis of a ray that can still be captured by the aperture.

Optical fiber: A long, thin glass structure that can guide light.

Optically dense: Transmitting light at a relatively slow speed; having a high refractive index.

Perturbation analysis: Mathematical process of determining approximately the effects of a relatively weak disturbance of some system that is otherwise in equilibrium.

Power spectrum: Description of some quantity that varies in space or time in terms of the decomposition of its power into constituent sinusoidal components of different spatial or temporal frequencies or periodicities.

Propagation constant: The spatial rate of phase progression of a wave.

Pulse spreading: Process whereby the width of a pulse increases as it propagates.

Rayleigh scattering: A scattering process associated with thermal density fluctuations in the constitution of the glass.

Reflection coefficient: Ratio of strength of reflected light to that of the incident light.

Refraction: Process of bending a ray of light away from its original direction.

Repeater: Electronic circuitry that takes in a degraded signal and restores or reconstitutes it for further transmission.

Scattering: Process by which portions of light energy are redirected (by encounters with microscopic obstacles or inhomogeneities) to undesired directions and thereby lost from the propagating wave.

Single-mode operation: Operation of an optical fiber under conditions that allow only one mode to propagate along it.

Snell's law: Law governing reflection (reflection angle equals incidence angle) and refraction (component of propagation vector tangential to the interface is preserved) of a ray of light encountering the interface between media of different optical density.

Spatial Fourier spectrum: Description of some quantity that varies in space in terms of its decomposition into constituent sinusoidal components of different spatial frequencies or periodicities.

Spatial frequency: The number of cycles per unit length of a quantity that varies periodically in space.

- Spatial wavenumber:** Reciprocal of a quantity's interval of periodicity in space.
- Standing wave:** Resultant of counterpropagating waves, with a spatial distribution that does not move.
- Step-index fiber:** The type of optical fiber whose core and cladding each have a uniform index of refraction.
- Total internal reflection:** Process of reflecting light incident from a denser medium toward a less dense one, at an angle sufficiently grazing to avert transmission into the less dense medium. All of the incident light power is reflected, although optical fields do appear beyond the interface.
- Transverse electric:** Descriptive of a mode of propagation whose electric field vector is entirely transverse to the direction of propagation.
- Transverse magnetic:** Descriptive of a mode of propagation whose magnetic field vector is entirely transverse to the direction of propagation.
- Waveguide:** A structure that can guide the propagation of light or electromagnetic waves along itself.

46.1 Introduction

Phenomenal advances in research results, development, and application of optical sources have occurred over the last decade. The two primary optical sources used in telecommunications are the semiconductor laser and the light emitting diode (LED). The LEDs are used as sources for low data rate (<200 Mb/s) and short distance applications, and lasers are used for high data rate and long distance applications. The fiber optic revolution in telecommunication which provided several orders of magnitude improvement in transmission capacity at low cost would not have been possible without the development of reliable semiconductor lasers. Today, semiconductor lasers are used not only for fiber optic transmission but also in optical reading and recording (e.g., CD players), printers, fax machines, and in numerous applications as a high power laser source. Semiconductor injection lasers continue to be the laser of choice for various system applications primarily because of their small size, simplicity of operation, and reliable performance. For most transmission system applications, the laser output is encoded with data by modulating the current. However, for some high data rate applications which require long distance transmission, external modulators are used to encode the data. This chapter describes the fabrication, performance characteristics, current state of the art, and research directions for semiconductor lasers and integrated lasers with modulators. The focus of this chapter is laser sources needed for fiber optic transmission systems. These devices are fabricated using the InP material system. For early work and thorough discussion of semiconductor lasers, see Refs. [1–4].

The semiconductor injection laser was invented in 1962 [5–7]. With the development of epitaxial growth techniques and the subsequent fabrication of double heterojunction, the laser technology advanced rapidly in the 1970s and 1980s [1–4]. The demonstration of CW operation of the semiconductor laser in the early 1970s [8] was followed by an increase in development activity in several industrial laboratories.

This intense development activity in the 1970s was aimed at improving the performance characteristics and reliability of lasers fabricated using the AlGaAs material system [1]. These lasers emit near 0.8 μm and were deployed in early optical fiber transmission systems (in the late 1970s and early 1980s).

The optical fiber has zero dispersion near 1.3 μm wavelength and has lowest loss near 1.55 μm wavelength. Thus, semiconductor lasers emitting near 1.3 μm and 1.55 μm are of interest for fiber optic transmission application. Lasers emitting at these wavelengths are fabricated using the InGaAsP/InP materials system and were first fabricated in 1976 [9]. Much of the fiber optic transmission systems around the world that are in use or are currently being deployed utilize lasers emitting near 1.3 μm or 1.55 μm .

Initially, these lasers were fabricated using liquid phase epitaxy (LPE) growth technique. With the development of metal-organic chemical vapor deposition (MOCVD) and gas source molecular beam epitaxy (GSMBE) growth techniques in the 1980s, not only the reproducibility of the fabrication process has improved but it has also led to advances in laser designs such as quantum well lasers and very high speed lasers using semi-insulating Fe doped InP current blocking layers [10].

46.2 Laser Designs

A schematic of a typical double heterostructure used for laser fabrication is shown in Fig. 46.1. It consists of n-InP, undoped $\text{In}_{1-x}\text{Ga}_x\text{P}_y\text{As}_{1-y}$, p-InP and p-InGaAsP grown over (100) oriented n-InP substrate. The undoped $\text{In}_{1-x}\text{Ga}_x\text{P}_y\text{As}_{1-y}$ layer is the light emitting layer (active layer). It is lattice matched to InP for $x \sim 0.45y$. The band gap of the $\text{In}_{1-x}\text{Ga}_x\text{P}_y\text{As}_{1-y}$ material (lattice matched to InP) which determines the laser wavelength is given by [11]

$$E_g(\text{eV}) = 1.35 - 0.72y + 0.12y^2$$

For lasers emitting near 1.3 μm , $y \sim 0.6$. The double heterostructure material can be grown by the LPE, GSMBE, or MOCVD growth technique. The double heterostructure material can be processed to produce lasers in several ways. Perhaps the simplest is the broad area laser (Fig. 46.1) which involves putting contacts on the p- and n-side and then cleaving. Such lasers do not have transverse mode confinement or current confinement, which leads to high threshold and nonlinearities in light vs. current characteristics. Several laser designs have been developed to address these problems. Among them are the gain guided laser, weakly index guided laser, and buried heterostructure (strongly index guided) laser. A typical version of these laser structures is shown in Fig. 46.2. The gain guided structure uses a dielectric layer for current confinement. The current is injected in the opening in the dielectric (typically 6 to 12 μm wide), which produces gain in that region and, hence, the lasing mode is confined to that region. The weakly index guided structure has a ridge etched on the wafer, and a dielectric layer surrounds the ridge. The current is injected in the region of the ridge, and the optical mode overlaps the dielectric (which has a low index) in the ridge. This results in weak index guiding.

FIGURE 46.1 Schematic of a double heterostructure laser.

FIGURE 46.2 Schematic of a gain guided, weakly index guided, and strongly index guided buried heterostructure laser.

The buried heterostructure design shown in Fig. 46.2 has the active region surrounded (buried) by lower index layers. The fabrication process of the DCPBH (double channel planar buried heterostructure) laser, involves growing a double heterostructure, etching a mesa using a dielectric mask, and then regrowing the layer surrounding the active region using a second epitaxial growth step. The second growth can be a single Fe doped InP (Fe:InP) semi-insulating layer or a combination of p-InP, n-InP, and Fe:InP layer. Generally, the MOCVD growth process is used for the growth of the regrown layer. Researchers have often given different names to the particular buried heterostructure laser design that they discovered. These are described in detail in Ref. [12]. For the structure of Fig. 46.2, the Fe doped InP layer provides both optical confinement to the lasing mode and current confinement to the active region. Buried heterostructure lasers are generally used in communication system applications because a properly designed strongly index guided buried heterostructure design has superior mode stability, higher bandwidth, and superior linearity in light vs. current (L vs. I) characteristics compared to the gain guided and weakly index guided designs. Early recognition of these important requirements of communication grade lasers led to intensive research on InGaAsP BH laser designs all over the world in the 1980s. It is worth mentioning that BH lasers are more complex and difficult to fabricate compared to the gain guided and weakly index guided lasers. A scanning electron micrograph of a capped mesa (CMBH) buried heterostructure laser along with the laser structure is shown in Fig. 46.3. The current blocking layers in this structure consist of i-InP (Fe doped InP), n-InP, i-InP, and n-InP layers. These sets of blocking layers have the lowest capacitance and are therefore needed for high-speed operation. An optimization of the thickness of these layers is needed for highest speed performance. The laser fabrication involves the following steps. One-micron wide mesas are etched on the wafer and the current blocking layers consisting of i-InP, n-InP, i-InP, and n-InP layers are grown on the wafer with an oxide layer on top of the mesa in place. The oxide layer is then removed and a third growth of p-InP cladding layer and p-InGaAs contact layer is carried out. The wafer is then processed using standard lithography, metallization, and cleaving techniques to produce the lasers.

The light vs. current characteristics at different temperatures of an InGaAsP BH laser emitting at $1.3 \mu\text{m}$ is shown in Fig. 46.4. Typical threshold current of a BH laser at room temperature is in the 5 to 10 mA range. For gain guided and weakly index guided lasers, typical room temperature threshold currents are in the 25–50 mA and 50–100 mA range, respectively. The external differential quantum efficiency defined as the derivative of the L vs. I characteristics above threshold is $\sim 0.25 \text{ mW/mA/facet}$ for a cleaved uncoated laser emitting near $1.3 \mu\text{m}$.

An important characteristic of the semiconductor laser is that its output can be modulated simply and easily by modulating the injection current. The relative magnitude of the modulated light output is plotted as a function of the modulation frequency of the current in Fig. 46.5 at different optical output powers. The laser is of the BH type (shown in Fig. 46.3), has a cavity length of $250 \mu\text{m}$, and the modulation current amplitude was 5 mA. Note that the 3 dB-frequency to which the laser can be modulated increases

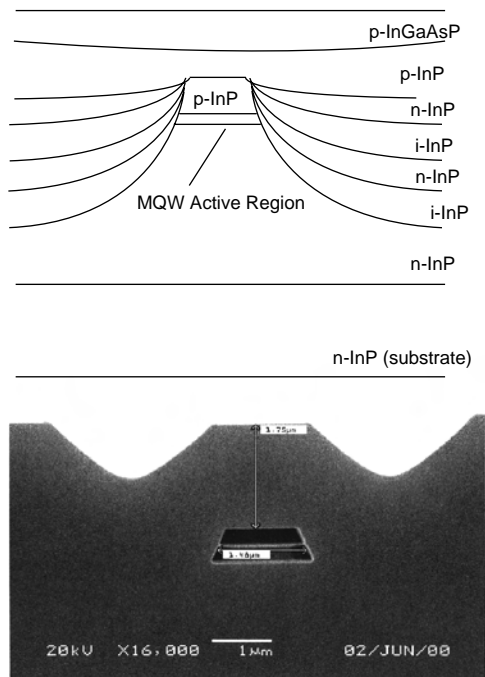

FIGURE 46.3 Schematic of a BH laser and scanning electron photomicrograph of the same laser.

FIGURE 46.4 Light vs. current characteristics of an InGaAsP buried heterostructure laser emitting at 1.3 μm .

with increasing output power and the modulation response is maximum at a certain frequency (ω). The resonance frequency ω_r is proportional to the square root of the optical power. The modulation response determines the data transmission rate capability of the laser; for example, for 10 Gb/s data transmission, the 3-dB bandwidth of the laser must exceed 10 GHz. However, other system level considerations, such as allowable error-rate penalty, often introduce much more stringent requirements on the exact modulation response of the laser.

A semiconductor laser with cleaved facets generally emits in a few longitudinal modes of the cavity. A typical spectrum of a laser with cleaved facets is shown in Fig. 46.6. The discrete emission wavelengths are separated by the longitudinal cavity mode spacing which is $\sim 10 \text{ \AA}$ for a laser ($\lambda \sim 1.3 \mu\text{m}$) with $250 \mu\text{m}$ cavity length. Lasers can be made to emit in a single frequency using frequency selective feedback, for example, using a grating internal to the laser cavity as described above.

FIGURE 46.5 Modulation response of a laser at different optical output powers.

FIGURE 46.6 Emission spectrum of a laser with cleaved facets.

46.3 Quantum Well Lasers

So far we have described the fabrication and performance characteristics of regular double heterostructure (DH) laser which has an active region ~ 0.1 to $0.2 \mu\text{m}$ thick. Beginning with the 1980s, lasers with very thin active regions, quantum well lasers, were being developed in many research laboratories [13–22]. Quantum well (QW) lasers have active regions of $\sim 100 \text{ \AA}$ thick which restricts the motion of the carriers (electrons and holes) in a direction normal to the well. This results in a set of discrete energy levels and the density of states is modified to a “two dimensional-like” density of states. This modification of the density of states results in several improvements in laser characteristics such as lower threshold current, higher efficiency, higher modulation bandwidth, and lower CW and dynamic spectral width. All of these improvements were first predicted theoretically and then demonstrated experimentally [23–32].

The development of InGaAsP QW lasers were made possible by the development of MOCVD and GSMBE growth techniques. The transmission electron micrograph (TEM) of a multiple QW laser structure is shown in Fig. 46.7. Shown are four InGaAs quantum wells grown over n-InP substrate. The well thickness is 70 \AA , and the wells are separated by barrier layers of InGaAsP ($\lambda \sim 1.1 \mu\text{m}$). Multi-quantum well (MQW) lasers with threshold current densities of 600 A/cm^2 have been fabricated [33].

FIGURE 46.7 The transmission electron micrograph of a multi-quantum well laser structure.

FIGURE 46.8 Schematic of multi-quantum well buried heterostructure laser.

The schematic of a MQW BH laser is shown in Fig. 46.8. The composition of the InGaAsP material from the barrier layers to the cladding layer (InP) is gradually varied in this structure over a thickness of $\sim 0.1 \mu\text{m}$. This produces a graded variation in index (GRIN structure) which results in a higher optical confinement of the fundamental mode than that for an abrupt interface design. A larger mode confinement factor results in lower threshold current. The laser has an MQW active region and it utilizes Fe doped semi-insulating (SI) InP layers for current confinement and optical confinement. The light vs. current characteristics of an MQW BH laser is shown in Fig. 46.9. The laser emits near $1.5 \mu\text{m}$. The MQW lasers have lower threshold currents than regular DH lasers. Also, the two-dimensional like density of states of the QW lasers makes the transparency current density of these lasers significantly lower than that for regular DH lasers [30]. This allows the fabrication of very low threshold lasers using high reflectivity coatings.

The optical gain (g) of a laser at a current density J is given by

$$g = a(J - J_0) \tag{46.1}$$

where a is the gain constant and J_0 is the transparency current density. Although a logarithmic dependence of gain on current density [23] is often used in order to account for gain saturation, a linear dependence is used here for simplicity. The cavity loss α is given by

$$\alpha = \alpha_c + (1/L)\ln(1/R_1R_2) \tag{46.2}$$

where α_c is the free carrier loss, L is the length of the optical cavity, and R_1, R_2 are the reflectivity of the two facets. At threshold, gain equals loss, hence it follows from Eqs. (46.1) and (46.2) that the threshold

FIGURE 46.9 Light vs. current characteristics of a multiquantum well buried heterostructure laser at different temperatures.

FIGURE 46.10 Light vs. current of a quantum well laser with high reflectivity coatings on both facets.

current density (J_{th}) is given by

$$J_{th} = \alpha_c/a + (1/La) \ln(1/R_1R_2) + J_0 \quad (46.3)$$

Thus, for a laser with high reflectivity facet coatings ($R_1, R_2 \sim 1$) and with low loss ($\alpha_c \sim 0$), $J_{th} \sim J_0$. For a QW laser, $J_0 \sim 50 \text{ A/cm}^2$ and for a DH laser, $J_0 \sim 700 \text{ A/cm}^2$, hence it is possible to get much lower threshold current using QW as the active region.

The light vs. current characteristics of a QW laser with high reflectivity coatings on both facets is shown in Fig. 46.10 [33]. The threshold current at room temperature is $\sim 1.1 \text{ mA}$. The laser is $170 \mu\text{m}$ long and has 90% and 70% reflective coating at the facets. This laser has a compressively strained MQW active region. For a lattice matched MQW active region, a threshold current of 2 mA has been reported [34]. Such low threshold lasers are important for array applications. Recently, QW lasers were fabricated which have higher modulation bandwidth than regular DH lasers. The current confinement and optical confinement in this laser is carried out using MOCVD grown Fe-doped InP lasers similar to that shown

FIGURE 46.11 Schematic of a laser designed for high speed (Morton et al. [35]).

FIGURE 46.12 Modulation response of multiquantum well high speed lasers (Morton et al. [35]).

in Fig. 46.2. The laser structure is then further modified by using a small contact pad and etching channels around the active region mesa (Fig. 46.11). These modifications are designed to reduce the capacitance of the laser structure. The modulation response of the laser is shown in Fig. 46.12. A 3-dB bandwidth of 25 GHz is obtained [35].

Strained Quantum Well Lasers

Quantum well lasers have also been fabricated using an active layer whose lattice constant differs slightly from that of the substrate and cladding layers. Such lasers are known as strained quantum well lasers. Over the last few years, strained quantum well lasers have been extensively investigated all over the world [36–43]. They show many desirable properties such as (1) a very low threshold current density and (2) a lower linewidth than regular MQW lasers both under CW operation and under modulation. The origin of the improved device performance lies in the band-structure changes brought about by the mismatch-induced strain [44,45]. Figure 46.13 shows the band structure of a semiconductor under tensile and

FIGURE 46.14 Broad-area threshold current density as a function of cavity length for strained and lattice-matched InGaAs/InP MQW lasers (Tsang et al. [39]).

compressive strains. Strain splits the heavy-hole and the light-hole valence bands at the Γ point of the Brillouin zone where the bandgap is minimum in direct bandgap semiconductors.

Two material systems have been widely used for strained quantum-well lasers: (1) InGaAs grown over InP by the MOCVD or the CBE growth technique [36–40] and (2) InGaAs grown over GaAs by the MOCVD or the MBE growth technique [41–43]. The former material system is of importance for low-chirp semiconductor lasers for lightwave system applications, while the latter material system has been used to fabricate high-power lasers emitting near $0.98 \mu\text{m}$, a wavelength of interest for pumping erbium-doped fiber amplifiers.

The alloy $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ has the same lattice constant as InP. Semiconductor lasers with an $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ active region have been grown on InP by the MOCVD growth technique. Excellent material quality is also obtained for $\text{In}_{1-x}\text{Ga}_x\text{As}$ alloys grown over InP by MOCVD for nonlattice-matched compositions. In this case, the laser structure generally consists of one or many $\text{In}_{1-x}\text{Ga}_x\text{As}$ quantum well layers with InGaAsP barrier layers whose composition is lattice matched to that of InP. For $x < 0.53$, the active layer in these lasers is under tensile stress, while for $x > 0.53$, the active layer is under compressive stress.

Superlattice structures of InGaAs/InGaAsP with tensile and compressive stress have been grown by both MOCVD and CBE growth techniques over an n-type InP substrate. Figure 46.14 shows the broad-area threshold current density as a function of cavity length for strained MQW lasers with four $\text{In}_{0.65}\text{Ga}_{0.35}\text{As}$ [39] quantum wells with InGaAsP ($\lambda \sim 1.25 \mu\text{m}$) barrier layers. The active region in this laser is under 0.8% compressive strain. Also shown for comparison is the threshold current density as a function of cavity length of MQW lattice-matched lasers with $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ wells. The entire laser structure, apart from the quantum well composition, is identical for the two cases. The threshold current density is lower for the compressively strained MQW structure than that for the lattice-matched MQW structure.

Buried-heterostructure (BH) lasers have been fabricated using compressive and tensile strained MQW lasers. The threshold current of these lasers as a function of the In concentration is shown in Fig. 46.15 [46]. Lasers with compressive strain have a lower threshold current than that for lasers with tensile strain. This can be explained by splitting of the light hole and heavy hole bands under stress [47,48]. However, more recent studies have shown that it is possible to design tensile strained lasers with lower thresholds [37,42].

Strained quantum well lasers fabricated using $\text{In}_{1-x}\text{Ga}_x\text{As}$ layers grown over a GaAs substrate have been extensively studied [41,43,49–54]. The lattice constant of InAs is 6.06 Å and that of GaAs is 5.654 Å. The $\text{In}_{1-x}\text{Ga}_x\text{As}$ alloy has a lattice constant between these two values, and to a first approximation it can be assumed to vary linearly with x . Thus, an increase in the In mole fraction x increases the lattice mismatch relative to the GaAs substrate and therefore produces larger compressive strain on the active region.

A typical laser structure grown over the n-type GaAs substrate is shown in Fig. 46.16 [41] for this material system. It consists of an MQW active region with one to four $\text{In}_{1-x}\text{Ga}_x\text{As}$ wells separated by

FIGURE 46.15 Threshold current of buried heterostructure $\text{In}_x\text{Ga}_{1-x}\text{As}/\text{InP}$ MQW lasers plotted as a function of In concentration x (Temkin et al. [46]).

FIGURE 46.16 Typical $\text{In}_{1-x}\text{Ga}_x\text{As}/\text{GaAs}$ MQW laser structure.

GaAs barrier layers. The entire MQW structure is sandwiched between n- and p-type $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ cladding layers, and the P-cladding layer is followed by a p-type GaAs contact layer. Variations of the above structure with different cladding layers or large optical cavity designs have been reported. Emission wavelength depends on the In composition, x . As x increases, the emission wavelength increases, and for x larger than a certain value (typically ~ 0.25), the strain is too large to yield high-quality material. For $x \sim 0.2$, the emission wavelength is near $0.98 \mu\text{m}$, a wavelength region of interest for pumping fiber amplifiers [49]. Threshold current density as low as $47 \text{ A}/\text{cm}^2$ has been reported for $\text{In}_{0.2}\text{Ga}_{0.8}\text{As}/\text{GaAs}$ strained MQW lasers [52]. High-power lasers have been fabricated using an $\text{In}_{0.2}\text{Ga}_{0.8}\text{As}/\text{GaAs}$ MQW active region. Single-mode output powers of greater than 200 mW have been demonstrated using a ridge-waveguide-type laser structure.

Frequency chirp of strained and unstrained QW lasers has been investigated. Strained QW lasers ($\text{InGaAs}/\text{GaAs}$) exhibit the lowest chirp (or dynamic linewidth) under modulation. The lower chirp of strained QW lasers is consistent with a small linewidth enhancement factor (α -factor) measured in such devices. The α -factor is the ratio of the real and imaginary part of the refractive index. A correlation between the measured chirp and linewidth enhancement factor for regular double-heterostructure, strained and unstrained QW lasers is shown in Table 46.1. The high efficiency, high power, and low chirp of strained and unstrained QW lasers make these devices attractive candidates for lightwave transmission applications.

Other Material Systems

A few other material systems have been reported for lasers in the $1.3 \mu\text{m}$ wavelength range. These are the $\text{AlGaInAs}/\text{InP}$ and InAsP/InP materials grown over InP substrates and, more recently, the InGaAsN material grown over GaAs substrates. The $\text{AlGaInAsP}/\text{InP}$ system has been investigated with the aim of producing lasers with better high temperature performance for uncooled transmitters [55]. This material

TABLE 46.1 Linewidth Enhancement Factor and Chirp of Lasers

Laser Type	Linewidth Enhancement Factor	FWHM Chirp at 50 mA and 1 Gb/s (A)
DH Laser	5.5	1.2
MQW Laser	3.5	0.6
Strained MQW Laser	1.0	0.2
InGaAs/GaAs, $\lambda \sim 1 \mu\text{m}$		
Strained MQW Laser	2.0	0.4
InGaAsP/InP, $\lambda \sim 1.55 \mu\text{m}$		

Note: FWHM = full width at half maximum.

FIGURE 46.17 Band diagram of an AlGaInAs GRINSCH with five quantum wells (Zah et al. [55]).

FIGURE 46.18 Light vs. current characteristics of a AlGaInAs quantum well laser with five wells (Zah et al. [55]).

system has a larger conduction band offset than the InGaAsP/InP material system which may result in lower electron leakage over the heterobarrier and, thus, better high temperature performance. The energy band diagram of a GRINSCH (graded index separate confinement heterostructure) laser design is shown in Fig. 46.17. The laser has five compressively strained quantum wells in the active region. The 300 μm long ridge-waveguide lasers typically have a threshold current of 20 mA. The measured light vs. current characteristics of a laser with 70% high reflectivity coating at the rear facet is shown in Fig. 46.18. These lasers have somewhat better high temperature performance than InGaAsP/InP lasers.

The InAsP/InP material system has also been investigated for 1.3 μm lasers [56]. InAsP with an arsenic composition of 0.55 is under 1.7% compressive strain when grown over InP. Using the MOCVD growth technique, buried heterostructure lasers with InAsP quantum well, InGaAsP ($\lambda \sim 1.1 \mu\text{m}$) barrier layers, and InP cladding layers have been reported. The schematic of the laser structure is shown in Fig. 46.19. Typical threshold currents of the BH laser diodes are ~ 20 mA for 300 μm cavity length.

FIGURE 46.19 Schematic of a buried heterostructure InAsP/InGaAsP quantum well laser (Kusukawa et al. [56]).

The material InGaAs, when grown over GaAs, can have very large (~ 300 meV) conduction band offset which can lead to much better high temperature performance than the InGaAsP/InP material system [57]. The temperature dependence of threshold is characterized by $I_{th}(T) = I_0 \exp(T/T_0)$ where T_0 is generally called the characteristic temperature. Typical T_0 values for an InGaAsP/InP laser is ~ 60 – 70 K in the temperature range of 300 – 350 K. The predicted T_0 value for the InGaAs/GaAs system is ~ 150 K, and, recently, $T_0 = 126$ K has been reported for an InGaAs laser emitting near $1.2 \mu\text{m}$ [57].

46.4 Distributed Feedback Lasers

Semiconductor lasers fabricated using the InGaAsP material system are widely used as sources in many lightwave transmission systems. One measure of the transmission capacity of a system is the data rate. Thus, the drive towards higher capacity pushes the systems to higher data rates where the chromatic dispersion of the fiber plays an important role in limiting the distance between regenerators. Sources emitting in a single wavelength help reduce the effects of chromatic dispersion and are, therefore, used in most systems operating at high data rates (>1.5 Gb/s).

The single wavelength laser source used in most commercial transmission systems is the distributed feedback (DFB) laser, where a diffraction grating etched on the substrate close to the active region provides frequency selective feedback which makes the laser emit in a single wavelength. This section reports on the fabrication, performance characteristics, and reliability of DFB lasers [58].

The schematic of our DFB laser structure is shown in Fig. 46.20. The fabrication of the device involves the following steps. First, a grating with a periodicity of 2400 \AA is fabricated on a (100) oriented n-InP substrate using optical holography and wet chemical etching. Four layers are then grown over the substrate. These layers are (1) n-InGaAsP ($\lambda \sim 1.3 \mu\text{m}$) waveguide layer, (2) undoped InGaAsP ($\lambda \sim 1.55 \mu\text{m}$) active layer, (3) p-InP cladding layer, and (4) p-InGaAsP ($\lambda \sim 1.3 \mu\text{m}$) contact layer. Mesas are then etched on the wafer using an SiO_2 mask and wet chemical etching. Fe doped InP semi-insulating layers are grown around the mesas using the MOCVD growth technique. The semi-insulating layers help confine the current to the active region and also provide index guiding to the optical mode. The SiO_2 stripe is then removed and the p-InP cladding layer and a p-InGaAsP contact layer is grown on the wafer using the vapor phase epitaxy growth technique. The wafer is then processed to produce $250 \mu\text{m}$ long laser chips using standard metallization and cleaving procedures. The final laser chips have antireflection coating ($<1\%$) at one facet and high reflection coating ($\sim 65\%$) at the back facet. The asymmetric facet coatings help remove the degeneracy between the two modes in the stop band.

The CW light vs. current characteristics of a laser are shown in Fig. 46.21. Also shown is the measured spectrum at different output powers. The threshold current of these lasers are in the 15 to 20 mA range. For high fiber coupling efficiency, it is important that the laser emit in the fundamental transverse mode. The measured far field pattern parallel and perpendicular to the junction plane at different output powers

FIGURE 46.20 Schematic of a capped mesa buried heterostructure (CMBH) distributed feedback laser.

FIGURE 46.21 CW light vs. current characteristics and measured spectrum at different output powers. Temperature = 30°C.

of a device is shown in Fig. 46.22. The figure shows that the laser operates in the fundamental transverse mode in the entire operating power range from threshold to 60 mW. The full width at half maximum of the beam divergences parallel and normal to the junction plane are 40° and 30°, respectively.

The dynamic spectrum of the laser under modulation is an important parameter when the laser is used as a source for transmission. The measured 20 dB full width is shown in Fig. 46.23 at two different data rates as a function of bias level. Note that for a laser biased above threshold, the chirp width is nearly independent of the modulation rate.

Tunable Lasers

Tunable semiconductor lasers are needed for many applications. Examples of application in lightwave transmission systems are (1) wavelength-division multiplexing where signals at many distinct wavelengths are simultaneously modulated and transmitted through a fiber and (2) coherent transmission systems where the wavelength of the transmitted signal must match that of the local oscillator. Several types of tunable laser structures have been reported in the literature [59–64]. Two principle schemes are (1) multi-section DFB laser and (2) multisection distributed Bragg reflector (DBR) laser. The multisection DBR lasers generally exhibit higher tunability than the multisection DFB lasers. The design of a multisection DBR laser is shown schematically in Fig. 46.24 [59]. The three sections of this device are (1) the active region section that provides the gain, (2) the grating section that provides the tunability, and (3) the phase-tuning section that is needed to access all wavelengths continuously. The current through each of these sections can be varied independently. The tuning mechanism can be understood by noting that the emission wavelength λ of a DBR laser is given by $\lambda = 2n\Lambda$, where Λ is the grating period and n is

FIGURE 46.22 Measured far field pattern parallel and perpendicular to the junction plane.

FIGURE 46.23 Measured chirp as a function of bias.

FIGURE 46.24 Schematic of a multisection DBR laser. The laser has an MQW active region. The three sections are optically coupled by the thick waveguide layer below the MQW active region (Koch et al. [59]).

FIGURE 46.25 Frequency tuning characteristics of a three-section MQW DBR laser (Koch et al. [59]).

FIGURE 46.26 Measured CW linewidth plotted as a function of the inverse of the output power for an MQW DFB laser with a cavity length of 850 μm .

the effective refractive index of the optical mode in the grating section. The latter can be changed simply by varying the current in the grating section.

The extent of wavelength tunability of a three-section DBR laser is shown in Fig. 46.25 [61]. Measured wavelengths are plotted as a function of phase-section current for different currents in the tuning section. A tuning range in excess of 6 nm can be obtained by controlling currents in the grating and phase-tuning sections.

An important characteristic of lasers for applications requiring a high degree of coherence is the spectral width (linewidth) under CW operation. The CW linewidth depends on the rate of spontaneous emission in the laser cavity. For coherent transmission applications, the CW linewidth must be quite small. The minimum linewidth allowed depends on the modulation format used. For differential phase-shift keying (DPSK) transmission, the minimum linewidth is approximately given by $B/300$, where B is the bit-rate. Thus, for 1-Gb/s transmission rate, the minimum linewidth is 3 MHz. The CW linewidth of a laser decreases with increasing length and varies as α^2 , where α is the linewidth enhancement factor. Since α is smaller for a multi-quantum well (MQW) laser, the linewidth of DFB or DBR lasers utilizing an MQW active region is smaller than that for lasers with a regular DH active region. The linewidth varies inversely with the output power at low powers (<10 mW) and shows saturation at high powers. The measured linewidth as a function of output power of a 850 μm long DFB laser with an MQW active region is shown in Fig. 46.26. The minimum linewidth of 350 kHz was observed for this device at an operating power of 25 mW. For multisection DBR lasers of the type shown in Fig. 46.24, the linewidth varies with

FIGURE 46.27 Measured CW linewidth as a function of wavelength for a 3-section MQW DBR laser (Koch et al. [61]).

changes in currents in the phase-tuning and grating sections. The measured data for an MQW three-section DBR laser is shown in Fig. 46.27. Measured linewidths are plotted as a function of phase-section current for different currents in the tuning section.

46.5 Surface Emitting Lasers

Semiconductor lasers have cleaved facets that form the optical cavity. The facets are perpendicular to the surface of the wafer and light is emitted parallel to the surface of the wafer. For many applications requiring a two-dimensional laser array or monolithic integration of lasers with electronic components (e.g., optical interconnects), it is desirable to have the laser output normal to the surface of the wafer. Such lasers are known as surface-emitting lasers (SEL). A class of surface emitting lasers also have optical cavity normal to the surface of the wafer [65–72]. These devices are known as vertical-cavity surface-emitting lasers (VCSEL) in order to distinguish them from other surface emitters.

A generic SEL structure utilizing multiple semiconductor layers to form a Bragg reflector is shown in Fig. 46.28. The active region is sandwiched between n- and p-type cladding layers which are themselves sandwiched between the two n- and p-type Bragg mirrors. This structure is shown using the AlGaAs/GaAs material system which has been very successful in the fabrication of SELs. The Bragg mirrors consist of alternating layers of low index and high index materials. The thicknesses of each layer is one-quarter of the wavelength of light in the medium. Such periodic quarter wave thick layers can have very high reflectivity. For normal incidence, the reflectivity is given by [73]

$$R = \frac{(1 - n_4/n_1(n_2/n_3)^{2N})^2}{(1 + n_4/n_1(n_2/n_3)^{2N})^2} \quad (46.4)$$

where n_2 and n_3 are the refractive indices of the alternating layer pairs, n_4 and n_1 are the refractive indices of the medium on the transmitted and incident sides of the DBR mirror, and N is the number of pairs. As N increases, R increases. Also, for a given N , R is larger if the ratio of n_2/n_3 is smaller. For an AlAs/Al_{0.1}Ga_{0.9}As set of quarter wave layers, typically 20 pairs are needed for a reflectivity of ~99.5%. Various types of AlGaAs/GaAs SELs have been reported [74–82].

For an SEL to have a threshold current density comparable to that of an edge-emitting laser, the threshold gains must be comparable for the two devices. The threshold gain of an edge emitting laser is ~100 cm⁻¹. For an SEL with an active-layer thickness of 0.1 μm, this value corresponds to a single-pass gain of ~1%. Thus, for the SEL device to lase with a threshold current density comparable to that of an edge emitter, the mirror reflectivities must be >99%.

FIGURE 46.28 Schematic illustration of a generic SEL structure utilizing distributed Bragg mirrors formed by using multiple semiconductor layers. DBR pairs consist of AlAs (711 Å thick) and $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ (605 Å thick) alternate layers. Active layer could be either a quantum well or similar to a regular double-heterostructure laser.

FIGURE 46.29 Typical reflectivity spectrum of an SEL stack.

The reflectivity spectrum of an SEL structure is shown in Fig. 46.29. The reflectivity is >99% over a 10 nm band. The drop in reflectivity in the middle of the band is due to the Fabry–Perot mode.

The number of pairs needed to fabricate a high reflectivity mirror depends on the refractive index of layers in the pair. For large index differences, fewer pairs are needed. For example, in the case of CaF_2 and ZnS for which the index difference is 0.9, only six pairs are needed for a reflectivity of 99%. By contrast, for an $\text{InP}/\text{InGaAsP}$ ($\lambda \sim 1.3 \mu\text{m}$) layer pair for which the index difference is 0.3, more than 40 pairs are needed to achieve a reflectivity of 99%.

Five principal structures (Fig. 46.30) used in SEL fabrication are (1) etched mesa structure, (2) ion-implanted structure, (3) dielectric isolated structure, (4) buried heterostructure, and (5) metallic reflector structure. Threshold currents of $\sim 0.3 \text{ mA}$ have been reported for $\text{InGaAs}/\text{GaAs}$ SEL devices. An SEL design has been demonstrated whose output can be focussed to a single spot [80]. The laser has a large area ($\sim 100 \mu\text{m}$ dia) and it has a Fresnel zone-like structure etched on the top mirror (Fig. 46.31). The lasing mode with the lowest loss has π phase shift in the near field as it traverses each zone. The laser emits 500 mW in a single mode.

FIGURE 46.30 Schematic of several SEL designs.

FIGURE 46.31 Schematic of a high power SEL with a Fresnel zone.

An important SEL structure for the AlGaAs/GaAs material system is the oxide aperture device [81] (Fig. 46.32). AlAs has the property that it oxidizes rapidly in the presence of oxygen to aluminum oxide which forms an insulating layer. Thus, by introducing a thin AlAs layer in the device structure, it is possible to confine the current to a very small area. This allows the fabrication of very low threshold (<0.2 mA) and high bandwidth (~ 14 GHz) lasers.

Central to the fabrication of low-threshold SELs is the ability to fabricate high-reflectivity mirrors. In the late 1970s, Soda et al. [83] reported on an SEL fabricated using the InP material system. The surfaces of the wafer form the Fabry–Perot cavity of the laser. Fabrication of the device involves the growth of a double heterostructure on an n-InP substrate. A circular contact is made on the p-side using an SiO₂ mask. The substrate side is polished, making sure that it is parallel to the epitaxial layer, and ring electrodes (using an alloy of Au–Sn) are deposited on the n-side. The laser had a threshold current density of ~ 11 kA/cm² at 77 K and operated at output powers of several milliwatts.

InGaAsP/InP SELs have been investigated by many researchers over the last few years [83–89]. Many of the schemes utilize alternating layers of InP and InGaAsP to produce Bragg mirrors (Fig. 46.33)[86]. The refractive index difference between InGaAsP ($\lambda \sim 1.3$ μ m) and InP layers is smaller than that in GaAs SELs, hence InGaAsP/InP SELs utilize more pairs (typically 40 to 50) to produce a high reflectivity ($>99\%$) mirror. Such mirror stacks have been grown by both chemical beam epitaxy (CBE) and MOCVD growth techniques and have been used to fabricate InGaAsP SELs. Room temperature pulsed operation of InGaAsP/InP SELs using these mirror stacks and emitting near 1.5 μ m have been reported [88].

FIGURE 46.32 Schematic of a selectively oxidized SEL consisting of AlGaAs/GaAs multilayers and buried aluminum oxide layers. AlGaAs layers with higher Al content are oxidized more.

FIGURE 46.33 Schematic of an InGaAsP SEL fabricated using multilayer mirrors (Yang et al. [86]).

FIGURE 46.34 Schematic of an InGaAsP SEL fabricated using wafer fusion (Babic et al. [89]).

An alternative approach is using the technique of wafer fusion [89,90]. In this technique, the Bragg mirrors are formed using a GaAs/AlGaAs system grown by MBE, and the active region of InGaAsP bounded by thin InP layers is formed by MOCVD. The post type structure of a 1.5 μm wavelength SEL formed using this technique is shown in Fig. 46.34 [89]. The optical cavity is formed by wafer fusion of the InGaAsP quantum well between the Bragg mirrors. Room temperature CW threshold currents of 2.3 mA have been reported for the 8 μm dia post device [89].

46.6 Laser Reliability

The performance characteristics of injection lasers used in lightwave systems can degrade during their operation. The degradation is generally characterized by a change in the operational characteristics of the lasers and, in some cases, is associated with the formation and/or multiplication of defects in the active region. The degraded lasers usually exhibit an increase in the threshold current which is often accompanied by a decrease in the external differential quantum efficiency. For single wavelength lasers, the degradation may be a change in the spectral characteristics, e.g., the degraded device may no longer emit in a single wavelength although the threshold or the light output at a given current has changed very little.

The dominant mechanism responsible for the degradation is determined by any or all of the several fabrication processes including epitaxial growth, wafer quality, device processing, and bonding [91–101]. In addition, the degradation rate of devices processed from a given wafer depends on the operating conditions, i.e., the operating temperature and the injection current. Although many of the degradation mechanisms are not fully understood, extensive amounts of empirical observations exist in the literature which have allowed the fabrication of InGaAsP laser diodes with extrapolated median lifetimes in excess of 25 years at an operating temperature of 20°C [93].

The detailed studies of degradation mechanisms of optical components used in lightwave systems have been motivated by the desire to have a reasonably accurate estimate of the operating lifetime before they are used in practical systems. Since for many applications, the components are expected to operate reliably over a period in excess of 10 years, an appropriate reliability assurance procedure becomes necessary, especially for applications such as an undersea lightwave transmission system where the replacement cost is very high. The reliability assurance is usually carried out by operating the devices under a high stress (e.g., high temperature), which enhances the degradation rate so that a measurable value can be obtained in an operating time of a few hundred hours. The degradation rate under normal operating conditions can then be obtained from the measured high temperature degradation rate using the concept of an activation energy [93].

The light output vs. current characteristics of a laser change after stress aging. There is generally a small increase in threshold current and a decrease in external differential quantum efficiency following the stress aging. Aging data for 1.3 μm InGaAsP lasers used in the first submarine fiber optic cable is shown in Fig. 46.35 [91].

Some lasers exhibit an initial rapid degradation after which the operating characteristics of the lasers are very stable. Given a population of lasers, it is possible to quickly identify the “stable” lasers by a high

FIGURE 46.35 Operating current for 3 mW output at 60°C as a function of operating time. These data were generated for 1.3 μm InGaAsP lasers used in the first submarine fiber optic cable (Nash et al. [91]).

FIGURE 46.36 Operating current as a function of operating time for 3 mW output power at 60°C for lasers emitting near 1.55 μm (courtesy of F. R. Nash).

FIGURE 46.37 Spectrum of a DFB laser before and after aging.

stress test (also known as the purge test) [91,92,102,103]. The stress test implies that operating the laser under a set of high stress conditions (e.g., high current, high temperature, high power) would cause the weak lasers to fail and stabilize the possible winners. Observations on the operating current after stress aging have been reported by Nash et al. [91]. It is important to point out that the determination of the duration and the specific conditions for stress aging are critical to the success of this screening procedure.

The expected operating lifetime of a semiconductor laser is generally determined by accelerated aging at high temperatures and using an activation energy. The lifetime (t) at a temperature T is experimentally found to vary as $\exp(-E/kT)$, where E is the activation energy and k is the Boltzmann constant [104,105]. The measured injection current for 3 mW output power at 60 C for buried heterostructures DFB lasers as a function of operating (or aging) time is shown in Fig. 46.36. The operating current increases at a rate of less than 1%/khr of aging time. Assuming a 50% change in operating current as the useful lifetime of the device and an activation energy of 0.7 eV, this aging rate corresponds to a light emitting lifetime of greater than 100 years at 20 C.

A parameter that determines the performance of the DFB laser is the side mode suppression ratio (SMSR), i.e., the ratio of the intensity of the dominant lasing mode to that of the next most intense mode. An example of the spectrum before and after aging is shown in Fig. 46.37 [105]. The SMSR for a laser before and after aging as a function of current is plotted in Fig. 46.38. Note that the SMSR does not change significantly after aging, which confirms the spectral stability of the emission.

FIGURE 46.38 Side mode suppression ratio (SMSR) as a function of current before and after aging.

FIGURE 46.39 Change in emission wavelength after aging is plotted in the form of a normal probability distribution.

For some applications such as coherent transmission systems, the absolute wavelength stability of the laser is important. The measured change in emission wavelength at 100 mA before and after aging of several devices is shown in Fig. 46.39. Note that most of the devices do not exhibit any change in wavelength, and the standard deviation of the change is less than 2 Å. This suggests that the absolute wavelength stability of the devices is adequate for coherent transmission applications.

Another parameter of interest in certifying the spectral stability of a DFB laser is the change in dynamic linewidth or chirp with aging. Since the chirp depends on data rate and the bias level, a certification of the stability of the value of the chirp is, in general, tied to the requirements of a transmission system application. A measure of the effect of chirp on the performance of a transmission system is the dispersion penalty. We have measured the dispersion penalty of several lasers at 600 Mb/s for a dispersion of 1700 ps/nm before and after aging. The median change in dispersion penalty for 42 devices was less than 0.1 dB and no single device showed a change larger than 0.3 dB. This suggests that the dynamic linewidth or the chirp under modulation is stable.

46.7 Integrated Laser Devices

There have been a significant number of developments in the technology of optical integration of semiconductor lasers and other related devices on the same chip. These chips allow higher levels of functionality than that achieved using single devices. For example, laser and optical modulators have been integrated, serving as simple monolithic transmitters.

FIGURE 46.40 Schematic of two adjacent devices in a laser array.

FIGURE 46.41 Light vs. current characteristics of all the lasers in a ten element array.

Laser Arrays

The simplest of all integrated laser devices are one-dimensional arrays of lasers, LEDs, or photodetectors. These devices are fabricated exactly the same way as individual devices except the wafers are not scribed to make single-device chips but left in the form of a bar. The main required characteristics of a laser array are low threshold current and good electrical isolation between the individual elements of the array. The schematic of two adjacent devices in a 10-channel low threshold laser array is shown in Fig. 46.40 [106]. These lasers emit near $1.3 \mu\text{m}$ and are grown by MOCVD on a p-InP substrate. The lasers have multi-quantum well active region with five 7 nm thick wells, as shown in the insert of Fig. 46.40. The light vs. current characteristics of all the lasers in a 10 element array are shown in Fig. 46.41. The average threshold current and quantum efficiency are 3.2 mA and 0.27 W/A, respectively. The cavity length was $200 \mu\text{m}$ and the facets of the lasers were coated with dielectric to produce 65% and 90% reflectivity, respectively [106].

The vertical cavity surface emitting laser (SEL) design is more suitable for the fabrication of two dimensional arrays than the edge emitting laser design. Several researchers have reported two-dimensional arrays of SELs. Among the individual laser designs used are the proton implanted design and the oxide confined design. These SELs and SEL arrays have been fabricated so far using the GaAs/AlGaAs material system for emissions near $0.85 \mu\text{m}$.

Integrated Laser Modulator

Externally modulated lasers are important for applications where low spectral width under modulation is needed [107–110]. The two types of integrated laser modulator structures that have been investigated are the integrated electroabsorption modulated laser (EML) and the integrated electrorefraction modulated laser. The electrorefraction property is used in a Mach–Zehnder configuration to fabricate a low chirp modulated light source.

FIGURE 46.42 Schematic of an electroabsorption modulated laser structure (Takeuchi et al. [111]).

FIGURE 46.43 Schematic of an integrated laser and Mach-Zehnder modulator.

For some applications it is desirable to have the laser and the modulator integrated on the same chip. Such devices, known as electroabsorption modulated lasers (EMLs), are used for high data rate transmission systems with large regenerator spacing. The schematic of an EML is shown in Fig. 46.42 [111]. In this device, the light from the DFB laser is coupled directly to the modulator. The modulator region has a slightly higher band gap than that of the laser region, which results in very low absorption of the laser light in the absence of bias. However, with reverse bias, the effective band gap decreases, which results in reduced transmission through the modulator. For very high-speed operation, the modulator region capacitance must be sufficiently small, which makes the modulator length small resulting in low on/off ratio. Recently very high-speed EMLs have been reported using a growth technique where the laser and modulator active regions are fabricated using two separate growths, thus allowing independent optimization of the modulator band gap and length for high on/off ratio and speed. 40 Gb/s operation has been demonstrated using this device [111].

EML devices have also been fabricated using the selective area epitaxy growth process [112]. In this process, the laser and the modulator active region are grown simultaneously over a patterned substrate. The patterning allows the materials grown to have slightly different band gaps resulting in separate laser and modulator regions. EMLs have been fabricated with bandwidths of 15 GHz and have operated error free over 600 km at 2.5 Gb/s data rate.

An integrated laser Mach-Zehnder device is shown in Fig. 46.43. This device has a ridge-waveguide type DFB laser integrated with a Mach-Zehnder modulator, which also has a lateral guiding provided by a ridge structure. The Mach-Zehnder traveling wave phase modulator is designed so that the microwave and optical velocities in the structure are identical. This allows good coupling of the electrical and optical signal.

FIGURE 46.44 Schematic of a photonic integrated circuit with multiple lasers for a WDM source.

Multichannel WDM Sources

An alternative to single channel very high speed (>20 Gb/s) data transmission for increasing transmission capacity is multichannel transmission using wavelength division multiplexing (WDM) technology. In WDM systems, many (4, 8, 16, or 32) wavelengths carrying data are optically multiplexed and simultaneously transmitted through a single fiber. The received signal with many wavelengths is optically demultiplexed into separate channels which are then processed electronically in a conventional form. Such a WDM system needs transmitters with many lasers at specific wavelengths. It is desirable to have all of these laser sources on a single chip for compactness and ease of fabrication like electronic integrated circuits.

Figure 46.44 shows the schematic of a photonic integrated circuit with multiple lasers for a WDM source [113]. This chip has four individually addressable DFB lasers, the output of which are combined using a waveguide based multiplexer. Since the waveguide multiplexer has an optical loss of ~ 8 dB, the output of the chip is further amplified using a semiconductor amplifier. The laser output in the waveguide is TE polarized and, hence, an amplifier with a multiquantum well absorption region which has a high saturation power is integrated in this chip.

Spot Size Converter (SSC) Integrated Laser

A typical laser diode has too wide ($\sim 30^\circ \times 40^\circ$) an output beam pattern for good mode matching to a single mode fiber. This results in a loss of power coupled to the fiber. Thus, a laser whose output spot size is expanded to match an optical fiber is an attractive device for low loss coupling to the fiber without a lens and for wide alignment tolerances. Several researchers have reported such devices [114,115]. Generally, they involve producing a vertically and laterally tapered waveguide near the output facet of the laser. The tapering needs to be done in an adiabatic fashion so as to reduce the scattering losses. The schematic of an SSC laser is shown in Fig. 46.45 [115]. The laser is fabricated using two MOCVD growth steps. The SSC section is about $200 \mu\text{m}$ long. The waveguide thickness is narrowed along the cavity from 300 nm in the active region to $\sim 100 \text{ nm}$ in the region over the length of the SSC section. The laser emits near $1.3 \mu\text{m}$, has a multiquantum well active region, and a laser section length of $300 \mu\text{m}$. The light vs. current characteristics of a SSC laser [115] at various temperatures are shown in Fig. 46.46. A beam divergence of 13° was obtained for this device. Beam divergences of 9° and 10° in the lateral and vertical direction have been reported for similar SSC devices [115].

FIGURE 46.45 Schematic of a spot size converter (SSC) laser (Yamazaki et al. [115]).

FIGURE 46.46 Light vs. current characteristics of an SSC laser at different temperatures (Yamazaki et al. [115]).

46.8 Summary and Future Challenges

Tremendous advances in semiconductor lasers have occurred over the last decade. The advances in research and many technological innovations have led to the worldwide deployment of fiber optic communication systems that operate near $1.3 \mu\text{m}$ and $1.55 \mu\text{m}$ wavelengths and compact storage disks which utilize lasers for read/write purposes. Although most of these systems are based on digital transmission, lasers have also been deployed for carrying high quality analog cable TV transmission systems. However, many challenges remain.

The need for higher capacity is pushing the deployment of WDM-based transmission which needs tunable or frequency settable lasers. An important research area continues to be the development of lasers with very stable and settable frequency. Integration of many such lasers on a single substrate would provide the ideal source for WDM systems.

The laser-to-fiber coupling is also an important area of research. Recent development in spot size converter integrated lasers is quite impressive, but some more work, perhaps, needs to be done to make them easy to manufacture. This may require more process developments.

Lasers with better high temperature performance constitute an important area of investigation. The InGaAsN based system is a promising candidate for making lasers that emit near $1.3 \mu\text{m}$ with good high temperature performance. New materials investigation is important.

Although WDM technology is currently being considered for increasing the transmission capacity, the need for sources with very high modulation capability remains. Hence, research on new mechanisms for very high-speed modulation is important.

The surface emitting laser is very attractive for two-dimensional arrays and for single wavelength operation. Several important advances in this technology have occurred over the last few years. An important challenge is the fabrication of a device with characteristics superior to that of an edge emitter.

Finally, many of the advances in the laser development would not have been possible without the advances in materials and processing technology. The challenges of much of the current laser research are intimately linked with the challenges in materials growth, which include not only the investigation of new material systems but also improvements in existing technologies to make them more reproducible and predictable.

47.1 Introduction

In the last 15 years, optical fiber transmission systems have progressed enormously in terms of information handling capacity and link distance. Some major advances in transmitter technology, both electronic and optoelectronic, have made this possible. The single longitudinal mode infrared emission from semiconductor distributed feedback (DFB) laser diodes can be coupled efficiently into today's low-loss silica single-mode fibers. In addition, these lasers can be switched on and off with transition times on the order of 100 ps to provide data rates up to approximately 10 Gb/s. The outstanding performance of these laser diodes has, in fact, provoked considerable effort to improve the switching speed of digital integrated circuits in order to fully utilize the capability of the optoelectronic components.

The performance of directly modulated laser transmitters greatly surpasses that of light emitting diode (LED) transmitters both in terms of optical power coupled into the fiber and switching speed. Short-distance (<10 km), low-capacity (<1 Gb/s) links use LED transmitters. For these applications, such as for local area networks, for example, LED transmitters can provide a cost-effective alternative to the laser.

Where high bit rates and a large regenerator spacing are required, optical pulse distortion occurring in the fiber between the transmitter and receiver is very important. Because of the advent of the optical amplifier, these requirements are now commonplace in terrestrial as well as submarine communication systems because amplifiers can cost-effectively eliminate the loss of very long fiber links. With loss out of the way, distortion becomes a major issue. Phase/frequency shifts accompany the switching of semiconductor lasers. Commonly referred to as **chirp**, these shifts cause rapid deterioration of the pulse shape in dispersive optical fibers, thereby limiting the reach of directly modulated transmitters. For example, at a bit rate of 2.5 Gb/s, a distance of 200 km represents the limit of what is currently achievable using conventional single-mode fiber (assuming an operating wavelength in the 1550 nm low-loss window). Higher performance transmitters use external modulators to exceed these limits. External modulators exist which produce little or no switching phase shift.

The following sections include some information about the characteristics of laser diodes used in directly modulated optical transmitters and the electronic circuits to drive them. A brief description of packaging technology is also provided. A section is included on the performance characterization of high-speed digital lightwave transmitters. The use of external modulators introduces a new set of design requirements. These are also discussed.

Whereas digital transmission dominates the field of optical fiber transmission systems, analog systems are also important for the transmission of cable TV signals and microwave signals for remote antenna location and phase array radar systems, for example. The requirements for analog transmitters depend on the type of signal to be transmitted and are generally quite different from those of digital systems. Properties which are not very important in digital systems, such as linearity and signal-to-noise ratio, are very important in analog systems because, once degraded, the signal quality cannot be restored. More information about analog transmission is contained in Kolner and Dalfi [1987], Atlas [1996], and Linder et al. [1995].

47.2 Directly Modulated Laser Transmitters

The design of a state-of-the-art laser transmitter requires the combining of several different technologies. The laser diode is, of course, the critical component whose properties govern the transmitter performance. Its electrical and optical properties are both very important. The electrical driver circuit and the link between it and the laser are also critical design areas. Finally, the package design is a specialized combination of a microwave and optical enclosure.

Laser Diode Characteristics

The laser diode must launch optical pulses into the optical fiber at the required wavelength, with high spectral purity, with a high **extinction ratio**, and with a low-intensity noise. These properties have been discussed in a previous chapter. The optical format is typically **non-return to zero (NRZ)**, but **return-to-zero (RZ)** format is also used. The ideal optical signal will reproduce the data stream faithfully without **jitter**, ringing, or chirp. These cannot be eliminated entirely, and each contributes to the overall system performance.

A look at the **light, current (L/I) characteristic** of a DFB laser reveals a lot about its basic character (see Fig. 47.1). The light output is relatively small until the current reaches a certain value, called the **threshold current**. Thereafter, the optical intensity rises approximately linearly with increasing current. For digital modulation, the current to the laser switches between two levels, the 0 level current being near the threshold current and the 1 level current being higher. The problems associated with typical

FIGURE 47.1 L/I (light vs. current) characteristic of a DFB laser.

FIGURE 47.2 Switching waveforms of DFB lasers: (a) logic 0 bias below the threshold current and (b) logic 0 bias above the threshold current.

laser diodes are that the curve bends over at high current and tends to shift and bend to the right with increasing temperature and as the laser ages. In addition, the L/I characteristic often exhibits small kinks, which are usually related to the level of optical power reflected back into the device [Tsu et al., 1992]. Wavelength fluctuations accompany these kinks. In high bit rate systems, an **optical isolator** prevents reflections from disturbing the laser. The changes due to temperature and time can, to a large extent, be countered using electronic feedback circuitry, as described in the next section. Often, a temperature-controlled laser mount is also used. Keeping the temperature constant also reduces wavelength drift, and a low temperature extends the laser's lifetime.

Measurement of laser output while switching the input current between two levels indicates that the dynamic response of these diodes is not straightforward. When switching from low optical power to a higher power, there is first a turn-on delay, which has a random component. A rapid increase in power follows, ringing at the **relaxation resonance** frequency. An unwanted frequency modulation accompanies the ringing. The turn-off is a smooth exponential decay, which is somewhat slower than the turn-on transition time. Typical waveforms for various current levels are shown in Fig. 47.2. The turn-on delay decreases as the off-state (bias) current is increased. For many digital applications, the bias is carefully set close to the laser threshold current to minimize the turn-on delay while at the same time providing a high-extinction ratio.

The dynamic behavior just described can be modeled using the **laser rate equations**. The single-mode rate equations are frequently presented as:

$$\frac{d}{dt}N = \frac{I_A}{q \cdot V_{act}} - \frac{N}{\tau_n} - g_0 \cdot (N - N_{0g}) \cdot (1 - \epsilon \cdot S) \cdot S \quad (47.1)$$

$$\frac{d}{dt}S = \Gamma \cdot g_0 \cdot (N - N_{0g}) \cdot (1 - \epsilon \cdot S) \frac{1}{\tau_p} \cdot S + \Gamma \cdot \beta \cdot \frac{N}{\tau_n} \quad (47.2)$$

where N = electron density; q = electron charge; τ_n = electron lifetime; N_{0g} = electron density for zero gain; S = photon density; τ_p = photon lifetime; I_A = current injected into active layer; V_{act} = volume of active layer; g_0 = differential gain constant; ϵ = gain compression factor; Γ = optical confinement factor; β = spontaneous emission factor.

Computer programs intended for nonlinear circuit analysis, such as the Berkeley SPICE simulation program, can be used to solve these equations by defining a circuit to represent them [Tucker, 1985; Wedding, 1987]. The electron and photon densities are represented by circuit node voltages. The technique is powerful because it enables additional electronic circuitry to be included in the analysis. For example, the driver circuit, bond wires, and the laser electrical parasitics, as well as the rate equations, can all be modeled in the same analysis. This provides a versatile tool for analyzing the dynamic properties of laser transmitters.

Electronic Driver Circuit Design

A simple approach to driving a laser diode is to connect the output of a current driver circuit directly to the laser diode, as shown in Fig. 47.3. This approach is frequently adopted when the operating frequency is below 1 GHz. However, the inductance of the bond wires combined with the capacitance associated with the driver circuit and the laser can significantly degrade the risetime and cause ringing in the current pulses. This approach is difficult at higher frequencies because it might be impossible to reduce the inductance sufficiently. For narrow-bandwidth designs, sometimes a matching circuit can be used to cancel the effect of the inductance, but for very high-speed digital designs, a different approach is required. Flip-chip laser mounting on top of the driver circuit [Pedrotti et al., 1992] and fully integrated lasers and drivers [Eriksson et al., 1996] are the subjects of ongoing research, but typically some form of transmission line is needed between driver and laser. This leads to new requirements for the driver circuit. It is generally difficult to implement a characteristic transmission line impedance as low as the typical dynamic resistance of a laser ($3\text{--}8\ \Omega$), and so a technique frequently used is to increase its load resistance to a more manageable value using a closely mounted series resistor. The series resistor increases the power dissipation of the resultant load for a given modulation current and also the required voltage swing. The former has adverse consequences related to laser thermal effects, and the latter affects the driver circuit requirements. Low impedances are normally used (in the range $12\text{--}25\ \Omega$), although, when the driver circuit is completely separated from the laser package, the standard $50\text{-}\Omega$ transmission line impedance is frequently used for convenience, allowing the use of standard coaxial connectors (such as sub-miniature A (SMA) type) and commercial amplifiers to drive the laser. Testing is also simplified because most high-frequency test equipment uses $50\text{-}\Omega$ interconnects as standard. An example of a current switch driver circuit with transmission line link to the laser is shown in Fig. 47.4. The modulation current is equal to the current in the tail of the differential output pair, which is controlled by the voltage at the V_{gmod} input. The laser bias current (the logic 0 current) is determined by the current in the separate bias source. One example of a high-speed GaAs hetero-junction bipolar transistor (HBT) laser driver circuit is that reported in Runge et al. [1992], which is a monolithic design with several stages of current amplification

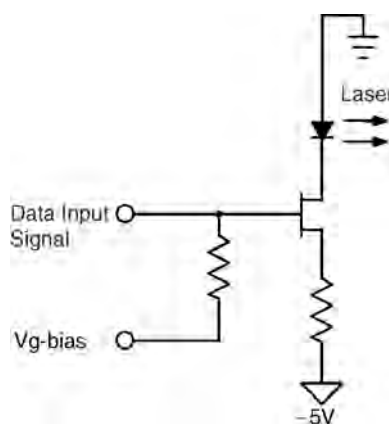

FIGURE 47.3 FET laser driver directly connected to laser diode.

FIGURE 47.4 Current switch laser driver with transmission line coupling to laser diode.

FIGURE 47.5 Average power control circuit.

for the laser drive. This circuit includes a Cherry–Hooper amplifier stage driving a cascaded differential pair output driver.

Typically, various feedback loops are used in practical laser transmitter designs to compensate for the behavior of laser diodes when influenced by variations in data rate, temperature, and aging effects. The simplest average power control circuit is shown in Fig. 47.5. The laser is connected in the collector lead of a typical differential pair driver stage. The data signal is applied to one side of the differential pair and a reference voltage is applied to the other. In addition, the drive transistor is connected in parallel with another transistor, which serves as a bias current source. This current source is controlled by the output of a monitor photodiode. A portion of the output power from the laser, typically taken from the laser's

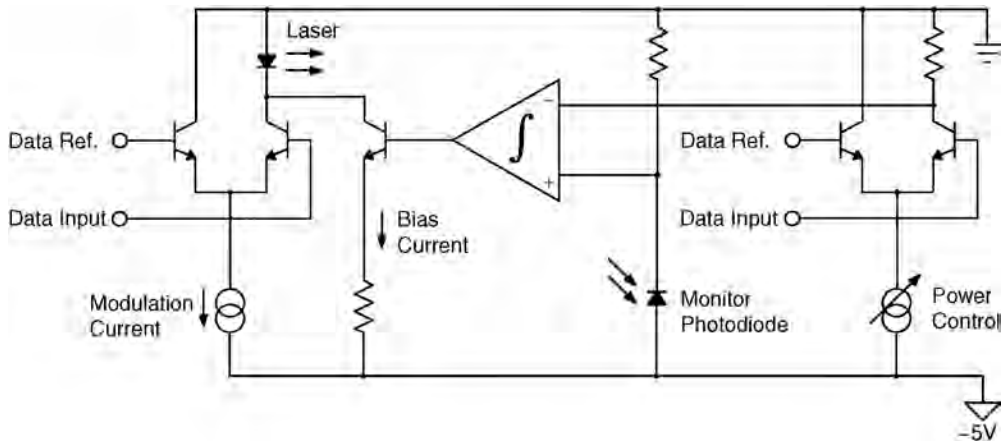

FIGURE 47.6 Average power control with mark density compensation.

rear facet, is incident on this detector. The circuit keeps the 0 and 1 levels constant with variations in threshold current as long as the slope of laser's L/I characteristic does not change.

The average number of 1s relative to the number of 0s, the mark density, is linearly related to the average power. If the mark density of the data changes, then the laser bias point will shift using the circuit of Fig. 47.5. In the extreme case of a long string of zeros, the average power feedback circuit will continue to increase this zero level up to the setpoint for the average power. To alleviate this problem, a circuit similar to that shown in Fig. 47.6 can be used. The V_{power} reference input of the average power feedback circuit is replaced with a signal proportional to the mark density. Now, in the case of a long string of zeros, the reference voltage increases, causing the laser bias current to decrease, maintaining the correct bias current to the laser. This approach now compensates for threshold current shifts and mark density variation but not for changes in the slope of the L/I curve.

An approach that allows slope correction is given in Smith [1978]. To detect whether the zero level is near threshold, the amplitude of the current is modulated at a low frequency when the data input is zero. By detecting the slow ripple from the photodiode output at this modulation frequency, a signal whose amplitude is sensitive to the L/I curve slope at the logical zero level is obtained. Since the slope changes abruptly around the threshold current, the logical zero can be maintained close to the threshold current using a feedback circuit. When used in conjunction with an average power controller, a constant amplitude high-extinction ratio optical signal can be maintained for changes in both threshold current and slope.

For high bit rate transmitters, sometimes the 0 level current must be set significantly above the threshold current in order to reduce turn-on delay, ringing, and chirp. The resulting extinction ratio penalty is often a small price to pay for the improved system performance when chromatic dispersion is present. In such circumstances, the circuit shown in Fig. 47.7 may be used [Chen, 1980]. Here, in addition to average power control, the AC component of the detected current is fed back to the modulation control of the laser driver. By keeping this constant, slope variations are compensated, and the extinction ratio is held approximately constant. Mark density compensation can be incorporated, as shown in Fig. 47.6. A disadvantage of the circuit shown is that a broadband monitor photodiode might be needed. This can be avoided by adding to the bias current a small low-frequency tone with an amplitude proportional to the modulation current. This can be detected accurately with low-frequency circuitry to obtain a measure of the optical modulation amplitude.

Various other methods have been investigated for use in the stabilization of laser output. Among these are encoding to ensure a suitable balance of 1s and 0s in the circuit, encoding both clock and data, and using the clock component to adjust the laser drive condition. Albanese [1978] developed a method to monitor the laser threshold without the use of a monitor photodiode by monitoring the change in laser electrical characteristics near the threshold.

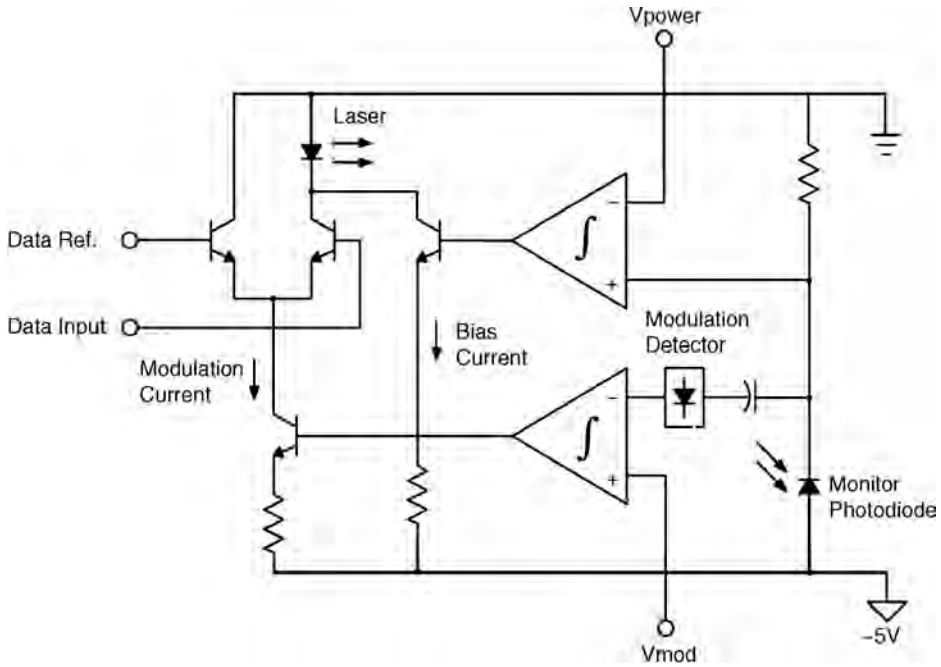

FIGURE 47.7 Average power and modulation amplitude control circuit.

FIGURE 47.8 Laser package.

Optoelectronic Package Design

An illustrative example of a laser diode package is shown in Fig. 47.8. In this particular example, the laser diode is mounted on a diamond heat spreader, which is mounted on a ceramic carrier. Lasers such as these, which may be purchased from many vendors, allow ease of handling, testing, and replacement without handling the device itself. Laser and carrier are mounted on a **thermoelectric cooler** with a thermistor to monitor the temperature and a large-area optical detector, which is used to monitor the optical power by intercepting the backward wave emission of the laser. It is generally preferred to limit heat generating components mounted on the cooler to a minimum to keep down the cooling requirements.

Frequently, the temperature controller will be set to keep the temperature near 25°C or a little higher in order to maximize the range over which stabilization can be maintained (the cooler can be used to heat as well as cool). The electrical link from the driver circuit is provided by a transmission line, as shown in the diagram. This critical link is designed carefully, taking into account dimensional tolerances in order to repeatedly obtain good performance. To couple power into the optical fiber, a graded index (GRIN) or spherical lens is mounted close to the front facet of the laser to produce a collimated beam. The beam passes through a small optical isolator and is focused into the fiber using a second lens. An angled optical arrangement is used to reduce reflections. The alignment and stability of this arrangement is critical to achieve a low coupling loss of about 3 dB. For applications that do not require the use of an isolator to reduce reflections, adequate coupling efficiency may be obtained by directly coupling from the laser into the fiber. The end of the fiber is normally tapered, and the tip is formed into a convex lens to match the laser light into the fiber.

Transmitter Performance Evaluation

The methods of evaluating digital optical transmitters and systems have, to a certain extent, been standardized in recent years due to the introduction of synchronous optical network (SONET) and synchronous digital hierarchy (SDH) optical systems standards [Bell, 1994]. One of the purposes of these standards is to specify a set of requirements to allow interoperability of equipment from different manufacturers. An additional objective is that transmitters from one manufacturer operate with receivers made by another manufacturer. Clearly, to achieve this, their characteristics must be sufficiently well specified.

Evaluating the performance of an optical transmitter requires certain measurements of the optical signal produced. Using a broadband optical detector, an electrical signal proportional to the optical intensity is obtained, allowing the intensity modulation to be examined using standard electrical measurement techniques. The signal is filtered using a low-pass filter with well-defined characteristics to provide a standard receiver response. For example, a fourth-order Bessel–Thompson filter with a 3-dB bandwidth equal to 0.75 of the bit rate is specified for testing SONET transmitters. Using an oscilloscope, the signal can then be displayed in the form of an **eye pattern**. The signal shape must meet certain criteria defined by an eye pattern mask (see Fig. 47.9). Measurement software overlays these masks on the oscilloscope screen, measures violations of the limits specified by the masks, and also measures the other characteristics such as extinction ratio and jitter.

Eye pattern measurements of the transmitter output signal do not give any indication of phase or frequency modulation of the optical signal. These, however, are critically important for long-distance

FIGURE 47.9 Eye pattern mask test.

transmission through dispersive fiber. The spectral width is one indicator which is helpful here. A wide spectrum is very susceptible to the effects of chromatic dispersion in the transmission medium. For this reason, a specification is imposed on the spectral width of the transmitted signal. In addition, degradation of the signal must be tested by passing it through a length of optical fiber. Typically, the signal power required at a reference optical receiver input, for example, defined by a 10^{-10} error rate, when the signal is passed through a given length of optical fiber, is compared with the power required when the transmitted signal is passed through a very short length of fiber. The optical power going into the receiver is adjusted using an optical attenuator. The measured power ratio is usually expressed in decibels of **dispersion power penalty** for a given chromatic dispersion. A small value is indicative of a high-performance, low-chirp transmitter.

As transmission rates increase, the impairments due to laser chirp combined with chromatic dispersion as well as other signal degradation mechanisms become more severe. One solution to this problem is to use lower chirp modulator sources, as investigated in the following section. Another that can be used in conjunction with either lasers or external modulators is to use forward error correction (FEC) encoding. The fundamentals of FEC are dealt with in detail elsewhere in this volume. Encoding the signal by the addition of extra bits at the transmitter, their values depending on the bit pattern to be sent, allows the receiver to not only detect the existence of errors but also to correct them. For example, using the ITU-G.975 optical coding standard which is a Reed–Solomon (255b/239b) code, a received signal with a bit error rate of $\sim 8 \times 10^{-5}$ with no coding can be received with $\sim 1 \times 10^{-15}$ BER using the FEC code. This improvement is sometimes expressed in terms of coding gain, which is the difference in received power with and without FEC necessary to achieve a certain BER. This gain depends on the BER used for comparison, but improvements of ~ 5 dB are common. This transmission improvement can be used to increase the transmission distance or to allow the use of less expensive components or fiber with wider specification variations. This improvement in transmission comes at the cost of the addition of extra bits and requires that the transmitter operate at a higher bandwidth, 7% higher in the case of the ITU standard. At 40 Gbit/s, the problems associated with limited electrical bandwidth, device imperfections, and fiber nonlinearities require the use of FEC in the transmitter to allow reasonable transmission distances with practical components. The application of other coding schemes with greater coding gain but more complicated coding and decoding algorithms are the topics of current investigation.

47.3 Externally Modulated Optical Transmitters

Absorptive modulators and interferometric types are considered here. Because the former type can be made of the same materials used in the fabrication of lasers, the popularity of these lies in the possibility of integrating them with the laser diode to save cost [Watanabe, Sato, and Soda, 1992]. The most commonly used interferometric type, the **Mach–Zehnder**, normally uses the electro-optic properties of lithium niobate to provide very precise control over the amplitude and phase of the signal, for high-performance applications.

Characteristics of External Modulators

Electroabsorption (EA) modulators are monolithic semiconductor devices, usually indium phosphide (InP) based. They rely on either the Franz–Keldysh effect (FKE) or the quantum-confined Stark effect (QCSE) and have optical waveguide p-i-n structures grown epitaxially, typically using the InGaAsP-InP or InGaAs-InAlAs material systems [Chin, 1995; Kawano et al., 1992]. Compatibility with laser structures makes the integration of laser and modulator possible and very attractive. The advantages of using these modulators compared with direct laser modulation are that the chirp associated with the laser relaxation resonance is avoided (although there is some inherent chirp in the modulators [Koyama and Iga, 1988]), the input impedance is high, and these modulators are capable of very high-speed modulation.

A comprehensive comparison of the relative merits of different types of EA modulators is beyond the scope of this text. Some of the factors that affect their suitability in different applications are drive level

requirements, extinction ratio, bandwidth, operating wavelength range, chirp, temperature stability, and, for analog systems, linearity.

Electrically, EA modulators are diodes that operate in reverse bias. The absorption is dependent on the applied voltage. For high-frequency applications, the capacitance of the device must be considered. A sufficiently low-driving impedance is used so that the low-pass pole caused by the capacitor does not limit the bandwidth too much. A transmission line link to the drive circuit will frequently be required. In that case, the line could be terminated using a resistor connected in parallel with the modulator at the end of the transmission line to prevent reflections. For bandpass applications, microwave matching techniques are used to improve the modulation efficiency. The bandwidth can also be improved by incorporating the device capacitance into a lumped transmission line structure. The electrical techniques appropriate to the use of these devices are those that also apply to many other high-impedance devices such as FETs and varactor diodes.

Mach-Zehnder modulators operate using interference by splitting the input into two paths, which are later recombined (see Fig. 47.10). Using lithium niobate or another electro-optic material for the optical waveguides, the phase delay is dependent on the electric field applied to the waveguides. Phase modulators

FIGURE 47.10 Mach-Zehnder modulators: (a) package outline, (b) lithium niobate crystal, and (c) detail.

can, therefore, be incorporated in one or both of the split paths allowing electrical control of the phase of the two signals. Depending on their relative phases when they are recombined, constructive or destructive interference occurs, resulting in amplitude modulation. The phase modulator electrodes are usually formed into transmission lines following the path of the optical waveguides. In this way, over a certain path length, an applied electrical pulse will continue to modulate an optical signal as both waves progress along their respective waveguides. If the velocities are not well matched, which is usually the case, the optical and electrical waves will not track each other over a long distance and the high-frequency response is affected. For a given required bandwidth, the length of interaction must be limited, which in turn limits the phase shift induced by a given applied voltage. Typically, therefore, high-bandwidth designs require relatively high-drive voltages compared with lower bandwidth designs. The drive voltage requirements are usually denoted by a value for $V\pi$, the change in voltage required to produce π -rad phase shift between the two paths. This corresponds to the voltage needed to go from maximum to minimum amplitude. Typical values are in the order of 10 V for a device with a 10-GHz modulation bandwidth, though this is continually being improved. The extinction ratio for these devices, the ratio of maximum to minimum value expressed in decibels, is dependent on the amplitude balance in the two paths, as well as the level of other unwanted transmission modes through the device. Typical values are >20 dB.

In modulators for optical transmitters, the path lengths may be several centimeters, equivalent to many wavelengths of the light passing through them. Although great care is taken to maintain device symmetry, the path lengths are not generally identical, and so the required voltage for maximum amplitude transmission is usually some random value. In addition, temperature gradients, stresses, and the presence of impurities in the optical waveguides all have an effect on the relative phase. For these reasons, care is taken in the packaging and package mounting to avoid mechanical stresses. The terminating resistors for the electrical transmission lines are usually isolated from the lithium niobate crystal to prevent heating. Measures are taken to minimize the absorption and subsequent diffusion of impurities in order to reduce long term drifts in the phase difference.

Various transmission line electrode arrangements are possible. Commonly, a single $50\text{-}\Omega$ coplanar waveguide is designed to apply electric fields to both optical waveguides simultaneously such that one optical path is retarded while the other is advanced. If the phase shifts are equal but opposite in the two paths, the resultant amplitude modulation is free of phase modulation (chirp); whereas if only one path is phase modulated, the resultant modulation contains both amplitude and phase modulation components. Researchers have discovered [Gnauch et al., 1991] that under certain conditions of chromatic dispersion, transmission distances are actually enhanced if a small amount of phase modulation accompanies the amplitude modulation by comparison with a completely chirp-free modulation, so now some commercial modulators provide this optimum amount of chirp. Another type of modulator simply provides two separate electrical inputs, each one controlling one arm of the Mach–Zehnder. By controlling the relative amplitude and sign of the two inputs, the amount and direction of the accompanying chirp can be precisely controlled. In addition, a differential output driver circuit need supply only half the voltage swing to each input compared with single-ended drive.

Chirp control is a very important issue when high bit rates are combined with long-distance transmission through dispersive fiber. Another approach to phase control is to add a phase modulator in cascade with the Mach–Zehnder. It can, of course, be integrated with the Mach–Zehnder by extending it and incorporating another electrode on the input or output waveguide. The drive waveforms must then be coordinated between the Mach–Zehnder and the phase modulator to obtain the required simultaneous phase and amplitude modulation. Allowance must be made for the optical delay between the two modulators, and delay must be provided in the drive signals to compensate.

Whichever electrode configuration is used, the output intensity vs. input voltage is usually the same shape for all Mach–Zehnder modulators. It is shown in Fig. 47.11, and is sinusoidal in character. For digital modulation, the 1 level is aligned with a peak and the 0 level is aligned with an adjacent trough. Restated, the modulator is biased to a half-way point and a modulation swing equal to $V\pi$ (peak-to-peak) is applied. If the modulator has chirp, the sign of the chirp will depend on the sign of the slope, and so the correct side of the peak must be used. Some advantages of the sinusoidal characteristic are

FIGURE 47.11 Electrical/optical (E/O) transfer function of Mach–Zehnder modulator.

FIGURE 47.12 Effect of E/O transfer function on optical waveform.

readily apparent. First, because the transfer function is flat at both the peaks and the troughs, noise or spreading of the electrical logic levels will have little effect on the optical intensity levels. Second, the gradient of the transfer function is steepest at the bias point. Provided the bandwidth of the modulator is sufficiently high, this can result in a reduction in the output optical transition times compared with the electrical transition times of the drive waveform. The two factors together give rise to an optical output waveform, which is superior in many ways to the electrical waveform used to generate it. This is in marked contrast with the case of direct laser modulation, where the output optical waveforms not only contain the imperfections of the drive waveform, but also include some added aberrations caused by the laser itself. The waveform improvement is demonstrated in Fig. 47.12.

For most intensity modulation (IM) transmitters, the bias point is at the half-maximum power point, corresponding to phase quadrature between the two paths. The intensity vs. drive voltage characteristic is symmetrical, and the curve is most linear at this point. For most direct detection systems (those in which the received optical power is directly converted to a proportional electrical signal), this is the preferred operating point. However, for some applications, the modulator can be biased at the minimum

amplitude point. The modulator then behaves very much like the balanced mixers used, for example, as upconverters in microwave radio systems. An electrical signal applied to the modulator will be reproduced at optical frequencies in two sidebands on either side of the (suppressed) optical carrier. This means that many of the techniques used to generate radio signals can also be applied to the generation of optical signals. The upconversion is quite linear (sinusoidal in fact) so that the electrical signal properties, both time domain and frequency domain, are preserved in the conversion. If the electrical signal is filtered to reduce its electrical bandwidth, the optical sidebands will have the same bandwidth. Two references provide examples of such a use, Izutsu et al. [1981] and Price and Le Mercier [1995].

Modulator Driver Circuit Design

A common feature of EA modulators and Mach–Zehnder modulators is that electrically, by contrast with laser diodes, they present a high impedance to the driving circuit. A low-output impedance circuit, such as an emitter follower, is therefore appropriate for situations where the driver is connected directly to the modulator. However, as is true for laser driver circuits, the requirements change somewhat when the driver must be separated from the modulator, or when the bond wire inductance becomes a significant factor. Then resonances must be dampened using an appropriate driving resistance or load resistor. In the case of a transmission line link between driver and modulator, or when the modulator uses transmission line electrodes, it is essential to either resistively terminate the line, drive the line using a resistive source, or do both. Again, a 50- Ω transmission line is frequently chosen for convenience and standardization.

When transmission lines are used, the main driver amplifier requirements for both laser drivers and modulator drivers become very similar: they must generate electrical pulses of the required power in the transmission line. The current switch topology of Fig. 47.4 is appropriate for modulators as well as lasers. The main difference is that the required voltage swings are significantly greater for modulators, especially existing Mach–Zehnder designs, compared with laser drivers. For this reason, relatively highpower broadband 50- Ω amplifiers are frequently used to drive modulators. Power output requirements between 20 and 30 dB (1 mW) are typical. Hybrid GaAs metal-semiconductor field-effect transistor (MESFET) designs are used. Integrated circuit solutions include distributed amplifiers.

Automatic control algorithms for Mach–Zehnder modulators contrast those of other optical transmitters because the transfer characteristic (see Fig. 47.11) is quite different and there exists the potential for multiple operating points and an unlimited lateral drift due to temperature and aging. Typically, some optical power is tapped from the output of the modulator and detected in a low-bandwidth optical detector. One method to automatically control the bias point of the modulator is to apply a low-frequency modulation to the gain of the driver amplifier. A signal will be generated in the detector if the bias point is not at the quadrature point as intended. By comparing the phase of the detected signal with the original low-frequency modulation, using a synchronous detector, an error signal can be obtained, which is used to force the bias point to the quadrature point. Inverting the sense of the feedback loop forces the bias point to move to the adjacent quadrature point of opposite slope, causing an inversion of the optical data and the chirp. Methods also exist to optimize the modulation amplitude in order to maintain a good optical output waveform. A problem with some Mach–Zehnder modulators is that, over a period of time, the phase shift might continue to drift over many cycles of phase. An automatic bias circuit is not able to continue to apply higher and higher voltages to track this drift, so a warning circuit is sometimes included to indicate that the voltage might soon reach a limit, after which it would fail to track. At a convenient time, the circuit is reset by remote control before failure occurs.

Most fielded optical systems today rely on NRZ encoding. However, for long distance transmission such as for undersea links, soliton transmission has for many years been a topic of serious research interest [Agrawal, 1997; Mollenauer et al., 1997]. A soliton is a particular type of pulse that maintains its shape during propagation in a dispersive medium. This is the result of a balancing between the effects of nonlinear self phase modulation due to the Kerr nonlinearity in the fiber with fiber dispersion. To launch a soliton, a rather high power (sufficient to bring the self phase modulation to an appropriate level) and

narrow pulse of a particular shape is launched into the fiber. Transmitters to create sequences of suitable pulses can be realized using mode-locked fiber ring lasers, gain switched DFB lasers, mode-locked semiconductor lasers in hybrid or monolithic extended cavities, and modulators injected with CW beams. Information is typically encoded onto these pulse trains using another Mach–Zehnder interferometer to either pass or block the individual pulses, resulting in an RZ encoded pulse train. The spacing between these pulses is much greater than their width so that many such pulse trains can be interleaved in time to create very high bit rate time-division multiplexed signals. New fibers, transmitters, and receivers are resulting in commercialization of the first such soliton systems.

Another related application of RZ modulation is emerging for high bit rate systems operating at rates of 10 Gb/s and higher. Here, the use of a similar approach to externally modulate a train of short pulses provides greater link lengths at high bandwidths although true solitons are not used. The short pulses are generated by the use of CW light injected into an external or monolithically integrated modulator. With appropriate modulator bias and modulation [Veselka, et. al., 1996], a series of short pulses with accurately controlled repetition rate can be generated. These can then be modulated using another amplitude modulator to create the RZ signal. The advantage for high bit rate systems is that the first modulator can operate narrowband at the pulse repetition frequency using a sinusoidal electrical signal. The resulting narrow pulses define the edge rates of the transmitted pulses; the second modulator, which must operate with broadband data, can now have relaxed bandwidth and edge rate response without incurring excessive inter-symbol interference (ISI), which can also ease the design of the modulator driver electronics. Further, the launch power can be increased, increasing regenerator spacing, and some advantage can be obtained from the interplay of the self phase modulation and fiber dispersion. Additionally, 2-5 dB of receiver sensitivity improvement can be realized by the use of this impulsive encoding, depending on the sources of noise in the transmission channel and receiver [Winzer, Kalmar, 1999; Boivin et. al. 1997].

Defining Terms

Chirp: A frequency or phase shift associated with the switching on or off of a laser diode or modulator.

Dispersion power penalty: The power penalty in decibels associated with the increase in receiver optical power level required to achieve a specified error rate, for example, 10^{-10} , when the signal is subjected to a specified amount of chromatic dispersion.

Electroabsorptive (EA) modulator: Semiconductor modulators using the Franz–Keldysh effect (FKE) or the quantum-confined Stark effect (QCSE).

Extinction ratio: The ratio of maximum to minimum insertion loss for an amplitude modulator. The term also applies to the ratio (in decibels) of the average optical energy in a logic 1 level to the average optical energy in a logic 0 level of a digitally modulated optical signal.

Eye pattern: Picture built up by overlaying traces corresponding to all possible sequences of a digital waveform (see Fig. 47.9).

Jitter: Random and systematic deviations of the arrival times of pulses or transitions in digitally transmitted data. Observed as a horizontal spreading of an eye pattern displayed on an oscilloscope (see Fig. 47.12).

Laser rate equations: Set of equations representing the dynamic behavior of electron and photon population densities in a laser.

Laser threshold current: Current threshold at which the gain inside the laser cavity exceeds the losses. Below the threshold current, light emission is spontaneous. Above the threshold current, stimulated emission also occurs.

L/I characteristic: Graph of light output vs. injected current, which exhibits a characteristic knee at the laser threshold current (see Fig. 47.1).

Mach–Zehnder modulator: A two-path optical interferometer that uses phase shifters in one or both paths to provide amplitude modulation.

Non-return to zero (NRZ): Digital format in which the logic 1 pulses occupy the whole bit period (cf. return to zero).

- Optical isolator:** A device that utilizes the Faraday effect to allow transmission through the device in one direction only. These devices are used to isolate lasers from the effects of reflections.
- Relaxation resonance:** Internal resonance between electrons and photons in a laser diode.
- Return to zero (RZ):** Digital format in which the logic 1 pulses occupy a fraction (usually 50%) of the bit period.
- Thermoelectric (TE) cooler:** Device utilizing the Peltier effect to pump heat from one surface to the other. Reversing the direction of current flow reverses the direction of heat flow, so that the same device may be used to heat or cool as necessary.
- V π :** When referred to a phase modulator, it is the voltage change required to give a phase shift of π rad (180°). For a Mach-Zehnder modulator, this corresponds to the voltage required to change from maximum to minimum extinction.

48.3 Receiver Sensitivity: General

Signal Current • Sources of Noise

48.1 Introduction

The optical receiver is an integral part of an optical link. Its function is to detect the received optical power, amplify the signal, retiming, regenerate, and reshape the signal where it may remain as an electrical signal (terminal), or be used to drive an optical transmitter which then feeds another fiber section.

Goal

The goal of the optical receiver is to achieve the desired system performance while requiring the minimum amount of received optical power. System performance criteria include bit error ratio (BER) and eye margin for digital systems, signal-to-noise ratio (SNR) for analog systems, and dynamic range (ratio of largest to smallest signal levels for which the BER or SNR can be achieved).

Over the past 20 years there has been a large amount of work on optical receivers. This work is well covered by review papers and book chapters [Kasper, 1988; Muoi, 1984; Smith and Personick, 1982]. Although the field is fairly mature, there are still advances being made, such as the use of *optical preamplifiers* to improve receiver sensitivity [Olsson, 1989].

48.2 The Receiver

A block diagram of the optical receiver is shown in [Fig. 48.1](#). The receiver consists of a photodetector, a preamplifier, postamplifier, filter, timing recovery, and decision circuit.

The Photodetector

The purpose of the photodetector is to convert the received optical signal into a photocurrent. It is essentially a photon-to-electron converter. The most widely used forms of photodetectors used in optical communications are the p-i-n photodiode and the avalanche photodiode (APD). In the case of the p-i-n, a single electron-hole pair is generated for each photon absorbed by the detector. In the case of the APD, electronic gain within the detector itself generates secondary electron-hole pairs, multiplying the photocurrent and generally improving the receiver sensitivity. (See chapter on optical detectors for a discussion of photodetectors.)

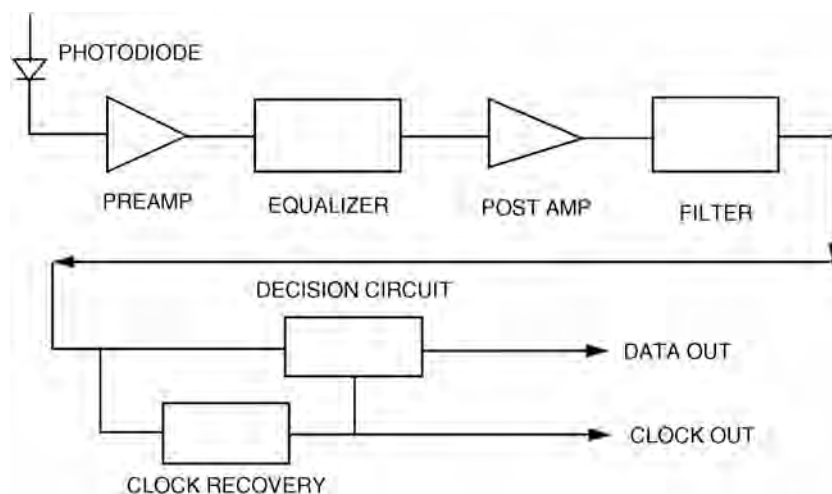

FIGURE 48.1 Schematic diagram of an optical receiver.

Preamplifier

The preamplifier or front end is the most important element of the receiver in determining the optical sensitivity. Its principal function is to amplify the generally small photocurrent with the least amount of added noise. Under most circumstances (especially with a p-i-n detector), the preamplifier noise is dominant in determining the sensitivity. The preamplifier must also have sufficient frequency response so as not to severely distort the received signal shape (*eye margin*). In addition to noise level and frequency response, the front end must be able to respond to a wide range of received optical power levels without severely distorting the signal (dynamic range). Often, these objectives are in conflict and compromises must be made.

Optimized optical receivers differ in several ways from receivers used at RF or microwave frequencies. This difference arises from the fact that the photodetectors generally used (p-i-n, APD) are current sources, and therefore have inherently high impedance. Optimal signal generation therefore requires the front end to have a high impedance, which differs from other types of receivers which are typically driven by low-impedance detectors.

A second major difference between optical systems derives from the relatively large energy of a photon. For a given received power, there are orders of magnitude fewer photons at optical frequencies than at microwave or lower frequencies. In the limit of low received optical power, and, hence, low number of received photons and photogenerated hole–electron pairs, the random arrival rate results in signal related shot noise, which is often important in determining receiver sensitivity.

Optical receiver front ends can be broadly classed into one of three types: high-impedance or *integrating* front end; *transimpedance* front end; and low-impedance front end, typically a 50- Ω impedance level. Although the distinction is not hard and fast, these categories characterize the various approaches to receiver design.

The high-impedance front end achieves the best sensitivity for a given detector. This design approach minimizes the thermal noise generated by resistors, given by $4kT/R$, by increasing their values such that the noise is reduced to a level where it is small compared to other noise sources. As a result of the increased impedance level, the frequency response, determined by the combination of the resistor and the capacitance at the input node of the receiver, is generally very much limited, typically being a factor of 10 or more smaller than that required to reproduce the signal shape. Such a receiver integrates the signal, hence the sometimes used description as an integrating front end. The accepted approach to the limited

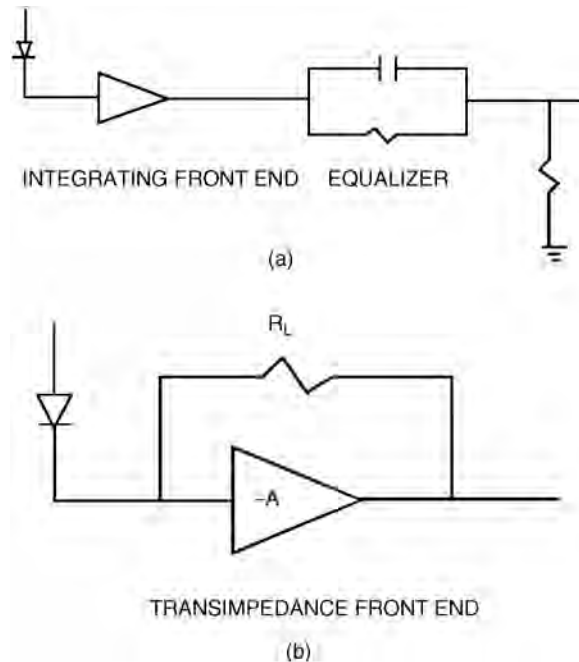

FIGURE 48.2 Schematic diagrams: (a) an integrating front end with equalization and (b) a transimpedance front end.

bandwidth is to equalize the signal after sufficient amplification. A simplified schematic of an equalized, high-impedance front end is shown in Fig. 48.2(a).

The high-impedance front end reduces the thermal noise associated with the input resistor, which has two major consequences. The first is related to the dynamic range of the receiver. Although the signal fidelity is restored by the equalizer, the low-frequency components of the received signal generate large voltages at the input node of the receiver. At received optical signals well in excess of the minimum, this signal buildup will eventually cause the active device (input transistor) to overload, distorting the signal, or perhaps cutting off the receiver. For many applications, dynamic ranges of 20 to 30 dB of optical power (40 to 60 dB electrical) are required. This requirement and the limited dynamic range of the high-impedance type of front end limit the usefulness of this approach.

The second consequence of the equalization is to accentuate the noise generated at the output of the amplifying stage. Because of the effect of the equalization, the noise spectral density associated with the output stage is proportional to the square of the input capacitance. Optimization (reduction) of the equivalent noise of the output stage, and, hence, the receiver front end, requires the minimization of the input capacitance, a goal of all optical receiver designs. The details of such optimization and the relevant formulas giving the analytical expressions for the resulting noise can be found in Kasper [1988], Muoi [1984], and Smith and Personick [1982], and are summarized subsequently.

At the other extreme of receiver design is the low-impedance front end typified by a 50- Ω input impedance amplifier. The low-impedance front end is the least sensitive of the receivers as its noise level is much larger than that of both the high-impedance and transimpedance approaches. Low-impedance receivers find use in laboratory experiments and are used in practical optical communication systems only in conjunction with optical preamplifiers.

The transimpedance receiver is schematically shown in Fig. 48.2(b). It is essentially a current-to-voltage converter. The bandwidth of the receiver is often dominated by the parasitic capacitance of the feedback resistor,

which can be very small. Hence, for a given resistor value, the bandwidth of the transimpedance receiver will be greater than the high-impedance receiver. Under practical conditions, the transimpedance receiver is usually designed with a bandwidth sufficient to reproduce the signal without recourse to equalization. Typically, this results in a higher noise level and hence a poorer sensitivity compared to a high-impedance receiver. It does, however, have an improved dynamic range as the input node is effectively a low impedance due to the electrical feedback. The transimpedance receiver is generally used in optical systems as it offers a good compromise between the various receiver requirements.

Early receivers were realized with discrete transistors. At the present time, many designs are realized using integrated circuits, especially Si bipolar and GaAs field-effect transistor (FET) designs. The GaAs receiver designs generally provide superior receiver sensitivity but are more expensive than their Si bipolar counterparts. Metal-oxide-semiconductor (MOS) integrated circuit (IC) technology has not found much application in optical receiver front ends, but is used in associated circuitry where the speed is sufficient. Generally speaking, the best sensitivities are still achieved with discrete FET front ends, but for economic considerations, integrated circuits are widely used.

Postamplifier

Front ends, as usually employed, typically generate relatively small output signal levels. The output from the front end is usually amplified by a postamplifier. Because the range of optical input signals can be as much as 30 dB (60-dB electrical), the postamplifier usually employs some form of output level control. This is typically achieved by an automatic gain control (AGC) function or by using a limiting amplifier. The output signal level is typically of the order of 1 V, which is sufficient to toggle the decision circuit.

Filtering

The main purpose of the filter shown in Fig. 48.1 is to improve the SNR by reducing the noise. Under ideal conditions, where the effective bandwidths of the components in the system prior to the filter are large, the filter function is such that the signal in a given time slot has zero signal level in all adjacent time slots. The effective bandwidth of such a filter is approximately 0.6 to 0.7 times the signalling rate, B . In a practical system, the pulse shape incident upon the filter is not ideal as a result of limited bandwidth in the transmitter, front end, postamplifier, and dispersion in the transmission fiber. The actual filter function required is one which transforms the waveform prior to the filter into one that produces an acceptable waveform at the decision circuit while minimizing the noise. In many practical lightwave systems, there is little or no actual filtering done due to the limited bandwidth of components preceding the filter. Often, the filtering is accomplished by the preamplifier or front end.

Timing Recovery

In nearly all lightwave systems it is necessary to recover the clock in the process of regenerating the signal. Several commonly used methods of clock recovery make use of phase locked loops or surface acoustic wave filters, with the latter being the most widely used for high-frequency systems which have strict requirements on the phase transfer function. Because the commonly used nonreturn to zero (NRZ) format does not contain energy at the clock frequency, it is necessary to use some form of nonlinear device, such as a rectifier or exclusive OR gate, to produce frequency components at or near the clock frequency. This signal is then passed through a narrowband filter such as a surface acoustic wave (SAW) filter or dielectric resonator to extract the clock. The extracted clock, suitably phased, is used to clock the decision circuit and may be used elsewhere in the terminal or regenerator as needed.

Decision Circuit

The decision circuit receives the signal (plus noise) from the postamplifier along with the recovered clock. The decision circuit produces an output which is reshaped and retimed.

48.3 Receiver Sensitivity: General

The sensitivity of a receiver is usually measured in terms of the average optical power required to produce the desired level of system performance. For digital systems, the measure of performance is the BER or bit error ratio (often referred to as the bit error rate, although incorrectly). The performance measure commonly used is for a $BER = 10^{-9}$, although many systems require significantly better performance. For analog applications, the measure of performance is usually the carrier-to-noise ratio (CNR). Power is measured in terms of decibels referred to 1 mW of received power. Further, for digital systems, sensitivity is measured in terms of the *average* power received, taking into account the population of marks and spaces (i.e., 1s and 0s). The average power is thus approximately one-half of the peak power or 3 dB below the peak received power. In order to evaluate the receiver sensitivity, it is necessary to evaluate both the photogenerated signal current and the sources of noise which corrupt the signal.

Signal Current

The photocurrent generated by a received optical power P is given by

$$I_s = \left[\frac{q\eta}{h\nu} \right] P \quad (\text{p-i-n}) \quad (48.1)$$

where h is Planck's constant ($6.623\text{E-}34$ J/s), ν is the optical frequency, q is the electronic charge, and η is the quantum efficiency of the detector (defined in terms of the number of photoelectrons generated per photon received). In well-designed detectors, the quantum efficiency is usually between 0.8 and 1.0. When a p-i-n detector is used, Eq. (48.1) becomes the signal current; for an avalanche photodiode, the signal current is given by

$$I = MI_s = M \left[\frac{q\eta}{h\nu} \right] P \quad (\text{APD}) \quad (48.2)$$

where M is the expectation value of the avalanche gain.

Sources of Noise

Amplifier or Circuit Noise

As the received signal level (photocurrent generated in the photodetector) is small it must be amplified by an electronic amplifier, which contributes noise to the system. The principal sources of noise in the amplifier are thermal noise from resistors and noise generated in the amplifying transistors. It is common practice in the analysis of optical receivers to refer all noise sources to the input node where they can be compared to the signal current, Eq. (48.1) or (48.2).

In evaluating the contributions of the various sources of noise, account is taken of the frequency response of the various components of the receiver. The details of this computation are too numerous to be included in this summary and may be found in Personick [1973, 1979] and in Smith and Personick [1982]. We will summarize here the essential results described in the aforementioned references.

The variance of the circuit noise for an FET front end is given by

$$\langle i^2 \rangle_{\text{ckt}} = \frac{4kT}{R_L} \mathfrak{F}_2 B + 2qI_g \mathfrak{F}_2 B + \frac{4kT\Gamma}{g_m} (2\pi C_T)^2 \mathfrak{F}_3 B^3 \quad (\text{FET}) \quad (48.3)$$

where k is Boltzmann's constant, T is the absolute temperature, R_L is the load resistance at the input node, q is the electronic charge, I_g is the gate leakage current, g_m is the transconductance of the input transistor,

C_T is the total capacitance at the input node, B is the design bit rate, and Γ is a parameter characterizing the channel noise, which has a value ^a1. The parameters \mathfrak{S}_2 and \mathfrak{S}_3 , referred to as the *Personick integrals*, are dimensionless numbers, which derive from the details of the transfer function of the system. Typical values of j_2 and j_3 are 0.6 and 0.1, respectively. (A detailed explanation of the Personick integrals may be found in Personick [1973] and Smith and Personick [1982].) The B^3 dependence of the last term arises from the referral of the output noise source to the input.

The corresponding equation for the variance of the noise for a bipolar front end, neglecting the effect of noise due to base resistance, is given by

$$\langle i^2 \rangle_{\chi\kappa\tau} = \frac{4kT}{R_L} \mathfrak{S}_2 B + 2qI_b \mathfrak{S}_2 B + \frac{2qI_c}{g_m^2} (2\pi C_T)^2 \mathfrak{S}_3 B^3 \quad (\text{bipolar}) \quad (48.4)$$

For a bipolar transistor, $I_c = \beta I_b$ and the transconductance g_m is proportional to the collector current I_c ; hence, the noise can be minimized by operating the input transistor at the optimum collector current. The minimum bipolar circuit noise is given by

$$\langle i^2 \rangle_{\beta 1 \pi \chi \kappa \tau / \mu \nu} = \frac{4kT}{R_L} \mathfrak{S}_2 B + 8\pi k T C_T \sqrt{\frac{\mathfrak{S}_2 \mathfrak{S}_3}{\beta}} \quad (48.5)$$

Signal Shot Noise

The random arrival rates of photons at the detector result in an additional source of noise, which is proportional to the received photocurrent, referred to as *signal-dependent shot noise*. The spectral density of this noise source is given by

$$\frac{d}{df} \langle i^2 \rangle_{\sigma \nu \gamma} = 2qI \quad (48.6)$$

where I is the average current. This signal-dependent noise constitutes a major difference in optical systems compared to radio frequency and microwave systems. The variance of this contribution to the noise is found by integrating the noise spectral density over the transfer function of the system giving

$$\langle i^2 \rangle_{\sigma \nu \gamma} = 2qI \mathfrak{S}_1 B \quad (48.7)$$

where \mathfrak{S}_1 is another Personick integral, which has a value ^a0.5, and B is the bit rate.

Shot Noise with an Avalanche Photodiode

In many receivers, an avalanche photodiode is used in place of a p-i-n photodiode. As discussed in the chapter on optical detectors in this volume, the APD multiplies the received primary photocurrent given by Eq. (48.1) by an average multiplication factor M ,

$$I_{\text{APD}} = MI = M \left[\frac{q\eta}{h\nu} \right] P$$

For receivers employing an APD, this becomes the signal current [see Eq. (48.2)].

If the avalanche multiplication process were ideal (i.e., deterministic), the shot noise spectral density associated with the signal would be given by

$$\frac{d}{df} \langle i^2 \rangle = 2qIM^2 \quad (48.8)$$

The avalanche process is, however, a random process and not deterministic. This randomness adds additional noise, which is accounted for by a multiplicative noise factor, referred to as the excess noise

factor, and denoted $F(M)$. In this case, the signal-dependent shot noise spectral density becomes

$$\frac{d}{df} \langle i^2 \rangle_{\sigma_V} = 2qIM^2 F(M) \quad (48.9a)$$

and the mean square noise after integration with respect to frequency is

$$\langle i^2 \rangle_{\sigma_V} = 2qIM^2 F(M) \mathcal{F}_1 B \quad (48.9b)$$

Many approximations for $F(M)$ have been given. Among the most commonly used are

$$F(M) = M^x \quad (48.10a)$$

and

$$F(M) = M \left[1 - (1-k) \left(\frac{M-1}{M} \right)^2 \right] \quad (48.10b)$$

In Eq. (48.10a), x is an empirical constant, usually between 0 and 1, and in Eq. (48.10b), k is the ratio of the ionization coefficients of holes and electrons (not to be confused with Boltzmann's constant). The value of k is between 0 and 1 if the avalanche is initiated by the most ionizing carrier, as it should be in a well-designed device. Equation (48.10b) provides a better approximation to the excess noise factor and is generally used.

Sensitivity of a Digital Receiver

In a digital system, the objective is to correctly identify transmitted marks (1s) and spaces (0s). Incorrectly identifying the transmitted signal produces an error. The probability of making an error in turn depends on the signal level and the probability distribution of the system noise. Under many circumstances, but not always, the probability distribution of the noise is Gaussian, with an associated standard deviation σ .

Gaussian Approximation

The assumption of a Gaussian distribution permits simplified analytical approximations to sensitivity calculations, which are generally close to the more rigorous computational approaches. In optical systems, the noise levels associated with the different signal states are not necessarily identical. The standard deviation of the noise associated with a transmitted 1 is denoted by σ_1 and for a transmitted 0 by σ_0 . The ratios of the signal levels relative to the decision level D normalized to the associated root mean square (rms) noise levels are given by

$$Q_1 = \frac{S_1 - D}{\sigma_1} \quad (48.11a)$$

and

$$Q_0 = \frac{D - S_0}{\sigma_0} \quad (48.11b)$$

With these definitions, and using the Gaussian approximation, the probability of misinterpreting a transmitted 0 as a 1 is given by

$$P(0,1) = \frac{1}{2\pi\sigma_0} \int_D^\infty \exp \frac{-(S-D)^2}{2\sigma_0^2} dS = \frac{1}{2\pi} \int_{Q_0}^\infty \exp \frac{-Q^2}{2} dQ \approx \frac{1}{2\pi Q_0} \exp \left(-\frac{Q_0^2}{2} \right) \quad (48.12a)$$

FIGURE 48.3 Probability of error vs. Q value.

and the probability of misinterpreting a transmitted 1 is given by

$$\begin{aligned}
 P(1,0) &= \frac{1}{\sqrt{2\pi}\sigma_1} \int_{-\infty}^D \exp\left[-\frac{(S-D)^2}{2\sigma_1^2}\right] dS \\
 &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{Q_1} \exp\left[-\frac{Q^2}{2}\right] dQ \approx \frac{1}{\sqrt{2\pi}Q_1} \exp\left[-\frac{Q_1^2}{2}\right]
 \end{aligned} \tag{48.12b}$$

To a good approximation, the minimum probability of error occurs when each probability of error is the same, that is, $P(0, 1) = P(1, 0)$, resulting in $Q_1 = Q_0 = Q$ with

$$Q = \frac{S_1 - S_0}{\sigma_1 + \sigma_0} \tag{48.13}$$

The probability of error as a function of the Q factor is shown in Fig. 48.3. The desired error performance determines the value of Q . The average required signal level is given by

$$\bar{S} = \frac{S_1 + S_0}{2} \tag{48.14}$$

with

$$S_1 - S_0 = Q(\sigma_1 + \sigma_0) \tag{48.15}$$

When the decision level is not optimally placed ($Q_1 \neq Q_2$), the probability of error becomes

$$P(E) = 0.5[P(1, 0) + P(0, 1)] \tag{48.16}$$

Receiver Sensitivity: p-i-n Detector

We are now in a position to calculate the sensitivity of a receiver using a p-i-n detector. Combining Eqs. (48.1) and (48.15), we find that the required *peak* signal current is

$$I_s = Q(\sigma_1 + \sigma_0) \tag{48.17}$$

where we assume the signal in the 0 state is identically zero and $S_1 = I_s$. The variance of the noise σ^2 is given by the sum of the circuit noise and the signal shot noise, Eq. (48.7).

$$\sigma^2 = \langle i^2 \rangle_{\text{ckt}} + \langle i^2 \rangle_{\text{sig}} = \langle i^2 \rangle_{\text{ckt}} + 2qI_s\mathfrak{S}_1B \tag{48.18}$$

The circuit noise for an FET front end is calculated from Eq. (48.3) and for an optimally biased bipolar front end by Eq. (48.5). Since the signal current equals I_s in the 1 state and 0 in the 0 state, the variances become

$$\sigma_0^2 = \langle i^2 \rangle_{\text{ckt}} \quad (48.19a)$$

and

$$\sigma_1^2 = \langle i^2 \rangle_{\text{ckt}} + 2qI_s \mathcal{F}_1 B \quad (48.19b)$$

Substituting Eqs. (48.19a) and (48.19b) into Eq. (48.17) gives

$$I_s = 2\sigma_0 Q + 2qQ^2 \mathcal{F}_1 B \quad (48.20)$$

The peak optical power is found from Eq. (48.1), and the sensitivity, measured in terms of the average power, is given by

$$\eta \bar{P}_s = \left(\frac{h\nu}{q} \right) [\sigma_0 Q + qQ^2 \mathcal{F}_1 B] \quad (\text{p-i-n}) \quad (48.21)$$

Under most circumstances, with a p-i-n detector, the second term in Eq. (48.21) is small compared to the first, leading to the commonly used expression for the p-i-n sensitivity

$$\bar{P}_s = \left(\frac{h\nu}{q} \right) Q \langle i^2 \rangle_{\text{ckt}}^{1/2} = \frac{1.24Q}{\lambda} \langle i^2 \rangle_{\text{ckt}}^{1/2} \quad (48.22)$$

where λ is the wavelength expressed in micrometers.

Receiver Sensitivity: Avalanche Photodiode Detector

For an APD receiver, the signal current is given by Eq. (48.2) and the variances of the noise in the two signal states become

$$\sigma_0^2 = \langle i^2 \rangle_{\text{ckt}} \quad (48.23a)$$

and

$$\sigma_1^2 = \langle i^2 \rangle_{\text{ckt}} + 2qI_s M^2 F(M) \mathcal{F}_1 B \quad (48.23b)$$

These relations neglect the effect of photodetector dark current and also assume the received signal is identically zero when a 0 is received. A more general account maybe found in Smith and Personick [1982]. Substituting these equations into Eq. (48.17) gives the result

$$\eta \bar{P}_s = \left(\frac{h\nu}{q} \right) \left[\frac{\sigma_0 Q}{M} + qQ^2 \mathcal{F}_1 B F(M) \right] \quad (48.24)$$

A plot of this expression vs. the gain of the APD, M , is shown in Fig. 48.4 for a receiver operating at 622 Mb/s [Tzeng, 1994]. For low gain, the sensitivity is seen to improve, reaching an optimum, and then declines for further increases in the gain. The initial improvement is associated with the amplification of the signal current by the APD, whereas the decrease at high gain results from the excess signal shot noise associated with the random nature of the avalanche process.

Receiver Sensitivity: Optical Pre-amplifier

A recent advance in optical fiber technology is the development of optical amplifiers. The most widely used is the Er-doped fiber amplifier EDFA (see Chapter 52 in this volume for a detailed discussion of

FIGURE 48.4 Sensitivity of an APD receiver at 622 Mb/s as a function of the APD gain.

FIGURE 48.5 Schematic diagram of an optical preamplifier.

optical amplifiers). One application of optical amplifiers is their use as an optical preamplifier preceding the optical receiver previously described. The optical preamplifier amplifies the received optical signal prior to detection by the photodetector. As with other types of amplifiers, optical amplifiers introduce noise resulting from spontaneous emission in the amplifying region. This type of noise is referred to as *amplified spontaneous emission* (ASE).

Figure 48.5 is a schematic of an optical preamplifier showing the important parameters defined as follows:

- η_{in} = coupling efficiency of transmission fiber to the optical amplifier
- η_{out} = coupling of optical amplifier to photodetector input including transmission loss of the optical filter
- η = detector efficiency
- G = small signal gain of the optical amplifier
- F_m = noise figure of the optical amplifier
- B_o = bandwidth of the optical filter, Hz
- B_e = electrical bandwidth of the receiver, Hz

The noise figure of the amplifier is defined as $2n_{sp}$ where n_{sp} is the spontaneous emission factor. See Chapter 52 on optical amplifiers in this volume for more detail.

Photocurrents

In receivers incorporating optical preamplifiers, p-i-n detectors are usually employed. For this case, the signal photocurrent is given by

$$I_s = \left(\frac{\eta q}{h\nu} \right) \eta_{in} \eta_{out} G P_s \quad (48.25)$$

and the photocurrent generated by the ASE is given by

$$I_{ASE} = F_m q \eta_{out} \eta (G - 1) B_o \quad (48.26)$$

Noise Sources

The photodetector behaves as a square law detector. The generated photocurrent, which is proportional to the square of the incident optical field, contains components proportional to signal* signal, ASE* ASE, and signal* ASE. Following the analysis of Olsson [1989], the components of the noise are given by

$$\sigma_{shot}^2 = 2q(I_s + I_{ASE})B_e \quad (48.27a)$$

$$\sigma_{spn-spn}^2 = \frac{1}{2} F_m^2 q^2 \eta_{out}^2 \eta^2 (G - 1)^2 (2B_o - B_e) B_e \quad (48.27b)$$

$$\begin{aligned} \sigma_{sig-spn}^2 &= [2qF_m \eta_{out} \eta (G - 1)] \left[\left(\frac{\eta q}{h\nu} \right) P_s \eta_{in} \eta_{out} G \right] B_e \\ &= 2q^2 F_m \eta_{in} \eta_{out}^2 \eta^2 G (G - 1) \left(\frac{1}{h\nu} \right) P_s B_e \end{aligned} \quad (48.27c)$$

The first term, S_{shot}^2 , is the shot noise generated by the amplified signal and ASE and contains a term proportional to the received signal. The second term, $S_{spn-spn}^2$, results from the ASE beating with itself in the detector. Since the bandwidth of the optical gain is large ($\sim 10^{12}$ Hz) compared to the signal bandwidth in common usage, the spectral width of the ASE is normally reduced by the use of an optical filter of bandwidth B_o . B_o can be reduced in principle until it approaches B_e . The problems of achieving a narrow optical filter bandwidth and of aligning the optical filter with the signal wavelength set the practical limit on B_o . The noise term $S_{spn-spn}^2$ is independent of the signal level and, hence, is present in both the 0 and 1 states of the signal.

The term $S_{sig-spn}^2$ results from the mixing of the signal and ASE fields. This noise term is proportional to the received optical signal power, and in an ideal system, when the received optical power is zero in the 0 state, $S_{sig-spn}^2 = 0$. The total noise associated with the 0 state, assuming zero power received, is given by

$$S_0^2 = S_{ckt}^2 + S_{shot}^2 (ASE) + S_{spn-spn}^2 \quad (48.28)$$

and for the 1 state the noise is given by

$$\sigma_1^2 = \sigma_{ckt}^2 + \sigma_{shot}^2 (ASE + \text{signal}) + \sigma_{spn-spn}^2 + \sigma_{sig-spn}^2 \quad (48.29)$$

The receiver sensitivity can be calculated by combining Eqs. (48.13) and (48.25–48.29), yielding

$$I_s = 2Q^2 \left[qB_e + qF_m \eta_{out} \eta (G - 1) B_e + \frac{\sigma_0}{Q} \right] \quad (48.30)$$

Typically, G is greater than or equal to 30 dB (1000), in which case the first term in brackets is negligible. Further, since $S_{spn-spn}^2$ varies as the square of the gain while S_{shot}^2 varies only as the first power of the gain and S_{ckt}^2 is independent of the gain,

$$\sigma_0^2 \approx \sigma_{spn-spn}^2 \quad (G \gg 1) \quad (48.31)$$

Substituting this limit gives

$$I_s = 2Q^2 \left\{ qF_m \eta_{\text{out}} \eta (G-1) B_e \left[1 + \frac{1}{Q} \left(\frac{B_o}{B_e} - \frac{1}{2} \right)^2 \right]^{\frac{1}{2}} \right\} \quad (48.32)$$

and the sensitivity measured in terms of the average received power incident on the optical amplifier in the limit of large gain is

$$\eta_{\text{in}} \bar{P}_s = Q^2 (h\nu) F_m B_e \left[1 + \frac{1}{Q} \left(\frac{B_o}{B_e} - \frac{1}{2} \right)^2 \right]^{\frac{1}{2}} \quad (48.33)$$

When the optical filter bandwidth is comparable to the electrical bandwidth (practical only at very high bit rates) and for very low BER ($Q \gg 1$), the limiting sensitivity becomes

$$\eta_{\text{in}} \bar{P}_s \approx Q^2 (h\nu) F_m B_e \quad (48.34)$$

When the bandwidth of the optical filter is large compared to the electrical bandwidth, Eq. (48.33) applies.

The value of the noise figure F_m depends on the detailed characteristics of the optical amplifier. Under ideal conditions of perfect inversion of the gain medium, $F_m = 2$. Typical values are somewhat higher. With an electrical bandwidth $B_e = B/2$, the limiting sensitivity for a receiver using an optical preamplifier is

$$\eta_{\text{in}} \bar{P}_s = Q^2 (h\nu) B \quad (48.35)$$

Sensitivity Limits

Quantum Limit. In the limit that the sensitivity is given by the statistics of the received photons which are characterized by a Poisson process, the ultimate sensitivity for a BER = 1 E-9 is 10 detected photons per bit received [Henry, 1985], which corresponds to

$$\eta \bar{P}_{\text{limit}} = 10(h\nu)B \quad (48.36)$$

Optical Amplifier Limit. With an optimized optical amplifier, the limiting sensitivity for BER = 1E-9 ($Q = 6$) is

$$\eta_{\text{in}} \bar{P}_{s\text{-opt.ampl}} = 36(h\nu)B \quad (48.37)$$

which is approximately four times the quantum limit. Demonstrated sensitivities are within a factor of three to four of this value at bit rates greater than 1 GB/s. See Park and Grandlund [1994] for a discussion of experimental results.

Practical Avalanche Photodiode Performance. The ultimate receiver sensitivity achievable with an APD is a function of the circuit noise and the excess noise factor associated with the avalanche process. Because the excess noise factor increases as the avalanche gain is increased, the optimum gain is in the range of 10–30 for existing APDs and is significantly below the gains used in optically preamplified receivers. The achievable sensitivity is accordingly poorer than the limit for an optical preamp, being in the range of a few hundred to as much as several thousand photons per bit and, hence, between a factor of 10–100 worse than the quantum limit.

Practical p-i-n Performance. In the absence of a gain mechanism, either avalanche or optical amplification, the receiver sensitivity is determined by the circuit noise, hence, depending on the design of the receiver front end. Typically, the sensitivity of a p-i-n-based receiver will be ≈ 10 dB poorer than an APD-based receiver and, hence, typically a few thousand photons per bit.

Defining Terms

Amplified spontaneous emission (ASE): The fundamental source of noise in optical amplifiers.

Avalanche photodiode (APD): A photodiode with internal current gain resulting from impact ionization.

Excess noise factor (ENF): A measure of the amount by which the short noise of an APD exceeds that of an ideal current amplifier.

Front end (FN): The input stage of the electronic amplifier of an optical receiver.

Integrating front end (IFE): A type of front end with limited bandwidth which integrates the received signal; requires subsequent equalization to avoid intersymbol interference.

Transimpedance front end (TFE): A type of front end which acts as a current to voltage converter; usually does not require equalization.

Further Information

This section has focused on direct detection of digital signals, which constitute the most widely used format in optical communication systems. Coherent optical systems have been studied for some time but have not yet found practical application. A discussion of this technology and the associated receiver sensitivities may be found in [Chapter 53](#) on coherent systems in this volume. Another application of optical fiber technology is in the distribution of analog video, which is being employed by community antenna television (CATV) distribution companies. A discussion of the sensitivity of analog receivers may be found in Smith and Personick [1982].

Bell Communications Research

49.1 Introduction

In recent years, the state of the art of optical fiber technology has progressed to where the achievable attenuation levels for the fibers are very near the limitations due to Rayleigh scattering. As a result, optical fibers, and particularly the single-mode fibers that are used in today's communications systems, can be routinely fabricated with attenuation levels below 0.5 dB/km at a wavelength of 1300 nm and 0.25 dB/km at 1550 nm. Employing these fibers in optical communications systems requires precise jointing devices such as connectors and splices. Considering the small size of the fiber cores, less than 10 μm in diameter for single mode and 100 μm for multimode fibers, it is not surprising that these interconnecting devices can easily introduce significant optical losses. Furthermore, since single-mode fibers have practically unlimited bandwidth, it is also not surprising that they have become the choice for optical communications applications. To provide low-loss connectors and splices for these single-mode fibers, reliable and cost-effective alignment accuracies in the submicrometer range are required.

This chapter will review the fundamental technology that is presently used for optical connectors and splices. In particular, since single-mode fibers dominate optical communications systems and also require the greatest precision and performance, we will focus mainly on the jointing of these fibers. However, for completeness, we will also briefly review multimode fiber jointing technology as well.

Before reviewing the technology, we should define the implied differences between an optical connector and a splice. The term *connector* is commonly used when referring to the jointing of two optical fibers in a manner that not only permits but also anticipates the unjointing, or unconnecting, through the design intent. Optical connectors are commonly used for terminating components, system configuration and reconfiguration, testing, and maintenance. In contrast, the term *splice* is commonly used when referring to the jointing of two optical fibers in a manner that does not lend itself to unjointing.

There are two types of splices: mechanical splices that join two butt-ended fibers and use index matching material between their endfaces, and fusion splices where the two fibers are heated to just below their melting point and are pressed together to form a permanent joint. Splices are commonly used when the total optical fiber span length can be realized only by the concatenation of shorter sections of fiber, and also for repairing severed fiber/cables.

49.2 Optical Fiber Coupling Theory

The optical forward coupling efficiency of a connector or splice, that is, the insertion loss, and the optical backward coupling efficiency (reflectance) are the main optical performance criteria for optical fiber joints, and, therefore, these two parameters are used to evaluate the joint’s optical performance over various climatic and environmental conditions [Miller, Mettler, and White, 1986].

The factors affecting the optical coupling efficiency of optical fiber joints can be divided into two groups, extrinsic and intrinsic factors (Table 49.1).

Factors extrinsic to the optical fiber, such as lateral or transverse offset between the fiber cores, longitudinal offset (endface separation), and angular misalignment (tilt), are directly influenced by the techniques used to join the fibers. In contrast, intrinsic factors are directly related to the particular properties of the two optical fibers that are joined. In the case of single-mode fibers, the important intrinsic factor is the fiber’s mode field diameter. With multimode fibers, the intrinsic factors are the core diameter and numerical aperture (NA). The fiber’s core concentricity and outside diameter are also commonly referred to as intrinsic factors, but practical connectors and splices must be designed to accommodate variations in these two parameters.

The effect that these factors have on coupling efficiency may also depend on the characteristics of the optical source, and in the case of multimode fiber joints, on the relative location of the joint in the optical path. For example, in the case of an incoherent optical source such as a light emitting diode (LED), the mode power distribution (MPD) along a continuous fiber’s path largely depends on the length and curvature of the fiber. With these sources and fibers, the effect a particular offset will have on the coupling efficiency will decrease until a steady-state mode distribution is realized. Because of these MPD effects, a much practiced method of evaluating multimode fiber joints is to use an over-moded launch condition (uniform) followed by a mode filter that selectively filters the higher-ordered modes, thereby establishing a steady-state MPD condition. Characterizing multimode fiber joints in this manner eliminates the uncertainty of different MPD effects. Of course, in use, the coupling efficiency of the connector or splice is dependent on the particular MPD (a function of the optical source and location along the optical path). In the case of single-fiber joints, it is only necessary that the fiber is operated in the single-mode wavelength regime.

Multimode Fiber Joints

Various experiments [Chu and McCormick, 1978] and analytical models have been used to quantify the effects that extrinsic factors have on coupling efficiencies for butt-jointed multimode fibers. Based on these studies, we have plotted (Fig. 49.1) the coupling loss as a function of normalized lateral, longitudinal, and angular offset for graded-index multimode fibers.

TABLE 49.1 Factors Affecting Coupling Efficiency

Extrinsic factors:
Lateral fiber cone offset
Longitudinal offset
Angular misalignment
Reflections
Intrinsic factors:
Mismatch in fiber core diameters (mode field diameters)
Mismatch in index profiles

FIGURE 49.1 Coupling loss vs. offsets for butt-jointed graded-index multimode fibers (where a is the fiber's core radius and d is the offset in micrometers).

FIGURE 49.2 Coupling loss vs. mismatches in numerical aperture NA and fiber core radius a for graded-index multimode fiber having a steady-state MPD. The subscripts r and t represent the receiving and transmitting fibers.

In Fig. 49.1, the coupling losses for various offsets are plotted for both a uniform MPD as well as a steady-state MPD. From these curves, it can be seen that as the quality of the alignments improve, the effect of the presence of higher order modes diminishes. For example, today's connectors and splices have high control on angular (tilt) and longitudinal (gap) offsets, and, as a result, the coupling loss is mainly due to lateral offset. Therefore, as can be seen in Fig. 49.1, a connection of a typical graded-index multimode fiber having a 50-mm core diameter and having a lateral offset of about $10 \mu\text{m}$ has a coupling loss of 0.25 dB with a steady-state MPD, whereas with a uniform MPD the same joint has a loss of 0.5 dB. It is, therefore, very important, in the case of multimode fibers, that the particular MPD be known at the site of each joint for correct estimation of the loss incurred in the system. It should also be pointed out that due to cross-coupling effects, the offsets at a joint can also change the MPD directly after the joint. Thus, in summary, because of the many factors that can change the MPD in a multimode fiber, such as optical launch conditions, offsets at joints, fiber length and deployment conditions, mode mixing, and differential mode attenuation of the particular fibers, there is no unique coupling or insertion loss for multimode fiber joints that is based only on their physical fiber alignment. It therefore is very important for the system designer to analyze the system for these factors and then make the appropriate assignment for expected loss of the connector and splices.

Intrinsic factors can also have a large effect on multimode fiber joints. Therefore, when evaluating the joint loss of multimode fiber joints one also must consider the characteristics of the fibers on either side of the joint, as well as the direction of propagation of the optical power through the joint. Again, various experiments and analytical models have been used to quantify these effects. Based on these studies, the dependence of the coupling loss on mismatches in numerical apertures and core radii is summarized in Fig. 49.2.

As can be seen in Fig. 49.2, we have plotted the coupling loss for the cases when the transmitting fiber has the larger core radius and larger NA. For the opposite cases, there is no loss incurred at the joints. Referring to Fig. 49.2, for a mismatch in core diameters of 48 and $52 \mu\text{m}$, the expected loss is about

FIGURE 49.3 Schematic representation of a fiber butt joint having lateral and longitudinal offset and angular misalignment.

0.25 dB, and for a mismatch in numerical aperture of 0.20–0.23 it is about 0.35 dB. These values are significant when compared to expected loss due solely to extrinsic alignment inaccuracies and are also propagation direction dependent. Therefore, the performance of multimode fiber connectors and splices are very deployment dependent, requiring a complete understanding of the characteristics of the optical path before expected loss values can be calculated with confidence.

Single-Mode Fiber Joints

In the case of single-mode fiber joints, it has been shown that the fields of single-mode fibers being used today are nearly Gaussian, particularly those designed for use at a wavelength of 1310 nm. Therefore, the coupling losses for the joints can be calculated by evaluating the coupling between two misaligned Gaussian beams [Marcuse, 1977]. Based on this model, the following general formula has been developed [Nemoto and Makimoto, 1979] for calculating the insertion loss (IL) between two single-mode fibers that have equal or unequal mode field diameters (an intrinsic factor) and lateral, longitudinal, and angular offsets, as well as reflections (extrinsic factors) as defined in Fig. 49.3:

$$IL = -10 \log \left[\left(\frac{16n_f^2 n_g^2}{(n_f + n_g)^4} \right) \frac{4\sigma}{q} \exp\left(-\frac{\rho\mu}{q}\right) \right] \text{ dB} \quad (49.1)$$

where

$$\begin{aligned} \rho &= 0.5(Kw_t)^2; & q &= G^2 + (\sigma + 1)^2 \\ \mu &= (\sigma + 1)F^2 + 2\sigma FG \sin q + \sigma(G^2 + \sigma + 1) \sin^2 \theta \\ F &= \frac{2x}{Kw_t}; & G &= \frac{2z}{Kw_t} \\ \sigma &= \left(\frac{w_r}{w_t}\right)^2; & K &= \frac{2pn_g}{\lambda} \end{aligned} \quad (49.1)$$

where

- n_f, n_g = refractive indices of the fiber and the medium between the fibers, respectively
- w_t, w_r = mode field radii of the transmitting and receiving fibers, respectively
- λ = operating wavelength
- x, z = lateral and longitudinal offset, respectively
- σ = angular misalignment

Although the fields of dispersion-shifted fibers (fibers having minimum dispersion near 1550 nm) are not truly Gaussian, this general formula is still applicable, particularly for the small offsets and misalignments that are required by connectors and splices designed for communication applications (<0.5 dB). In the preceding general formula, terms in the first parentheses, inside the square bracket, account for the loss due to reflection at two fiber/gap interfaces, which can be as high as 0.32 dB for air as a gap material. If fiber core-to-core contact is established in a connector or perfect index matching is used in a mechanical splice, this loss reduces to zero. The formula, however, does not account for the loss variation due to interference effects caused by multiple beam interference that may exist in joints with fiber endface separation [Wagner and Sandahl, 1982]. Even though high-performance connectors are designed for fiber core-to-core contact and therefore should not be subject to reflections caused by an air gap, the lack of workable standards and manufacturing tolerances may result in endface separation. Even if the end separation is less than a micrometer, it can still have severe results on insertion loss. Although index matching material is used in mechanical splices, the refractive index of the material is temperature dependent and, therefore, the resulting index mismatches can also have an impact on insertion loss. The effects from multiple beam interference and its impact on connector and splice performance are discussed in a later section.

The preceding general formula can be reduced to determine the coupling loss due only to a mode field diameter mismatch (intrinsic factor). Assuming no extrinsic factors, and assuming core-to-core contact, the formula reduces to

$$\text{coupling loss} = -10 \log \left[4 \left(\frac{w_t}{w_r} + \frac{w_r}{w_t} \right)^{-2} \right] \text{dB} \quad (49.2)$$

Using this expression, the loss due to a 10% mismatch in mode field diameters, typical for today's commercial fibers and with no other factors present, is calculated to be 0.05 dB. Generally, to control the fiber's cutoff wavelength and zero dispersion wavelength, the mode field diameters of communications single-mode fibers are usually within 10%. A typical requirement range for the mode field diameter of **dispersion-unshifted single-mode fiber** is from 8.8 to 9.5 μm . It can also be seen in the preceding expression that, contrary to multimode fiber joints, the loss of a single-mode fiber joint having mode field diameter mismatches is independent of the direction of propagation through the joint. In Fig. 49.4, the coupling loss between two fibers having different mode field radii is plotted as a function ratio of transmitting fiber's radii to the receiving fiber's radii.

Although for a given fiber type and design the mode field diameters are usually held to within 10%, the loss in Fig. 49.4 is plotted for ratios from 0.6 to 1.54. This large range is needed to describe the intrinsic loss for fiber joints between dispersion-shifted and **dispersion-unshifted fibers**. This ensemble of fibers may be experienced when and if dispersion-shifted fibers become prevalent in future fiber deployments. It is common to see references that the mode field diameter of dispersion-shifted fiber is similar to that

FIGURE 49.4 Plot of coupling loss vs. ratio of mode field radii.

TABLE 49.2 Mode Field Diameters of Different Fiber Types

Fiber Type	Mode Field Diameter (wavelength, 1310 nm)	Mode Field Diameter (wavelength, 1550 nm)
Dispersion-unshifted, mm	9.3	10.5
Dispersion-shifted, mm	6.5	8.1

FIGURE 49.5 Plot of coupling loss vs. lateral offset for various fiber type combinations.

of today's fiber of choice, 1310-nm optimized dispersion-unshifted fiber. Although this is true, if one uses the intended wavelength of propagation, 1550-nm for dispersion-shifted and 1310-nm for unshifted fibers, it becomes important to look at the mode field diameters at similar wavelengths. This condition can exist when these different fiber types meet in a connector joint. Furthermore, both wavelengths, 1310 and 1550 nm, can be experienced. Table 49.2 summarizes some typical mode field diameters.

It is noteworthy to look at the intrinsic loss for 1310 nm propagation. The diameter ratios for this wavelength of propagation are about 0.70 or 1.43, depending on which is the receiving fiber. As Fig. 49.4 shows, the intrinsic loss due only to mode field diameter mismatch is 0.55 dB. For the case of 1550-nm propagation, the ratios are 0.77 and 1.30, and the loss due to mode field diameter mismatch is 0.30 dB. Of course, this loss must be added to any extrinsic loss due to existing misalignments.

Continuing, we can also use this general formula to analyze the types of alignments that are necessary for high-performance connectors and splices. As previously stated, angular misalignments and longitudinal offsets (endface separation) are more easily minimized, in connectors and splices, than lateral offsets. Therefore, the main objective in connector and splice design is controlling the lateral offset between the adjacent fibers. For this reason, the preceding general formula can be reduced to the following expression that describes the dependence of insertion loss on lateral offset:

$$\text{insertion loss} = 4.343 \left(\frac{x}{w} \right)^2 \text{ dB} \quad (49.3)$$

This relationship assumes that identical fibers are in the joint, which is a valid assumption considering the small variation in mode field diameter in the manufacture of today's fibers and its effect on coupling loss. It also assumes no reflections, that is, zero end separation or perfect index matching. This expression has been used to plot insertion loss vs. lateral offset in Fig. 49.5 for both dispersion-shifted (DS) and unshifted (US) fibers at both 1310 and 1550 nm wavelengths. Also plotted (using the preceding general formula) are losses for joints between these two different types of fibers. It should be noted that Eq. (49.3) has been verified in numerous experiments [Kummer and Fleming, 1982].

In Fig. 49.5, coupling loss (insertion loss) is plotted as a function of lateral offset between various combinations of fiber types. Curve A represents a joint between dispersion-shifted and dispersion-unshifted fibers, and curve B represents a joint between two dispersion-shifted fibers; both curves are for a propagation wavelength of 1310 nm. Also plotted is curve C, which represents a joint between two

TABLE 49.3 Insertion Loss for 1.5 μm Lateral Offset

	US/USFibers (dB)	DS/DSFibers (dB)	DS/US Fibers (dB)
1310 nm(λ)	0.5	0.8	1.1
1310 nm(λ)	0.3	0.6	0.7

dispersion-unshifted fibers, and curve D, a joint between a dispersion-shifted and dispersion-unshifted fibers; both of these curves are for a propagation wavelength of 1550 nm. Finally, joints between two dispersion-shifted and two dispersion-unshifted fibers, both for a wavelength of 1550 nm, are shown by curves E and F, respectively.

A typical specification for today's connectors is a maximum loss of 0.5 dB and an average loss of 0.25 dB. As can be seen, a lateral alignment of 1.5 μm is required for 0.5 dB and about 1 μm for 0.25 loss, using today's standard dispersion-unshifted fibers and an operating wavelength of 1310 nm (curve C.) The information in Fig. 49.4 can then be used to predict the performance of today's connectors (connectors having 1.5 and 1 μm lateral offsets) with the various combinations of fiber types and operating wavelengths. Table 49.3 summarizes these losses for a 1.5 μm lateral offset.

The preceding discussion is based on the fact that today's insertion loss specifications for high-performance connectors, dominated by lateral offsets, are usually a maximum of 0.5 dB and show averages of 0.25 dB that imply lateral offsets of 1.5 and 1 μm , respectively. In addition, to minimize reflections and insertion loss, the connectors must achieve fiber core-to-core contact throughout the operating range. How this submicrometer control is achieved in these butt-joint ferrule connectors is discussed in a later section.

Reflectance Factors

Reflectance is the ratio of reflected power to incident power at a fiber joint, expressed in decibels. Reflectance can, therefore, be defined by the following expression:

$$\text{reflectance} = 10 \log \left(\frac{\text{reflected power}}{\text{incident power}} \right) \text{ dB} \quad (49.4)$$

Historically, insertion loss has been the only performance criterion for connectors and splices. Recently, it has been recognized that a fiber joint's reflectance performance is also important because optical reflections from refractive index discontinuities in the fiber path can adversely affect the performance of direct-detection, coherent-detection, and analog lightwave communications systems, particularly in single-mode fiber applications [Mazurczyk, 1981]. In cases having multiple reflectors in the fiber path (such as multiple connectors and splices), high reflectance may also result in the interferometric conversion of laser phase noise to intensity noise, resulting in system degradations and/or measurement limitations. Optical feedback may also cause detrimental changes in the performance characteristics of active components, resulting in further system degradations and measurement limitations. For example, optical feedback into a laser cavity can increase mode-partition noise and add noise caused by reflection-induced power fluctuations. In optical amplifiers, reflections can cause lasing or multiple reflection noise, thereby severely affecting amplifier characteristics, and drastically restricting the amounts of amplifier gain and/or reflectance that can be allowed in high-speed systems.

Thus, besides insertion loss, the reflectance of optical fiber connectors and splices has become an important optical performance criterion. In this regard, requirements for reflectance are not only routinely specified but are presently becoming more stringent, changing from the minimum of -30 to -40 dB.

Connectors

Since high-performance connectors are usually designed for **physical core-to-core contact** to reduce insertion loss, optically transparent fiber joints might be expected (effectively an optically continuous length of fiber). To understand why physical contact between fiber endfaces does not yet result in reflectances that are equivalent to a continuous fiber, we recall that when bulk silica glass is polished, a

FIGURE 49.6 The model of (a) a cleaved and (b) a polished fiber endface depicting the high-index layer on the polished endface.

FIGURE 49.7 Schematic representation of two beam interference of a fiber joint having a high index-layer.

FIGURE 49.8 A nonflat, polished fiber endface.

thin layer with a refractive index higher than the bulk glass is usually formed at the polished surface [Rayleigh, 1937]. This increase in refractive index is the result of compaction of the fiber endface material (increase in density) caused by the mechanics of the polishing process. Almost all connectors use polished endfaces. This polishing-induced increase in the refractive index of the fiber endface creates an interior index discontinuity parallel to the fiber endface. This index discontinuity occurs at a fraction of a micrometer from the fiber endface, and even when fiber endface contact is achieved, these two index discontinuities within the fibers result in increased reflectance. Figure 49.6 shows a model of the endface for the **cleaved fiber** [Fig. 49.6(a)] and for the polished fiber [Fig. 49.6(b)].

The refractive index of the bulk fiber material (here the small difference between the core and cladding index is neglected), the gap material (generally air), and the index of the thin high-index layer are denoted by n , n_1 , and n_2 , respectively. The thickness of the high-index layer is denoted by h .

When physical contact between two polished fiber endfaces occurs, even though the interface between the fiber endface and the gap material disappears, two index discontinuities separated by a distance $2h$ still remain near the joint (as shown in Fig. 49.7).

These two interfaces can cause a significant degradation in the connector's reflectance performance while only a negligible increase in insertion loss. This discussion assumes that the fiber endfaces are polished flat. Many of the commercially available ferrule-type physical-contact (PC) connectors use nonflat endfaces, as shown in Fig. 49.8.

Usually, the fiber endface is polished spherically convex, as shown in Fig. 49.8. The reason for using a nonflat fiber endface is to ensure fiber core-to-core contact. Because of point or line contact between the two contacting spherical surfaces, the axial compressive spring force in the connector body provides the necessary force to cause **controlled elastic deformation** of the fiber/ferrule endface, thereby achieving fiber endface contact. Thus, the model presented in Fig. 49.7 still holds for such *nonflat* fiber endfaces, and the reflectance performance is still limited by the two interfaces formed by the high-index layers previously described.

Furthermore, since the refractive index n_2 and the thickness h of the high-index layer at the polished fiber endface are dependent on various polishing conditions, such as the polishing material, polishing pressure, grit size of the polishing material, etc., the reflectance of PC connectors depends critically on the polishing technique. For example, polishing with diamond with grit size of 1 or 3 μm or with 1 μm grit size aluminum-oxide coated on a polyester sheet produces a smooth fiber endface having a high-index layer of almost 0.09 μm thick with the refractive index of about 1.54 compared 1.47 for bulk fiber glass. With such a layer present on a fiber endface, a theoretical value of approximately -30 dB is predicted for the reflectance of such a PC connector. Experimentally, -34 dB has been measured for similar connectors, indicating good agreement with theoretical predictions.

When it was recently realized that it was possible to obtain better reflectance performance by using enhanced polishing techniques to significantly minimize the thickness of the compacted endface layer, the performance for some connectors changed from -30 to -40 dB. However, some of these techniques may also produce fiber endfaces that are recessed from the ceramic ferrule endface, therefore making it more difficult to achieve fiber core contact in the connector. The reflectance performance also depends on various environmental conditions. Some conditions may produce an air gap in connectors designed for physical contact, resulting in multiple beam reflections.

Splices

Recall that there are two types of fiber splices: fusion splices and mechanical splices. Fusion of the two fibers together, with respect to reflectance, results in an optically transparent length of fiber. With these types of splices it is very difficult to measure any level of reflectance. On the other hand, because the index matching material used for mechanical splices is temperature dependent, mechanical splices can exhibit wide ranges of reflectance. It is not uncommon for a mechanical splice, cleaved perpendicular fiber endfaces, to have reflectances between -25 and -45 dB over a temperature range of -40°C and 80°C . In order to avoid this temperature dependence, cleaved angled fiber endfaces have been recently employed. With endface angles between 5° and 10° , and index matching material, mechanical splices with reflectance performances equal to fusion splices can be easily achieved. Furthermore, it can be theoretically shown that the fibers having angled endfaces can be joined within the splice hardware without regard to ensuring that the endfaces are parallel.

49.3 Multibeam Interference (MBI) Theory

MBI Effects on Transmission

The previous sections discussed factors that cause insertion loss and reflectance in the butt coupling of two single-mode fibers. It was shown that as long as fiber endface contact is achieved with connectors or perfect index matching is achieved with splices, the dominating factor that causes insertion loss in typical high-performance connectors and splices is lateral offset. Furthermore, as the connector's reflectance performance became an important performance criterion, it became a requirement that fiber core-to-core contact be achieved in order to minimize both insertion loss and reflectance. Consequently, it is necessary to ensure fiber endface contact over the expected environmental and climatic conditions. When contact is lost, an air gap is created between the fibers and two glass/air interfaces are formed. The Fresnel reflection at the two interfaces (here, for the sake of clarity, cleaved fiber endfaces are assumed) results in an additional insertion loss of 0.32 dB, as shown by the following formula:

$$\text{insertion loss} = -10 \log(1 - 2R) \text{ dB}$$

where

$$R = \text{Fresnel reflection} = \left(\frac{n_f - n_g}{n_f + n_g} \right)^2 \quad (49.5)$$

FIGURE 49.9 Multiple beam interference model for an air gap between two single-mode fibers.

FIGURE 49.10 Plot of insertion loss vs. endface separation of a butt-joint connector.

Although an increase in insertion loss of 0.32 dB nearly doubles the typical performance of high-performance connectors, it is even more important that the two adjacent fibers and the air gap in the connection form a Fabry–Perot etalon. The resulting multiple beam interference, from this gap, can cause additional increases in insertion loss. In analyzing this effect, consider the two beams, as shown in Fig. 49.9.

Figure 49.9 represents an air gap between two fiber endfaces. The two beams shown in Fig. 49.9 will interfere with each other both constructively and destructively, depending on the physical path length difference $2x$. The effect that this two-beam interference can have on the insertion loss performance of the connector can be quite severe. The following expression can be used to evaluate the effect of this multiple beam interference for the small end separations that unfortunately might develop in some high-performance connectors. In cases having larger end separation (not applicable to connectors or splices), it is necessary to include the effects of the coherence length of the optical source, aperturing of the fiber core, and diffraction of the emitted beam.

$$L = -10 \log \left[1 - 2R \left(1 - \cos \left(\frac{4\pi n_g s}{l} \right) \right) \right] \text{dB}$$

where

$$R = \left(\frac{n_g - n_f}{n_g + n_f} \right)^2 \tag{49.6}$$

This expression was used to plot insertion loss vs. end separation shown in Fig. 49.10. As shown, the insertion loss is highly dependent on the fiber endface separation x , and as a result, the insertion loss can increase by almost 0.7 dB for just a submicrometer air gap. When the realistic case of a polished connector is considered, the presence of a polishing-induced high-index layer on the fiber endface can increase the peak-to-peak variation in insertion loss from 0.7 dB to as much as 1.1 dB [Shah, Young,

FIGURE 49.11 Schematic representation of two-beam interference of a fiber joint having cleaved fiber endfaces.

and Curtis, 1987]. For a performance level of 0.5 dB, such large loss variations are clearly not acceptable and, therefore, must be avoided.

MBI Effects on Reflectance

Next, we consider the effect of multiple beam interference on reflectance performance. In analyzing this effect, consider the two reflected beams shown in Fig. 49.11.

We begin by analyzing the reflectance of a fiber butt joint that has fiber endface separation without index matching, an air gap. This type of fiber joint results in two fiber/air interfaces, and the reflectance is caused by the resulting Fresnel reflections. Again, in cases that have a large air gap, with reference to the coherence length of the optical source, multiple-beam interference effects can be neglected and the following expression can be used to calculate a reflectance of -11.4 dB:

$$\text{reflectance} = 10 \log(2R) \text{dB}$$

where

$$R = \left(\frac{n_g - n_f}{n_g + n_f} \right)^2 \tag{49.7}$$

where

- n_g = refractive index of gap
- n_f = refractive index of fiber

Even though a reflectance level of -11.4 dB is much greater than today's typical performance requirement of <-40 dB, interference effects can occur with air-gap joints that are even more of a concern. Referring to Fig. 49.11, the two reflected beams shown can interfere with each other both constructively and destructively depending on the physical path length difference x , and the effect that this two-beam interference can have on the reflectance performance of the connector can be quite severe. Figure 49.12 illustrates the results of an often verified theoretical analysis.

As Fig. 49.12 shows, a large dependence exists on the fiber endface separation x , and as a result, the reflectance can vary from -8.5 dB to $-\infty$ within a quarter-wavelength change in separation. Since the reflectance at its lowest value is an extremely sensitive function of air gap (asymptotic), its average value tends to be very close to the largest reflectance value, -8.5 dB for the case shown in Fig. 49.11. As previously discussed, a large change in the insertion loss (around 0.7 dB for cleaved endfaces) will simultaneously occur. Thus, when any air gap exists, the connector reflectance performance usually will be severely degraded and approach -8.5 dB, as compared to the extremely low reflectance when fiber endface contact is achieved.

In the case of the polished fiber endfaces, Fig. 49.13 is a schematic of the two-beam reflection model when a high-index layer exists on both fiber endfaces and physical contact between fiber endfaces is achieved. As Fig. 49.13 shows, the two-beam reflection model used in Fig. 49.11 can still be applied to determine the reflectance performance of the connection between two polished fiber endfaces under physical contact.

FIGURE 49.12 Theoretical plot of reflectance vs. endface separation for two cleaved fiber endfaces.

FIGURE 49.13 Schematic representation of two-beam interference of a fiber joint having a high-index layer.

FIGURE 49.14 Reflectance vs. high-index layer thickness for index of 1.54.

The amplitudes and relative phase-shifts of the two beams reflected from the polishing induced index discontinuities (shown in Fig. 49.13) are directly determined by the refractive index of the polishing-induced layer n_2 and the total thickness of this layer $2h$, thereby determining the connector's reflectance performance. Assuming the refractive index of the layer is 1.54, the reflectance performance can be calculated as a function of the total thickness $2h$. As Fig. 49.14 shows, the reflectance increases from $-\infty$ to -40 dB as the layer thickness increases from 0 to $0.0075 \mu\text{m}$ (total thickness is $0.015 \mu\text{m}$).

The reflectance attains its maximum value of about -21 dB for a layer thickness of $0.1 \mu\text{m}$ (total thickness is $0.2 \mu\text{m}$), for a wavelength of 1310 nm , and then decreases with further increase in layer thickness. As Fig. 49.14 shows, reflectances of -30 , -40 , and -60 dB require polishing techniques that result in a layer thickness of 0.009 , 0.0075 , and $0.00075 \mu\text{m}$, respectively.

Since physical contact may be lost due to environmental factors such as temperature changes and/or due to variations in fiber endface profiles resulting in an air gap at the joint, further analysis of the

FIGURE 49.15 Air-gap joint with two polished fibers having high-index layers.

FIGURE 49.16 Reflectance vs. endface separation for three different polishing procedures: -60, -40, and -30 dB; type 1, type 2, and type 3, respectively.

interference effects is required. Using the model in Fig. 49.15, three types of plugs, polished with different polishing procedures (different high-index layer thickness), are considered.

The hypothetical plugs are such that under physical contact condition, the connector reflectance values are -60, -40, and -30 dB, respectively. It is assumed that the index of refraction of the high index layer is 1.54 and that the plugs have different layer thicknesses that yield different reflectance performance.

The reflectances of each of these joints plotted as a function of air gap between the fiber endfaces at a wavelength of 1310 nm are shown in Fig. 49.16.

The plot is an expanded view of the region near zero endface separation showing a rapid asymptotic decrease in reflectance from its value at physical contact to $-\infty$ dB at a small nonzero separation. This effect is not consistent with the cleaved fiber endfaces, where the first reflectance minimum occurs at physical contact. The separations for minimum reflectance for the three plugs are 0.00038, 0.0056, and 0.0385 μm , respectively. Beyond these separations, the reflectance again increases. Thus, for polished fiber endfaces, a situation exists wherein the reflectance performance actually improves within a small range of nonzero endface separation.

In summary, excellent reflectance performance can be achieved with single-mode fiber, physical-contact connectors when appropriate endface polishing techniques are used. In particular, with the enhanced polishing techniques that have been recently developed, reflectance performance of <-40 dB can be routinely obtained, provided fiber endface contact is maintained. However, if the fiber/ferrule endface polishing techniques are not fully under control, the performance of physical contact connectors may not be maintained over all environmental conditions or with random intermating of connectors using different endface polishing treatments.

FIGURE 49.17 Schematic of an expanded-beam type optical fiber connector.

49.4 Connector Design Aspects

Introduction (Types of Connectors)

There are two types of connector designs that have received attention: the expanded-beam type and the butt-joint connector. The expanded-beam connectors have not yet found acceptance in communications systems, and are unlikely to find a niche (based on past results); therefore, this chapter does not discuss them in detail. However, for the sake of completeness, we will briefly describe the philosophy of this type of connector design.

The goal of the expanded-beam connector is to make the connector more tolerant to lateral alignment inaccuracies. To accomplish this, the fibers are terminated with a collimating/focusing element (lenses, as shown in Fig. 49.17) that expands and collimates the beam, thereby facilitating connecting and disconnecting [Nica and Tholen, 1981].

Initially, it appears that the expanded-beam connector has a large advantage over the butt coupling of fibers. However, there are aspects of the design that require the same degree of precision alignment. Although it is a fact that the expanded and collimated beam is more tolerant to lateral offsets, angular misalignments of the collimated beam, even as small as a few arc-seconds, can result in large insertion losses. These angular misalignments of the expanded beam result in a lateral displacement of the focus point, resulting in high coupling losses between the fiber and lens. Consequently, the fiber and lens must be aligned to the same submicrometer tolerances that are required in butt coupling of the fibers. Furthermore, to avoid spherical aberrations, and the resulting wavelength dependency of insertion loss, aspheric lenses must be used. Because of these concerns, and the general complexity of the designs, expanded-beam connectors have yet to find general acceptance in communications systems.

Communications systems, both multimode and single-mode fiber systems, have successfully used butt-joint connectors since the very first applications in the mid-1970s. Furthermore, despite the submicrometer alignment tolerances required, more than 30 million butt-joint connectors have been manufactured and deployed. This chapter focuses on the cylindrical-ferrule, physical-contact, butt-joint connectors that are the choice for optical communications systems. Two popular versions of these connectors, bayonet-lock fastened and push/pull snap-lock fastened are shown in Figs. 49.18 and 49.19, respectively.

Factors Contributing to Insertion Loss

Minimizing the lateral offsets between butt-coupled fibers and achieving fiber core-to-core contact are the two most challenging aspects of designing high-performance single-mode fiber connectors. The model in Fig. 49.20 shows the major inaccuracies encountered in minimizing the centering of the fiber's optical field within a single-mode fiber ferrule.

FIGURE 49.18 Bayonet-lock fastened cylindrical ferrule ST type connector.

FIGURE 49.19 Push/pull snap-lock fastened cylindrical ferrule SC type connector.

FIGURE 49.20 Model showing inaccuracies encountered in assembling a connector ferrule.

In analyzing the model, the first consideration is the quality of the fiber. As Fig. 49.20 shows, the axial offsets between the geometric center of the fiber and the fiber core center (optical center of the mode field diameter), and the clearance between the ferrule's hole and the outside diameter of the fiber, are major contributors to the final quality of the connector ferrule assembly (the lateral offset between the reference surface center of the ferrule and the fiber core).

The contributions from the physical dimensions of the ferrule must be also considered. Similarly to the fiber, fabrication of the connector ferrule results in additional inaccuracies that must be accommodated in the connector design. The outside diameter of the ferrule will vary, as will the hole diameter and the offset between the hole center and the reference surface center. As can be seen in Fig. 49.20, the offset that must be minimized is the offset between the fiber core center and the reference surface center. Recall that when two single-mode fibers are butt coupled, in order to achieve insertion losses <0.25 dB, the total lateral offset should be less than $1 \mu\text{m}$.

Statistical analyses of the inaccuracies shown in Fig. 49.20, such as Monte Carlo simulations, have been carried out to quantify the tolerances required for a specific optical performance [Young, 1984].

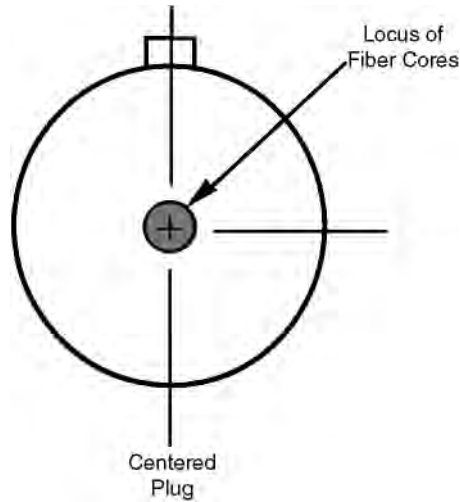

FIGURE 49.21 Ferrule having fiber cores centered to required tolerance.

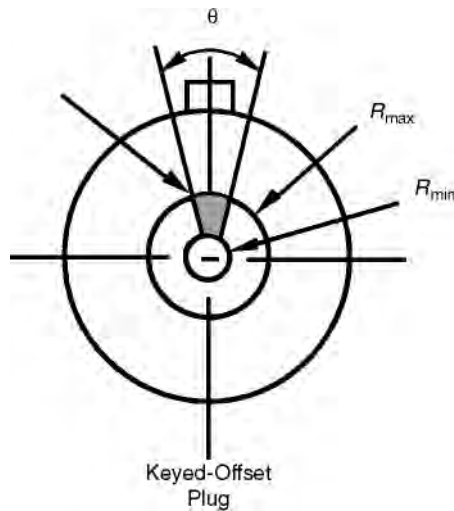

FIGURE 49.22 Model of a performance keyed ferrule.

These statistical analyses have also been experimentally verified. First, to achieve total lateral offsets of $<1 \mu\text{m}$, the diametral clearance between the hole in the ferrule and the fiber must also be $<1 \mu\text{m}$.

To more fully understand the difficulty in analyzing the required lateral offsets in the ferrule assembly, two popular ferrule assembly techniques are examined. To begin our analysis, recall that to achieve $1 \mu\text{m}$ lateral alignment between fiber cores within a connection, which is required for 0.25-dB insertion loss, we need on average $0.5 \mu\text{m}$ centering of the fiber core within each ferrule. This means that if the ferrules have the same outside diameters, and the ferrule axes are perfectly aligned by the alignment sleeve, then we need to consider only the overlap area that is established by the locus of the core centers in each ferrule assembly. This type of ferrule having the fiber cores centered to within less than $1 \mu\text{m}$ is shown in Fig. 49.21.

If we consider the popular ceramic cylindrical ferrule connectors, the manufacturing processes do not routinely yield the necessary hole centering. To overcome this aspect of these ferrules, **performance keying** or tuning is frequently used. Figure 49.22 demonstrates how performance keying can be used to

FIGURE 49.23 Schematic of a cylindrical ferrule alignment mechanism.

achieve a similar size area for the locus of fiber core centers that is achieved in the directly centered ferrules. In performance keying, the location of the key is determined after the fibers are inserted into the ferrules and the connector endface is finished. Usually, the keying is done by measuring the insertion loss as a function of ferrule rotation against a standard reference ferrule. The use of performance keying is widespread with single-mode fiber cylindrical ferrule connectors.

The final factor is aligning the two ferrules and realizing a connection requires an alignment sleeve. This alignment sleeve is usually allowed to float in a housing that has the appropriate coupling features (screw threads, etc.). This component is referred to as either a coupling or an adaptor. A schematic representation of a cylindrical ferrule connector is shown in Fig. 49.23. At first observation, it might appear that the cylindrical alignment sleeve is a trivial component. However, this is not the case. The materials of the sleeve have ranged from plastic, austenitic stainless steel, copper alloys, and glass to ceramic. It appears there is a tendency today to use **single-slit ceramic sleeves**. The concern over the alignment sleeve designs for the cylindrical ferrule connector is driven by the fact that the sleeve must coaxially align ferrules that have unequal diameters. Even though the diameter of ferrules can be manufactured to a tolerance of $1\ \mu\text{m}$, an insertion loss performance of $<0.25\ \text{dB}$ requires lateral alignment of the cores of $<1\ \mu\text{m}$. Additionally, this 1 mm tolerance has to accommodate all inaccuracies, including the fiber core offsets within the ferrules. For these reasons, the alignment sleeve is indeed an important component of an optical fiber connector.

Factors Contributing to Reflectance (Physical Core-to-Core Contact)

As mentioned previously, besides achieving submicrometer lateral alignments, in order to realize low insertion loss and low reflectance, high-performance connectors must achieve and maintain fiber core-to-core contact. Again referring to physical contact cylindrical ferrule connectors, at first glance (Fig. 49.23) it appears trivial to achieve physical core contact. However, one has to investigate the geometry in finer detail.

As stressed in this chapter, the lateral offset between adjacent single-mode fibers must be controlled to less than $1\ \mu\text{m}$ in order to achieve $0.25\ \text{dB}$ insertion loss performance. The cylindrical geometry therefore must maintain very small diametral clearances between the ferrules and the alignment sleeve to minimize lateral offsets. These small clearances require precise perpendicularity of the ferrule/fiber endfaces to achieve physical contact of the fiber cores. In practice, this required precision in perpendicularity has not been realized. As a result, the usual practice is to use spherically polished endfaces [Shintaku, Nagase, and Sugita, 1991]. In theory, the spherical endface should result in the fiber core being the highest point on the ferrule endface, thereby always achieving core contact. However, since the material of choice for manufacturing the submicrometer precision ferrule is a ceramic, spherical endface, polishing tends to result in a slight recessing of the fiber endface within the ferrule tip (Fig. 49.24). This recessing is caused by the differential polishing rates of the ceramic ferrules and the glass fibers. This recessing of the fiber endfaces is overcome in the cylindrical ferrule connector by using **controlled elastic deformation** of the ferrules.

Therefore, when two ferrules are forced into contact (Fig. 49.25) by the compression springs within the fastening hardware, line contact is established and large hertz contact forces are exerted on the ferrules' endfaces. If one correctly selects the ferrule's material properties, specifies the radius of the sphere, and controls the amount of fiber recess, then a **controlled elastic deformation** of the ferrule can be used that

FIGURE 49.24 Ferrule endface with recessed fiber.

FIGURE 49.25 Ferrule endface contact of spherical ferrule endfaces with fiber recess.

results in fiber core-to-core contact. If these parameters are not controlled, an unstable physical contact connection can result.

To summarize this section on fiber core-to-core contact connectors, the **controlled elastic deformation** technique with type PC connectors is presently the overwhelming choice for low reflectance and low insertion loss connections. There are many details and features that must be controlled to achieve and maintain this core-to-core contact to provide the appropriate elastic deformation within the connectors. Some of these are manufacturing know-how and must be fully developed and socialized within the connector community before appropriate intermateability standards can be realized.

49.5 Splicing Design Aspects

Fiber splices are used in applications where the goal is to achieve a permanent joint between two fibers. Since the splice will be permanent, there are no intermateability concerns as with connectors. Without these concerns, splices are easily designed to have very low insertion losses, <0.1 dB, and very low reflectance, <-55 dB. With the recent improvement in fiber geometry, multiple fiber splices are now becoming feasible as well. As previously mentioned, there are two types of fiber splices: mechanical splices and fusion splices. The recent use of angled endfaces in mechanical splices have made their optical performance equal to that of fusion. A large differentiator between them is the required level of initial capital investment. Fusion splicing is capital intensive, whereas mechanical splicing is more or less a buy-as-needed process.

TABLE 49.4 Typical Steps in Fusion Splicing

FIGURE 49.26 Schematic of a typical mechanical splice.

Mechanical Splices

Mechanical splicing techniques use butt-joint coupling similar to those used in connectors. However, the fact that the splice is permanent implies there do not need to be any intermateable parts. This fact results in their higher optical performance and lower cost. Essentially, the mechanical splice is a consumable part that mechanically aligns the fibers by referencing on their outside diameters [Patterson, 1988]. The splicing process is quite simple. The plastic coating on the fiber is removed and the fiber endface is cleaved, either perpendicular or with an angle. The two cleaved fibers are inserted or placed in the consumable part (the splice) and are usually held in place by a simple clamping method. The low loss is attributable to the use of a continuous alignment surface similar to a v-groove and the use of an index matching material in the very small gap that exists between the fibers to eliminate reflections. A typical mechanical splice is depicted in Fig. 49.26.

The first mechanical splices and most used today employ perpendicular endfaces. Since the cleaved endfaces are not exactly perpendicular, fiber core contact is not achieved within the splice. Consequently there exists a gap, which is filled with index matching material. Because the refractive index of the available materials varies with temperature, two index mismatches are created, one at each fiber end. These index mismatches result in multiple beam interference as in the case with connectors. These mismatches are not sufficient to cause significant increases in insertion loss (about 0.002 dB) but can severely affect the reflectance performance of the splice. As previously mentioned in this chapter, reflectances ranging between -25 and -40 dB over the expected temperature range can be realized. With the recent reflectance requirements of less than -40 dB, angled endfaces are starting to be used in mechanical splices to avoid this temperature dependence [Young, Shah, and Curtis, 1988]. Simple cleaving tools have been developed that provide endface angles ranging between 5° and 10° . These angled endfaces can be used in existing mechanical splices and thereby yield reflectance performance equal to that of fusion splices.

Fusion Splices

Much progress has been made in the performance of equipment used to perform arc fusion of optical fibers. Essentially, the process is quite simple: the fibers' butt ends are heated to just below their melting point and pressed together to form a continuous fiber [Kato et al. 1984]. After the fusion process is complete, a strength reinforcement member is applied to protect the bare fiber. Table 49.4 lists the typical steps used in the fusion process. In Fig. 49.27, a simple schematic of a holding and alignment mechanism that is part of most splicing machines is shown. In reality, these mechanisms are quite sophisticated, involving computer controlled movements to achieve accurate alignment and positioning. The machines are fully automatic and also provide an estimation of the splice loss.

FIGURE 49.27 Schematic of holding and alignment mechanism.

FIGURE 49.28 Example of a fusion splicing cycle.

An example of a fusion splicing cycle is depicted in Fig. 49.28. The cycle is usually fully automatic. The operator loads the cleaved fibers in the v-grooves and grossly positions the ends. The cycle begins by moving the fibers into contact and then separating them a fixed amount. Then the arc is energized with a specific current and the fibers are moved toward each other. This step is used to clean and round the edges of the fiber ends. When the fiber ends reach the contact point, the current is increased to soften the fibers and the fibers are driven past the original contact point (pressed together). Finally, the current is decreased and brought to zero. Although the process seems quite simple, the tolerances for these movements and currents can be quite demanding.

In the fusion splicing of multimode fibers, the surface tension between the fiber endfaces, while softened, can be used to self-align the fibers with reference to their physical geometric axes (outside diameters). This technique makes the fusion splicing of multimode fibers easy and reliable. With the small mode field diameters of single-mode fibers and the existence of fiber core eccentricities, this self-alignment technique has usually needed to be avoided. To avoid this self-alignment requires precise control of the temperature or softness of the end faces during fusion, the distance the fibers move beyond their original contact location (overlap distance), and the fiber cleave angles. Cleave angles of less than 1° , specific arc duration times within 0.1 s, and overlaps to within $1 \mu\text{m}$ are usually maintained. Also, since the insertion loss target is typically $<0.1 \text{ dB}$, it usually requires that the fibers are aligned with respect to their mode field diameters not their outside diameters. Various techniques have been used to achieve and monitor these alignments. For these reasons, the fusion splicer has developed into a very sophisticated apparatus.

Recently, there has been a marked improvement in the concentricity and diameters of single mode fibers. These improvements have had a positive impact on fusion splicing of these fibers. The self-aligning

FIGURE 49.29 Fusion splice reinforcement detail.

of the fibers is becoming acceptable. Also, the relaxed tolerances on fiber cleave angles and overlap distances have resulted in simpler and less costly splicers, as well as the multiple fiber fusion splices.

Finally, to complete the splicing operation, the splice must be reinforced. Typically, the tensile strength of an unprotected or reinforced splice is between 10 and 15% of the original coated fiber's strength. The strength of the splice can be improved to between 50 and 70% with the use of a reinforcement detail. An example of a reinforcement detail is shown in Fig. 49.29.

49.6 Conclusions

Major advances have been made in the past 20 years with regard to fiber optic connector and splicing technology. The performance of these components has dropped from 1.5 to 0.25 dB for connectors and to <0.1 dB for splices. Along with impressive improvement transmission performance, reflectance performances have also improved dramatically. Connectors and mechanical splices have been reported and marketed with reflectances < -55 dB. These performances have also been achieved with a drastic reduction in cost. However, in spite of a lot of work over the past 15 years, the intermateability standards for these connectors have not yet been published. Hopefully, intermateability standards will soon be finalized at the international level.

With regard to fusion splices there has also been impressive improvement in recent years. Much of this improvement can be attributed to the improvement in the geometry of the optical fibers themselves. The increase in the precision of the fibers has resulted in simpler and less costly splicing machines, as well as the feasibility of multifiber splicing.

Defining Terms

Cleaved fiber: A fiber having an endface prepared by a combination of a prescribed stress distribution and an induced flaw that follows the Griffith fracture theory.

Controlled elastic deformation: A technique used to achieve core-to-core contact when the fiber endfaces have been recessed below the endface of the connector's ferrule.

Dispersion-unshifted fiber: A single-mode fiber designed to have a minimum dispersion at a wavelength of 1550 nm, the intended operating wavelength window.

Dispersion-unshifted single-mode fiber: A single-mode fiber designed to have minimum dispersion at a wavelength of 1310 nm, the intended operating wavelength window.

Performance keying: A method used to overcome the errors in coaxially aligning the fiber core center with the ferrule's reference surface axis resulting in low insertion loss connections.

Physical core-to-core contact: A connector designed to achieve physical and optical contact between the core areas of adjacent fibers, thereby minimizing insertion loss and reflectance caused by reflections.

Reflectance: Reflectance is analogous with the term return loss, the only difference being that one term is the negative of the other.

Single-slit alignment ceramic sleeves: A ceramic sleeve having a precise inside diameter and a longitudinal slit along its length that increases its compliance to varying ferrule diameters.

Further Information

Several technical conferences provide the latest trends and results on fiber optic connectors and splices. Two of the major conferences to follow are the Optical Fiber Communications (OFC) Conference, sponsored by the Optical Society of America (OSA) and IEEE (LEOS), and the International Wire and Cable Symposium, sponsored by the U.S. Army Electronics Command, Fort Monmouth, NJ. Both of these conferences are held annually.

Three major journals that report latest work are the *Journal of Lightwave Technology* (OSA), *Applied Optics* (OSA), and *Electronic Letters* (IEE).

Generic requirements and future trends can be followed in the *Bellcore Digest of Technical Information*, Piscataway, NJ.

To follow the standardization of connectors and splices in the U.S., the Telecommunications Industries Association (TIA), Washington, D.C., is recommended. To follow international standardization, refer to the International Electrotechnical Commission in Geneva.

50.1 Introduction

Passive optical components play a large role in making simple fiber systems (such as point-to-point links) practical and extending their applications to more complicated systems (such as local-area and subscriber-distribution networks). This chapter limits its coverage to a few of the more important bulk passive components not covered elsewhere in this book.

The components to be described are the following optical devices: GRIN rod lens, isolator, directional coupler, star coupler, optical filter, attenuator, circulator, mechanical switch, and polarization controller.

50.2 Losses in a Passive Optical Component

A generic passive optical component is shown in [Fig. 50.1](#). It has several ports (as few as two and, in some cases, over 100), all of which can be input or output ports. The transmission loss generally refers to the coupling efficiency between any two ports. In terms of decibels, the transmission loss is then

$$L = -10 \log(P_{\text{out}}/P_{\text{in}}) \quad (50.1)$$

where P_{in} and P_{out} are the input and output powers at the two ports being considered. **Insertion loss** is commonly used to refer to the loss in a desired direction of signal travel, and **isolation** or **directionality** is used for the transmission loss between two ports where coupling is undesirable. Typical losses for different devices will be presented in the paragraphs where the devices themselves are described.

FIGURE 50.1 Passive optical component with N ports.

FIGURE 50.2 GRIN rod lens connector.

FIGURE 50.3 Isolator showing preferred direction of beam travel.

50.3 Grin Rod Lens

The GRIN rod lens is a short cylindrical length of graded index (GRIN) material that functions as a lens. It is shown schematically in Fig. 50.2 being used to couple between two fibers. An advantage of this connector is the improved tolerance to lateral offsets because of the expanded beam. Another advantage is that significant gaps can exist between the lenses without large losses because of the collimation of the beam. This property also allows the GRIN rod lens to be part of functional devices where gaps are needed to accommodate additional components such as filters, beamsplitters, and gratings. Examples of useful devices employing the GRIN lens will be described later.

50.4 Isolator

An isolator, illustrated in Fig. 50.3, is a one-way transmission line. Its defining characteristics are insertion loss (the loss in the direction of allowed propagation) and isolation (the loss in the undesired direction of propagation). Typical insertion losses are less than 1 dB and isolations are 25 dB or more.

Isolators are used to protect laser diodes from back reflections, which can increase the laser noise level. Isolators are also needed in optical amplifiers to prevent feedback, which could initiate unwanted oscillations of a beam bouncing back and forth through the amplifier due to reflections.

The principle of the isolator is illustrated in Fig. 50.4. A polarizer aligns the beam along one direction. The polarization is rotated 45° by a **Faraday rotator** to align it with an output polarizer. For a beam traveling in the opposite direction (to the left in the figure), the beam is rotated such that it aligns at 90° to the polarizer. It is thus blocked from further travel.

FIGURE 50.4 Principle of the optical isolator. P1 and P2 are polarizers that allow propagation of waves polarized in the directions indicated by the long arrows. The shorter solid arrows refer to waves traveling in the preferred direction (left to right). The dashed arrows refer to waves traveling in the reverse (undesired) direction. Ideally, no wave will get past polarizer P1 (traveling to the left) because the wave will enter P1 at 90° with respect to the allowed direction of wave polarization.

FIGURE 50.5 A four-port directional coupler.

FIGURE 50.6 Fused biconically tapered directional coupler. Two fibers are fused over length L .

50.5 Directional Couplers

The four-port directional coupler is shown schematically in [Fig. 50.5](#) [Palais, 1998]. Arrows in the diagram indicate the directions of desired power flow. Power entering port 1 is divided between ports 2 and 3 according to the desired splitting ratio. Any desired split can be obtained, but the most common one is a 50:50 split. Under ideal (lossless) conditions, the insertion loss to ports 2 and 3 would then be 3 dB and the isolation (coupling loss to port 4) would be (in decibels) infinite. In practice, there are **excess losses** associated with the coupler. Excess losses, which can be as low as a few tenths of a decibel for a good coupler, add to the splitting loss. That is, the total insertion loss is the sum of the splitting loss and the excess loss. Typical insertion losses for the 3-dB coupler are, thus, around 3.3 dB. Typical isolations are 40 dB or more.

Applications include local monitoring of the power levels of the transmitting light source, tapping power from a data bus in a local-area network, signal splitting in a subscriber distribution system, power splitting in an optical sensor, and combining signals in a heterodyne (coherent) receiver.

The fused biconically tapered coupler is one popular construction technique. Two fibers are fused together over a short length by heating. During the fusing process, the fibers are stretched, creating a tapered region in the fused section. The fused fiber coupler is shown schematically in [Fig. 50.6](#). The amount of light coupled between the two fibers depends on the coupling length (L) and can be varied from 0 to 100%. A 50% split, creating a 3-dB coupler, is most common.

Directional couplers can also be constructed using GRIN rod lenses. Illustrated in [Fig. 50.7](#) are a prism/beamsplitter and a reflective coating directional coupler.

50.6 Star Coupler

The star coupler is a multiport device (more than four ports) which commonly distributes power entering one port equally among a number of output ports. Referring to [Fig. 50.8](#), power entering any of the N input ports is equally distributed among all of the N output ports. As an example, an ideal 16×16 star coupler would deliver $1/16$ of the input power to each output port, resulting in an insertion loss of 12.04 dB. If the coupler were not ideal, for example, having a 2-dB excess loss, the actual insertion loss would be 14.04 dB.

FIGURE 50.7 Directional couplers: (a) prism/beam-splitter coupler and (b) GRIN rod lens reflective coupler.

FIGURE 50.8 A star coupler.

FIGURE 50.9 An 8 x 8 fused star coupler.

The star coupler is heavily used in the passive star local-area network architecture. Using the 16 x 16 coupler just described, 16 terminals (each with its own transmitter and receiver) can be interconnected.

The most common implementation is the fused tapered star coupler, as illustrated in Fig. 50.9, where 8 fibers are fused to produce an 8 x 8 star. The 16 x 16 star would require that 16 fibers be fused together.

50.7 Optical Filter

Optical filters separate (or combine) the power carried by different wavelengths that travel through a fiber. Just like electronic filters, they pass or block different wavelengths. Unlike electronic filters, they often also spatially separate the various wavelengths present, as indicated in Fig. 50.10.

Optical filters are necessary in wavelength-division multiplexing (WDM) systems where multiple optical carriers traverse the same fiber to increase system capacity. The fused directional coupler can be used for a two-channel system because the splitting is wavelength dependent. As an example, referring to the directional coupler in Fig. 50.6, if signals at wavelengths 1300 and 1550 nm are received along the same fiber, they can be separated by a coupler that transmits the 1300-nm beam from port 1 to 2 and the 1550-nm beam from port 1 to 3. At the transmitter, the same coupler can combine the two signals onto a fiber connected to port 1 if the 1300-nm signal enters port 2 and the 1550-nm signal enters port 3. As is commonly the case, the same device can serve as either a **multiplexer** or a **demultiplexer**.

The reflective coupler drawn in Fig. 50.7(b) can also serve as a two-channel multiplexer/demultiplexer. In this case, as illustrated in Fig. 50.11, the coating is reflective at one of the system wavelengths and transmissive at the other.

WDM systems carrying more than two channels require more complex multiplexers/demultiplexers. Two such devices are sketched in Fig. 50.12. One uses a GRIN rod to collimate the beam diverging from the input fiber. The collimated beam strikes the blazed grating, which directs different wavelengths into different directions. The lens then refocuses the collimated (but redirected) beams onto different output fibers leading to the receivers. In the second device, a curved reflector performs the same function as the GRIN rod lens. Both of these components can multiplex/demultiplex 10 or more channels (wavelengths). Insertion losses and isolations are on the order of 1 dB and 25 dB, respectively.

Another filter is based on Bragg reflection by a waveguide grating imbedded in the fiber, as illustrated in Fig. 50.13. This device has a periodic refractive index variation for a short length along the axis of the fiber. The variation is produced by exposing the fiber to a periodic variation in ultraviolet light, which permanently changes the refractive index of the glass fiber, thus producing a grating. The transmission characteristics are determined by the grating periodicity and the depth of the refractive index changes.

FIGURE 50.10 Optical filter used as a demultiplexer.

FIGURE 50.11 Two-wavelength demultiplexer. By reversing the direction of the arrows, the device acts as a multiplexer.

FIGURE 50.12 Two multiplexers/demultiplexers: (a) grating and GRIN rod lens; (b) grating and curved reflector.

FIGURE 50.13 Bragg reflection filter.

FIGURE 50.14 Fiber variable attenuator using an absorbing wheel.

FIGURE 50.15 Fiber variable attenuator using movable offset fibers.

50.8 Attenuator

Optical attenuators make it possible to change the light intensity in a fiber. Applications include testing receivers at various light levels (for example to determine the receiver's dynamic range) and adjusting the light intensity to prevent saturation of the receiver.

An absorbing type attenuator appears in Fig. 50.14. The absorbing wheel has a different amount of absorption at different points so that rotating it provides a variation in the attenuation. Misaligned fibers can also be used as attenuators, as indicated in Fig. 50.15. Varying the gap or the lateral offset provides variable attenuation.

50.9 Circulator

An optical circulator, whose operation is sketched in Fig. 50.16, directs the signal sequentially from one port to the next. That is, an input at port 1 exits at port 2, an input at port 2 exits at port 3, and an input at port 3 exits at port 1. Insertion losses are typically just under 1 dB and isolations are above 25 dB.

FIGURE 50.16 Fiber circulator.

FIGURE 50.17 Full duplex fiber transmission system.

FIGURE 50.18 A $1 \times N$ mechanical switch.

The circulator can be used to decouple transmitted and received signals traveling along the same fiber (that is, in a bidirectional communications system such as that sketched in Fig. 50.17).

A circulator uses a Faraday rotator, similar to that found in the optical isolator. A fuller description of the circulator appears in Kashima [1995].

50.10 Mechanical Switch

An optical switch allows an incoming signal to be diverted to any one of two or more different output fibers, as schematically shown in Fig. 50.18. A mechanical switch does this by physical movement of the fibers or some other element of the switch. The insertion loss (coupling to the desired port) should be no more than a few tenths of a decibel and the isolation (undesired coupling to any other port) should be more than 40 dB. Switching speeds are on the order of a few milliseconds, not fast by electronic and optical measures, but quick enough for many fiber applications.

On/off switches allow power to be supplied to a system under test only when needed. Multiple output port switches find applications in measurement systems (for example, to selectively measure the output power from a sequence of fibers). Switches can also redirect signals from a disabled fiber link onto an alternate fiber route. They are used to produce bypass paths directing signals around disabled equipment, such as a node in a local-area network.

In an on/off switch, a block is inserted into a small gap between fibers in the off position and removed in the on position. In a $1 \times N$ switch, the end of the transmitting fiber physically moves into alignment with the desired output fiber.

FIGURE 50.19 Fiber polarization controller.

50.11 Polarization Controller

The polarization controller is a fiber device for producing a desired state of polarization. Although most fiber systems operate independently of the state of polarization of the optical beam, coherent systems and certain sensors are very much dependent on the state of polarization of the optical signal.

A simple polarization controller is constructed by winding the fiber around a disk whose diameter is on the order of a centimeter [Chen, 1996]. Usually, two or three of these fiber disks are connected in series (Fig. 50.19). Rotating the disks about the axis of the fiber produces a differential change in the refractive index of the two normal orthogonally polarized beams traversing the fiber. Any desired polarization state can be obtained with the appropriate rotation of the disks.

Defining Terms

Demultiplexer: Separates different wavelengths entering from a single transmission fiber and directs them to separate receivers.

Directionality: The fractional change in power level (expressed in decibels) when a signal passes between two ports which are ideally meant to be uncoupled.

Excess losses: The fractional amount of input power (expressed in decibels) that reaches all the desired output ports of an optical component.

Faraday rotator: A component which rotates the polarization of the electric field passing through it. Often, the rotation of an incident linearly polarized beam is 45° . The rotation is nonreciprocal.

Insertion loss: The fractional change in power level (expressed in decibels) when a signal passes between two ports which are designed to be coupled.

Isolation: Same as directionality.

Multiplexer: Combines two or more wavelengths from separate light sources onto a single fiber for transmission.

51.1 Introduction

The deployment of optical amplifiers in fiber optic communications systems has received widespread attention over the past several years. Signal repeaters are needed to overcome inherent transmission losses including fiber absorption and scattering, distribution losses, and connector and component losses. Traditional repeaters are based on optoelectronic conversion where the optical signal is periodically converted to an electronic signal, remodulated onto a new optical signal, and then transmitted onto the next fiber section. An alternative approach is to use repeaters based on optical amplification. In optical repeaters, the signal is amplified directly without conversion to electronics. This approach offers distinct advantages including longer repeater spacings, simultaneous multichannel amplification, and a bandwidth commensurate with the transmission window of the optical fiber. The deployment of optical amplifiers in operational networks has reduced maintenance costs and provided a path for upgrading the existing fiberplants since the amplifiers and fibers are transparent to signal bandwidth.

Two classes of optical amplifiers are used in fiber-based systems: active fiber amplifiers and semiconductor optical amplifiers (SOAs). In this chapter we concentrate on semiconductor amplifiers. Fiber-based amplifiers have advanced more rapidly into the deployment phase due to their high-output saturation power, high gain, polarization insensitivity, and long excited state lifetime that reduces crosstalk effects. Fiber amplifiers have been successfully used in the $1.55\text{-}\mu\text{m}$ fiber transmission window but are not ideally suited for the $1.31\text{-}\mu\text{m}$ fiber transmission window. Fiber amplifiers are covered in detail in the companion chapter in this handbook. Recent developments in SOAs have led to dramatic improvements in gain, saturation power, polarization sensitivity, and crosstalk rejection. Semiconductor amplifiers also have certain characteristics that make their use in optical networks very desirable: (1) they have a flat gain bandwidth over a relatively wide wavelength range that allows them to simultaneously amplify

FIGURE 51.1 Spontaneous and stimulated emission occurring between the two energy states of an atom.

signals of different wavelengths, (2) they are simple devices that can be integrated with other semiconductor based circuits, (3) their gain can be switched at high speeds to provide a modulation function, and (4) their current can be monitored to provide simultaneous amplification and detection. Additionally, interest in semiconductor amplifiers has been motivated by their ability to operate in the $1.3\text{-}\mu\text{m}$ fiber transmission window. For these reasons, semiconductor optical amplifiers continue to be studied and offer a complementary optical amplification component to fiber based amplifiers.

In this chapter, we first discuss the principle of operation of SOAs followed by amplifier design considerations. The gain characteristics are described next with discussion on small-signal gain, wavelength dependence, gain saturation, dynamic range, polarization sensitivity, and noise. Amplification of optical pulses and multichannel amplification are treated followed by a brief discussion of applications.

51.2 Principle of Operation

A semiconductor optical amplifier operates on the principle of stimulated emission due to interaction between input photons and excited state electrons and is similar to a laser in its principle of operation. The semiconductor can be treated as a two energy level system with a ground state (valence band) and excited state (conduction band), as shown in Fig. 51.1. Current is injected into the semiconductor to provide an excess of electrons in the conduction band. When a photon is externally introduced into the amplifier, it can cause an electron in the conduction band to recombine with a hole in the valence band, resulting in emission of a second photon identical to the incident photon (**stimulated emission**). As these photons propagate in the semiconductor, the stimulated emission process occurs over and over again, resulting in **stimulated amplification** of the optical input. Since an SOA can amplify input photons, we can assign it a gain. As will be discussed in further detail, the **material gain** is only a function of the basic device composition and operating conditions, whereas the **amplifier gain** defines the relationship between the input and output optical power.

In addition to amplification of the input photons (signal), it is important to consider how noise is generated within the amplifier when an electron in the conduction band spontaneously recombines with a hole without the aid of a photon. This process, known as **spontaneous emission**, results in an emitted photon with energy equal to the energy difference between the electron and hole. Photons created from spontaneous emission will propagate in the amplifier and experience gain through stimulated emission. This process leads to amplification of spontaneous emission and is called **amplified spontaneous emission (ASE)**. ASE is a noise mechanism as it is not related to the input signal and is a random process. Additionally, ASE takes away amplifier gain that would otherwise be available to the signal.

51.3 Types of Semiconductor Optical Amplifiers

SOAs can be classified as either **subthreshold** or **gain clamped**. Subthreshold amplifiers are lasers operated below threshold, and gain-clamped amplifiers are lasers operated above threshold but used as amplifiers. Subthreshold SOAs can be further classified according to whether optical feedback is used. If the SOA amplifies the optical signal in a single pass, it is referred to as a **traveling wave amplifier (TWA)**, as shown in Fig. 51.2. The second type of subthreshold amplifier is a **resonant amplifier**, which contains

FIGURE 51.2 Classification of semiconductor optical amplifiers. (Source: Saitoh, T. and Mukai, T. 1991. In *Coherence, Amplification, and Quantum Effects in Semiconductor Lasers*, Ed. Y. Yamamoto, John Wiley & Sons, New York.)

FIGURE 51.3 Output optical spectrum of a gain clamped amplifier with the main lasing mode and the identified amplified signal.

a gain medium and some form of optical feedback. In this case, the gain is resonantly enhanced at the expense of limiting the gain bandwidth to less than that of the TWA case for an equivalent material. An example of a resonant amplifier is the **Fabry-Perot (FP) amplifier** shown in Fig. 51.2. The FP amplifier has mirrors at the input and output ends, which form a resonant cavity. The resonant cavity creates an optical **comb filter** that filters the gain profile into uniformly spaced **longitudinal modes** (also see Fig. 51.2). The TWA configuration has a bandwidth limited by the material gain itself but is relatively flat, which is desirable for an optical communications system application. Typical 3-dB bandwidths are on the order of 60–100 nm. Although the FP amplifier exhibits very large gain at wavelengths corresponding to the longitudinal modes, the gain rapidly decreases when the input wavelength is offset from the peak wavelengths. This makes the gain strongly dependent on the input wavelength and sensitive to variations that may occur in an optical communications system.

Gain-clamped semiconductor optical amplifiers operate on the principle that the gain can be held constant by a primary lasing mode and signals can be amplified if their wavelength is located away from the main lasing mode. Laser structures suitable for this approach are **distributed feedback (DFB)** and **distributed Bragg reflector (DBR)** lasers, which lase into a single longitudinal mode. Since only a single mode oscillates, the remainder of the gain profile is available for amplification. Figure 51.3 illustrates the output optical spectra of a gain-clamped amplifier with the main lasing mode and the amplified signal identified. A primary advantage of gain clamped amplifiers is a reduction in crosstalk in multichannel amplification applications discussed in Section 51.7.

51.4 Design Considerations

For optical communications systems, traveling wave SOAs are desirable due to the wide gain bandwidth and relatively small variation in gain over a wide signal wavelength range. Most practical TWAs exhibit some small ripples in the gain spectrum that arise from residual facet reflections. A large effort has been devoted to fabricate amplifiers with low cavity resonances to reduce **gain ripple**. For an amplifier with facet reflectivities R_1 and R_2 , the peak-to-valley ratio of the output intensity ripple is given by [Dutta and Simpson, 1993]

$$V = \left[\frac{1 + G_s \sqrt{R_1 R_2}}{1 - G_s \sqrt{R_1 R_2}} \right] \quad (51.1)$$

where G_s is the single-pass gain of the amplifier. For the ideal case $R_1, R_2 \rightarrow 0$, $V = 1$, that is, no ripple at cavity mode frequencies in the output spectrum. A practical value of V should be less than 1 dB. Thus, for an amplifier designed to provide gain $G_s = 25$ dB, the facet reflectivities should be such that $\sqrt{R_1 R_2}$ must be less than 3.6×10^{-4} .
